YALE UNIVERSITY

W. W. NORTON & COMPANY NEW YORK • LONDON

To Kristi, Derek, Dylan, and Martin

W. W. NORTON & COMPANY has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The firm soon expanded its program beyond the Institute, publishing books by celebrated academics from America and abroad. By midcentury, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of four hundred and a comparable number of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

Editor: Aaron Javsicas
Developmental Editor: Sandy Lifland
Manuscript Editor: Janet Greenblatt
Project Editor: Rachel Mayer
Electronic Media Editor: Callinda Taylor
Editorial Assistant: Shira Averbuch
Marketing Manager, Psychology: Lauren Winkler
Production Manager: Eric Pier-Hocking

About the Author

Frank C. Keil is the Charles C. and Dorathea S. Dilley Professor of Psychology and Linguistics and chair of the Psychology Department at Yale University. Keil received his B.S. in Biology from M.I.T. in 1973, an M.A. in Psychology from Stanford University in 1975, and a Ph.D. in Psychology from the University of Pennsylvania in 1977. He was a faculty member at Cornell University from 1977 to 1998 and has been at Yale since 1998. For over 35 years, he has taught an undergraduate lecture course in developmental psychology, as well as advanced seminars at the undergraduate and graduate level on topics in cognitive development and cognition.

Keil has published extensively on topics concerned with many areas of the development of cognition and language. He wrote two books on aspects of conceptual development and, with the philosopher Robert Wilson, he edited the *MIT Encyclopedia of the Cognitive Sciences*, which was selected as the Outstanding Book in Psychology by the Association of American Publishers in 1999. Keil served as president of the Society for Philosophy and Psychology and has received numerous awards for his scholarship, including the Boyd R. McCandless Award (Developmental Psychology), the Distinguished Scientific Award for an Early Career Contribution to Psychology, a Guggenheim Fellowship, a fellowship at the Center for Advanced Study in the Behavioral Sciences, a MERIT Award from the National Institutes of Health, and the Ann L. Brown Award for Excellence in Developmental Research. Keil served as Master of Morse College at Yale University from 2001 until 2012. Keil and his wife Kristi Lockhart, a clinical and developmental psychologist, are parents of three sons who are now in their twenties and thirties.

Contents in Brief

PART I Framing Psychological Development

Chapter 1 Approaching Psychological Development 2

Chapter 2 The Biology of Development 33

PART II Origins

Chapter 3 Coming to Perceive the World 76

Chapter 4 The Emergence of Action 115

Chapter 5 Coming to Understand the Physical World 145

Chapter 6 Connecting with the Social World 187

Chapter 7 The Origins of Emotion, Temperament, and Personality 227

PART III Developing Competencies

Chapter 8 Language Development 260

Chapter 9 The Growth of Knowledge 303

Chapter 10 The Growth of Cognitive Skills 343

Chapter 11 Intelligence and Schooling 385

PART IV The Self and Others

Chapter 12 Morality in Thought and Action 426

Chapter 13 Knowing Ourselves, Knowing Others 467

Chapter 14 Becoming Part of the Family 503

Chapter 15 Becoming Part of the Community 543

PART V Broader Developmental Context

Chapter 16 Psychopathology in Childhood 586

Chapter 17 Development after Childhood and Adolescence 629

PART I Framing Psychological Development

CHAPTER 1
Approaching Psychological Development 2

Why Study Development? 4
- Development as a Key to Understanding Children's Capabilities 4
- Development as a Means for Insight into the Mature Form 5
- Development and Social Policy 6

The Nature of Development 6
- Categorizing Developmental Phenomena 7
  - *Periods of Development*
  - *Areas of Development*
- Basic Questions about Psychological Development 9
  - *Is Development Stage-like or Continuous?*
  - *Is Development Global or Local?*
  - *How Do Nature and Nurture Shape Development?*

Perspectives on Development 14
- Empiricist and Nativist Perspectives 14
  - *Empiricism*
  - *Nativism*
- Comparative and Evolutionary Perspectives 17
- Cross-Cultural Perspectives 18
- Neuroscience Perspectives 19
- Behaviorist Perspectives 19
- Psychoanalytic Perspectives 20
- Cognitive Science Perspectives 20

Studying Psychological Development 22
- Observational Studies 22
- Experimental Studies 23
- Longitudinal Approaches 26
- Cross-Sectional Approaches 27
- Converging Methods 28
- Designing a Sound Study 28
  - *Reliability and Validity*
  - *Within-Subjects and Between-Subjects Designs*

Conclusions 30

Summary 31

CHAPTER 2
The Biology of Development 33

The Basis of Development 35
- Inputs to the Biological System 36
  - *The Genes*
  - *The Environment*
  - *Interactions between Genes and Environment*
- Constraints on Development 38
  - *Viability*
  - *Differentiation of Cells and Structures*
  - *Timing and Sequencing*

The Beginnings of Development 41

Meiosis and Fertilization 41
- *Meiosis and Mitosis*
- *Fertilization*

The First Patterns of Differentiation 43

Anatomical Development 44

Structures and Systems in the Embryo and Fetus 44
- *The Embryonic Period*
- *The Fetal Period*

Preterm Births 47

Why Does Anatomical Development Progress As It Does? 49

Diversity out of Uniformity 49

Sexual Differentiation 52

Adverse Influences on the Developing Embryo and Fetus 53

Brain Development 56

Major Changes to Brain Structures 57

Neurons and Neurotransmitters 58

Development of Neurons 60
- *Proliferation*
- *Migration and Synaptogenesis*
- *Consolidation*
- *Myelination*

Experience and Brain Development 63

Puberty and Brain Development 64

Behavioral Genetics 67

Heritability 67

Behavioral Genomics 68

Conclusions 70

Summary 72

PART II Origins

CHAPTER 3
Coming to Perceive the World 76

Vision 78

Perceiving Differences in Brightness and Acuity 79
- *Visual Acuity*
- *Visual Experience and Brain Development*

Color 84
- *Perceiving Hue and the Clustering of Hues*
- *Categorical Perception of Color*

Depth Perception 86
- *Cues to Depth*
- *Which Depth Cues Predominate? Gibson's Visual Cliff Studies*
- *Functional Significance of the Depth Perception System*

Perceiving Patterns and Recognizing Objects 91
- *Pattern Perception in Other Species*
- *Plasticity in Perceptual Development*
- *Perceptually Grouping the World*

Face Perception 95
- *Development of Face Perception: A Two-System Model*
- *Facial Attractiveness*

Hearing 100

Noticing and Remembering Sounds 100

Locating Sounds 101

Perceiving Complex Sound Patterns 104

The Chemical Senses: Taste and Smell 107

Taste 107

Smell 109

Intermodal Perception 109

Conclusions 112

Summary 112

CHAPTER 4
The Emergence of Action 115

Foundations of Motor Development 116

Reflexes in Infancy 117

Theories of Motor Development 118
- *The Maturational Account*
- *Dynamic Systems Theory*

Perception and Action 122
Coordination in Changing Bodies 122
Reaching 123
Empiricist View of Eye-Limb Coordination
Constraints on Links between Eye and Limb
Navigating Space 125
Active versus Passive Visual Experience and Action
Walking and Seeing

Learning to Engage in Specific Actions 131
Early Imitation 131
The Process of Imitation
The Development of Birdsong: Variations on the Imitation Theme
Imprinting, Action, and Critical Periods 135
Conditioning 136
Classical Conditioning
Operant Conditioning
Constraints on Learning

Conclusions 142
Summary 143

CHAPTER 5
Coming to Understand the Physical World 145

Piaget's Approach 146
Piaget's Theory of Cognitive Development 147
The Sensorimotor Period in Infancy 149
Stage 1: Use of Reflexes
Stage 2: Emergence of Primary Circular Reactions
Stage 3: Appearance of Secondary Circular Reactions
Stage 4: Coordination of Secondary Circular Reactions
Stage 5: Appearance of Tertiary Circular Reactions
Stage 6: Invention of New Means through Mental Combinations
Key Aspects of Piaget's Theory 154
Examining the A-Not-B Error 155

Infant Knowledge and Understanding 157
Thinking about the Unseen 158
Studies of Object Permanence and Solidity
Principles That Guide How Infants Understand
Comparative Considerations
Understanding Causation 164
The Use of Number 166
Spatial Knowledge in Infants 169
Categorization in Infants 171

Distinguishing the Physical World from the Social World 175
Action at a Distance and Social Contingency 176
Goal and Belief Attribution 177

Conclusions 183
Summary 184

CHAPTER 6
Connecting with the Social World 187

Developing Bonds between Infants and Caregivers 189

Early Perspectives on Infants' Bonds with Others 190
Psychoanalytic Approaches to Infant-Parent Bonds 190
Learning Theory Approaches 191
Bowlby's Ethological Approach 192

The Underpinnings of Attachment 194
Components of Attachment 194
Smiling
Clinging and Touching
Cuteness
Bases of Social Interactions 199
Contingent Responding
Social Referencing
Joint Attention and Gaze Following

Individual Differences in Attachment Style 201
Studying Attachment Styles in the Strange Situation 202
Causes of Different Attachment Styles 203
Parent Effects on Insecure Attachment
Child Effects on Insecure Attachment
Interactions of Parent Effects and Child Effects
Consequences of Different Attachment Styles 208
Correlations between Infant Attachment Styles and Children's Social Interactions
Long-Term Links between Infant Attachment Styles and Adult Relationship Styles
Cross-Cultural Differences in Attachment Styles 210

Effects of Early Social Deprivation 214
Social Deprivation in Humans 214
Deficits in Socially Deprived Infants
Untangling Causation
Deprivation Studies in Nonhuman Primates 218
Tactile Stimulation and Physiological Needs
Peer-Raised Infants
Critical-Period Effects? 222

Conclusions 223
Summary 224

CHAPTER 7
The Origins of Emotion, Temperament, and Personality 227

Emotional Development 228
Approaches to Emotional Development 229
Differentiation of Emotions in Infancy 230
Basic Emotions
Complex Emotions
Moral Emotions?
Perceiving and Thinking about Emotions 236
Recognizing Emotions in Others
Emotional Contagion

Emotional Regulation in Infancy 237
  - *Situational Factors*
  - *Attentional Deployment*
  - *Response Modification*

Evolutionary Preparedness and Emotional Development 242
  - *Preparedness for Acquiring Certain Fears*
  - *Preparedness and the Development of Disgust*
  - *Preparedness and the Development of Other Emotions*

Temperament and the Origins of Personality 247

Temperament-Based Components of Personality and Early Development 248

Determining Differences in Temperament 249
  - *The New York Longitudinal Study*
  - *Modern Approaches to Studying Temperament*
  - *Linking Temperament to Personality Development*

Child–Environment Interactions and Goodness of Fit 252
  - *Environments for "Squeaky Wheels"*
  - *Parental Influences on Temperament*

Conclusions 255

Summary 256

PART III Developing Competencies

CHAPTER 8

Language Development 260

The Structure and Complexity of Language 262

Components of Language 262

Universal Constraints on Language 263

Acquiring a First Language 263

Developmental Patterns 263
  - *Prelinguistic Perception and Communication*
  - *One-Word Utterances*
  - *Multiword Utterances*
  - *Linguistic Rules*

Child-Directed Speech 267

Theories of Language Acquisition 268

Behaviorist Approaches 269

Connectionist Approaches 270

Statistical Learning Approaches 270

Nativist Approaches 272

Discovering the Meanings of Words 273

Linking Words to Concepts 273

Constraints on Word Meanings 275
  - *Perceptual Constraints*
  - *Conceptual Constraints*
  - *Pragmatic Constraints*
  - *The Nature of Constraints on Word Meanings*

Developmental Changes in Word Meanings 278
  - *Overextensions and Underextensions*
  - *Linking Features with Meanings*

The Growth of Grammar 280

Effects of Age on Language Acquisition 281

Acquiring Language after the Critical Period 282

Acquiring American Sign Language after the Critical Period 283

Inventing a New Language 283

The Domain Specificity of Language 284

Neural Dissociations 285
  - *Aphasias*
  - *Williams Syndrome*
  - *Specific Language Impairment (SLI)*

Species Specificity 288
  - *Chimp as Child*
  - *Nonhuman Primates and Sign Language*
  - *Bonobos and Joint Attention*

Language and Thought 290

Linguistic Relativity and Linguistic Determinism 290
  - *The Sapir-Whorf Hypothesis*
  - *Color and Number*
  - *Other Influences of Language on Thought*

Language as an Amplifier of Thought 292

Influences of Cognitive Development on Language 294

Language and Communication 295

Conclusions 299

Summary 300

CHAPTER 9

The Growth of Knowledge 303

Dimensions of Cognitive Development 305
Qualitative versus Quantitative Development 305
Global versus Local Patterns of Development 306
Foundational versus Emergent Constraints 306

A Closer Look at Piaget's Theory 308
The Preoperational Period 308
The Concrete Operational Period 311
The Formal Operational Period 311
Alternative Explanations of Piaget's Theory and Results 313
- *Seriation*
- *Thinking about Classes*
- *Conservation*

Domains of Knowledge 320
Spatial Relations 321
Number 324
Biology 327
Other Domains of Thought 334
- *Beliefs about Physical Mechanics*
- *Beliefs about Substance*
- *Beliefs about Cosmology*

Sociocultural Views of the Development of Knowledge 337
Vygotsky's Views 337

Conclusions 339
Summary 340

CHAPTER 10

The Growth of Cognitive Skills 343

Memory 344
Components of Memory 345
Types of Long-Term Memory 346
- *Explicit Memory versus Implicit Memory*
- *Procedural Memory versus Declarative Memory*
- *Semantic Memory versus Episodic Memory*

Memory Strategies 349
Development of Metamemory 350
Memory and Expertise 352
Infantile and Early Childhood Amnesia 353
- *Memory Format Change Hypothesis*
- *Neural Change Hypothesis*
- *Cueing Hypothesis*
- *Culture, Gender, and Early Childhood Amnesia*

Emergence of Long-Term Autobiographical Memory 356

Attention 358
Attention as an Active Exploratory System 359
Three Components of Attention 359
- *Orienting*
- *Alerting*
- *Executive Functioning*

A Developmental Disorder in Attention: ADHD 363
- *Biological Bases of ADHD*
- *Misdiagnosis of ADHD*

Reasoning and Thinking about Knowledge 366
Analogical Reasoning 366
Scientific Reasoning 368
Metacognition and Accessing Knowledge 370
- *Illusions of Knowing*
- *Evaluating Others' Knowledge*

Three Specific Skills 372
Reading 372
- *Learning to Read*
- *Teaching Reading*
- *When Reading Is a Challenge: Dyslexia*

Mathematical Reasoning 376
- *Growth of Mathematical Skills*
- *Teaching Mathematics*
- *Developing Problem-Solving Strategies*

Using Symbolic Representations 378
- *Using Maps and Models*
- *Children's Drawings*

Conclusions 380
Summary 381

CHAPTER 11

Intelligence and Schooling 385

What Is Intelligence? 387
The Psychometric Approach 387
- *Interpreting Test Scores*
- *Correlates of Intelligence Test Scores*

Psychometric Theories of Intelligence 390
- *Spearman's Theory of General Intelligence*
- *Carroll's Three-Stratum Theory of Intelligence*
- *Cattell's Theory of Fluid and Crystallized Intelligence*

Alternative Views of Intelligence 393
- *Gardner's Theory of Multiple Intelligences*
- *Sternberg's Theory of Successful Intelligence*

Origins of Intelligence 396
Infant Indicators of Intelligence Test Performance 396
The Heritability of Intelligence 397

Group Differences and Intelligence Tests 400
Sex Differences 400
Ethnic and "Racial" Differences 402
Explaining Group Differences 402
- *Are Group Differences Irrelevant?*
- *Genetic Factors*
- *Socioeconomic Factors*
- *Sociocultural Stereotypes*

Group Differences over Time 406

Environmental Influences on Intelligence Test Scores 407
Enhancing Early Environmental Influences: Head Start Programs 408

Schooling 409
Characterizing Schools 409
  Two Prominent Models of Education
What Schools Do 411
  Schools as Socializing Agents
  Schools as Cultural Institutions
  Schools as Vehicles of Values
Schools and Thought 412
  Cognitive Science and Teaching
  Three Cognitive Science Themes for Education
  Implementing Cognitive Science Ideas in the Classroom
  Aptitude-Treatment Interactions

Creativity 417
Measures of Creativity 417
The Development of Extraordinary Creativity 420

Conclusions 421
Summary 422

PART IV The Self and Others

CHAPTER 12
Morality in Thought and Action 426

The Development of Moral Thought 427
Debating the Origins of Moral Thought 428
Evolutionary and Cultural Psychology and Morality 429
Characterizing the Basis of Moral Thought 430

Piaget's Theory of Moral Development 431
Piaget's Stages of Moral Reasoning 432
  Stage 0: Premoral Development
  Stage 1: The Heteronomous Stage
  The Transition between Stage 1 and Stage 2
  Stage 2: The Autonomous Stage
Evaluating Piaget's Account 434
  Distinguishing Morality from Conventions
  Accounting for Intentions
  Immanent Justice across Cultures

Kohlberg's Theory of Moral Reasoning 437
Kohlberg's Stages of Moral Reasoning 437
Evaluating Kohlberg's Theory 438
  Unclear Stages
  Cross-Cultural Variations
  Possible Gender Biases

Alternative Theories of Moral Development 440
Gilligan's Theory of Moral Development 440
A Pluralistic Approach to the Development of Moral Thought 441
  Contributions from Personality Psychology
  Contributions from Cultural Psychology
  Domain-Specific Moral Reasoning

The Development of Moral Behavior 444
Consistency of Moral Behavior 444
Antisocial and Prosocial Behavior 448
  Antisocial Behavior
  Prosocial Behavior
Temperament, Personality, and Moral Behavior 452
  Self-Regulation
  Arousal Level and Positive Emotionality
  Empathy
Social Influences on Moral Behavior 456
  Punishment and Learning Theories
  Modeling Theory and Moral Behaviors
  Parent-Child Interactions and the Development of Conscience

Conclusions 463
Summary 464

CHAPTER 13
Knowing Ourselves, Knowing Others 467

Self-Concepts and Self-Representations 468
Senses of Self 468
  Neisser's Five Senses of Self
The Mirror Test and Self-Concept 471
  Variations on the Mirror Test
Gender Identity 472

Developing a Sense of Self-Worth 474
Self-Esteem 474
Self-Efficacy 476
Self-Regulation 477
Brain Maturation and the Development of Self-Regulation 480
Contextual Influences on Self-Regulation 481
Developing a Theory of Mind 482
Early Aspects of Theory of Mind 483
Comparative Perspectives on Theory of Mind 484
Understanding False Beliefs 487
    Evaluating the False-Belief Task
A Theory of Mind Module? 490
Beyond False Beliefs 492
Making Attributions about Ourselves and Others 493
Emerging Explanations of Behavior 493
Traits and Optimism 496
Attribution, Motivation, and Creativity 497
Conclusions 499
Summary 501

CHAPTER 14

Becoming Part of the Family 503

Parenting 505
Parenting Styles 506
Parenting Contexts 508
    Parenting across Cultures
    Parenting across Socioeconomic Groups
    The Ecological Systems Approach
Interventions to Improve Parenting 510
Parent Effects in Relation to Other Influences 511
    Child Effects
    Genetic Effects
The Interactionist Approach to Family Dynamics 514
Gender Socialization in the Family: A Web of Interacting Influences 515
Siblings and Family Dynamics 518
Birth Order Effects 518
    An Interactionist Approach to Birth Order Effects
Sibling Relationships and Socialization 520
    Jealousy and Conflict between Siblings
    Siblings and Social Understanding
    Sibling Relationships within the Family
Changes in the Family 525
Changes in Parents' Age 525
Changes in Family Size 527
Working Parents and Child Care 529
Changes in Family Structures 530
    Single-Parent Families
    Same-Sex Parents
    Divorce
    Blended Families
Child Abuse 536
Effects of Abuse 537
Explaining the Cycle of Abuse 537
Foster Care 538
Conclusions 539
Summary 540

CHAPTER 15

Becoming Part of the Community 543

Levels of Affiliation 544
The Changing Nature of Social Interactions 545
Developing Relationships 546
    Friends
    Imaginary Companions
    Bully-Victim Relationships
    Enemies
    Dating and Romantic Relationships
Social Groups 553
    Cliques and Crowds
    Sociometric Status and Social Interaction
Developmental Patterns in Levels of Affiliation 558
Social Network Effects 558
Media Influences on Development 559
Television 560
    The Pervasiveness of Television Watching
    Changes in Television Watching with Age
    Positive Effects of Television
    Negative Cognitive Effects of Television
    Negative Social Effects of Television
    Responding to the Influences of Television Violence
    Stereotyping in the Media
Video Games, Computers, and the Internet 569
    Video Games
    Internet Communities
Roles in the Larger Culture 574
Distinctive Cultural and Subcultural Roles 574
Gender Roles and Stereotyping 576
Conclusions 581
Summary 582

PART V Broader Developmental Context

CHAPTER 16

Psychopathology in Childhood 586

Autism 588
Features of Autism 588
Diagnosis of Autism 589
Incidence of Autism 589
Causal Factors 590

Anxiety Disorders 592
Incidence of Anxiety Disorders 592
Causal Factors 593
  Cognitive Factors
  Biological Factors
Obsessive-Compulsive Disorder 595
  Types of Obsessive-Compulsive Disorder
  Incidence of Obsessive-Compulsive Disorder
  Diagnosis of Obsessive-Compulsive Disorder
  Causal Factors

Eating Disorders 598
Anorexia Nervosa 598
  Incidence of Anorexia
  Cognitive Distortions in Anorexia
  Genetic and Environmental Causal Factors
Bulimia Nervosa 602
  Incidence of Bulimia
  Causal Factors

Depression 603
Unipolar Depression 604
  Biological Causes
  Social Causes
  Cognitive Causes
Bipolar Disorder 607
  Causal Factors
  Diagnosis of Bipolar Disorder

Conduct Disorder: The Case of Psychopathy 609
Features of Psychopathy 610
Diagnosis of Psychopathy 611
Causal Factors 612

Schizophrenia 614
Features of Schizophrenia 614
Causal Factors 616
Early-Onset Schizophrenia 619

Treatment of Childhood Psychopathologies 619
Behavioral Therapies 619
Cognitive-Behavioral Therapy 620
Psychoanalytic Therapies 621
Family Therapies 622
Pharmacological Treatments 622
Evaluating Therapies 624

Conclusions 625
Summary 625

CHAPTER 17

Development after Childhood and Adolescence 629

Physical and Physiological Changes in Adulthood 630

Cognitive Changes in Adulthood 635
Reaction Time and Speed of Processing 635
Memory, Higher Cognitive Functions, and Reasoning 635
Daily Activities and Cognitive Aging 639
Circadian Rhythms, Cognition, and the Lifespan 641

Changes in Personality in the Lifespan: Individual and Group Changes 643
Changes in Individuals 643
Stressful Life Events 644
Group Changes 645

Stages of Life? 648
Erik Erikson's Approach 648
  Stage 1: Trust versus Mistrust
  Stage 2: Autonomy versus Shame/Doubt
  Stage 3: Initiative versus Guilt
  Stage 4: Industry versus Inferiority

Stage 5: Identity versus Role Confusion
Stage 6: Intimacy versus Isolation
Stage 7: Generativity versus Stagnation
Stage 8: Integrity versus Despair
Understanding Stages of Adult Development 652

What Does It Mean to Be Old? 652
Stereotypes and Ageism 654
Cultural Variation in Stereotypes and Ageism? 655

Conclusions 656
Summary 657

EPILOGUE 659

Preface

I have been deeply involved in teaching introductory courses in developmental psychology since my first year as a teaching assistant at Stanford University in 1973. And I have taught my own lecture course since joining the faculty of Cornell University in 1977. While there have always been a range of available textbooks for this course, I have always felt the need for a book that comes closer to my own vision of how developmental psychology should be taught. I thought that there should be a book celebrating the beauty and incredible complexity of psychological development while also offering clear and compelling accounts of why development occurs as it does. Equally important, I wanted a book that showed how an understanding of development is essential to understanding psychological processes in adults and how a developmental perspective offers unique insights into mature psychological functioning. I believed a textbook on developmental psychology should illustrate common developmental themes across all areas of psychology while also explaining how trajectories within broad domains can each take on their own special characteristics. And I thought that a textbook should discuss commonalities and contrasts across cultures and even across species, as well as considering how psychological development fits into a broader context of biological and neurobiological development. Moreover, I believed that to fully illuminate the study of development, a textbook should situate psychology within a larger set of disciplines—including anthropology, computer science, linguistics, neuroscience, philosophy, and sociology—that intersected with psychology. Different texts touched on some of these ideas, but none covered all of them, and many did not seem to have a single voice that wove topics and themes into an integrated whole.

Finally, and perhaps most immediately compelling, the birth of our first son in 1981 made me want to dive much more deeply into the broad literature on all aspects of psychological development. But this also created an unanticipated challenge. As any parent knows, a newborn child is an instant lesson into just how much we don't know about development, a lesson that keeps expanding in scope as that child grows up. Moreover, as soon as I thought I was making some progress in linking scholarly work to my own personal experiences, our second son was born, and then our third son. And each child offered dramatic new insights and perspectives into development. Many years later, after our youngest son finished college and was out in the world, it was finally time to finish writing this textbook.

I have worked on various drafts of this book for over 30 years, writing and rewriting as my insights changed and the field of developmental psychology itself has undergone dramatic changes. I have also used drafts of the text in my courses at Yale for over a decade, constantly refining it in response to feedback from my ever gracious and helpful students. Throughout this entire process, which has continued throughout most of my academic career, I have written and rewritten three or four drafts of the entire book, finally winnowing down the material into the book that you have before you. In the course of writing the book, I have gained an immense appreciation for all of my colleagues in the field who have contributed so spectacularly to the flowering of the discipline over the past few decades. Developmental psychology today is an incredibly vibrant and exciting field that is far more closely connected to the rest of the psychology and other disciplines than ever before, and my excitement and pleasure in writing about it has increased every year. I hope that some of that excitement and pleasure is contagious to readers of this text. I deeply appreciate how this first edition is only the beginning of an evolutionary process that will continue in future editions, but after three decades of immersion in this project, it finally seemed time to take it out of my classroom and share it more widely.

Overarching Themes and Principles

There are fascinating themes and principles that keep recurring throughout developmental psychology and that help to show how different threads of research mutually reinforce each other. These themes and principles serve as constant touchstones for organizing the material in the book. Seven themes stand out as recurring most frequently.

One key theme is the *centrality of feedback loops, both positive and negative.* Development is rarely, if ever, a one-way process in which one factor causes another to happen without some kind of feedback. Parents influence their children, who in turn influence their parents, in cycles of interaction that can reinforce desirable outcomes or aggravate undesirable ones. The simple acts of learning to walk and successfully reaching toward objects involve constant feedback loops between what a child sees and how she acts. Even at the neural level, the growth of neural circuits can depend on feedback from experience, which in turn can change how future events are experienced. In all areas of development, we will see the central importance of feedback loops.

A second major theme is that *development is a dynamic exploratory process in which the child is more than a passive recipient of experiences and information.* When children are viewed as actively engaging with the world, it is much easier to understand development, whether it is development of perception, cognition, motivation, or morality.

A third theme is to see that *development is constrained by factors that arise both internally from within the child and externally from the environment.* While constraints may seem to somehow hinder development they may actually foster development by acting as scaffolds and guiding frameworks that make otherwise overwhelming problems of learning and skill development manageable. We will see the value of constraints and how they can guide development in many areas, while still allowing for enormous diversity of outcomes. Discussions of constraints also allow for a balanced treatment of the tradeoffs between nativist and empiricist views of development and the related, often needlessly contentious, nature/nurture debate.

A fourth theme is to focus on *what children can do and how their basic capacities emerge and serve as foundations for later development, as opposed to focusing on what children cannot do compared with older children and adults*. While younger children and infants certainly have limitations that are not found in later years, it is almost always more fruitful to avoid "deficit models" of development and instead ask how children progress as they grow.

A related fifth theme that occurs in all areas of development is that *infants and children usually have some viable version of a skill throughout development; they rarely go "offline" as they retool or improve on a system.* Just as the human heart must beat continuously as it goes through remarkable anatomical and physiological changes from its early embryonic stages to birth and beyond, most perceptual, cognitive, emotional, and social systems must have some working functional capacity throughout development. For example, infants' emotional states have functional values both for themselves and for their interactions with others, and while their emotions change considerably in the first year of life, infants cannot simply shut down their emotional systems when transitioning to new kinds of emotions or emotional interaction patterns. The same is true for everything from language to friendship and is closely related to the idea that the most functionally vital aspects of systems often appear earliest in both development and in the evolutionary history of organisms.

A sixth theme is the *ever-present links and interdependencies between different areas of development.* It simply isn't possible to consider cognitive development without also considering social and emotional development, just as understanding social development depends on related changes in cognitive development, and a full account of emotional development depends on understanding both social and cognitive development. We will often focus primarily on one area at a time, but we will always take into account how the different areas of development also interact and must be understood in their entirety to obtain a full picture of what develops.

A final theme is that *developmental psychology is not just a human-based process.* All organisms with significant behavioral components grow from immature states to mature states and show fascinating patterns of change and constancy. Comparisons across these organisms and especially with humans are not just interesting in their own right, they can also greatly help us to understand what is unique about human psychological development, as well as telling us about what kinds of developmental problems tend to converge on one common class of solutions and what kinds of problems embrace an enormous diversity of possible solutions. This comparative perspective also highlights the ways in which evolutionary considerations can inform thinking about development. These seven themes and principles recur throughout this book and provide a way of weaving together all of the book's content to create an integrated and more memorable whole that reveals larger developmental patterns.

Linking Theory and Evidence

Developmental psychology has emerged robustly in the past few decades as a full-fledged science in which scholars propose theories and models and then test them rigorously. This book celebrates the ways in which ideas, many of which have been with us for centuries, are now being tested in carefully designed experiments or through powerful new statistical analyses of large data sets. It is fascinating to see how classic issues are now coming into much clearer focus as a result of clever new studies. Throughout this text, we will encounter theories, sometimes conflicting theories, and ask how they can be tested and what the current evidence tells us. In many cases, the debate continues with more than one view remaining viable, but also with a much better understanding of the research path forward.

I am convinced that even the most complex and intricate theories of development, ranging from neural growth patterns to changing social network analyses, can be explained in such a way that any introductory student can appreciate their key dimensions and how to evaluate them in light of the right kinds of studies and evidence emerging from those studies. All the theories and studies in this text have been written up, reviewed, and rewritten several times to ensure that they are clear and accessible and that the links to empirical research are compelling. I want all the readers of this text to be able to step into the shoes of leading investigators in developmental psychology so that they can understand what drove the researchers both in terms of theory and their passion to design and execute studies to answer developmental questions.

Integrated Treatment

As already is clear from the way our themes and principles cut across diverse areas, a hallmark of this text is the way it integrates material across all the chapters and keeps illustrating how certain patterns and ideas keep recurring. There are several forms of such integration throughout the book. Some themes recur across all the different times of development, from the prenatal period to the period of old age. Some themes recur across domains, ranging from perceptual to cognitive to social to moral domains. Some themes recur across cultures and even across species. The child develops as a whole person in which many different psychological systems are linked together and depend on each other and which have strong continuities with earlier and later periods of development. This book reflects that integration both in terms of how it has been organized and written and in terms of my own perspective. The book is topically organized within a chronological framework, which serves to provide maximum integrations in distinctive developmental periods, as well as providing more coherent treatments of each area of development. As a single author of this book, an increasingly vanishing breed of introductory text authors, I have been able to develop a voice and lines of thought that are woven throughout every chapter and that mutually reinforce each other. After reading a chapter or two, students should have a constantly building feeling of familiarity with ideas and approaches that helps make everything hang together. Near the end of the book, I offer a different kind of integration through a discussion of psychopathology in development. More than just a review of the psychopathology literature, Chapter 16 shows how aspects of development that are covered in earlier chapters, ranging from brain development to cognitive executive functioning to socialization, come together in an interwoven manner to contribute to the emergence of various forms of psychopathology. Students will see how all that they have learned bears on powerful and compelling problems. They will then experience a different form of integration of the same range of topics in the final chapter, which considers development after childhood and in which there is a fascinating set of questions that can have some striking resonances to earlier developmental questions and themes. I have taken great pains to present the full spectrum of theories and approaches but always with an eye toward how they relate to each other and to larger developmental issues that transcend any one school of thought. In doing so, I have immersed myself in reading the literature on different aspects of development, as well as engaging in many conversations and corresponding with experts across many disciplines, far more deeply than I ever could have imagined I would do when I first started on this project. The entire process has fed back into this book, and it has been great fun as well!

Distinctive Pedagogical Features

To best convey the themes and principles, to set forth the relations between theory and evidence, and to provide the most integrated treatment possible, this book has several distinctive pedagogical features. Throughout every chapter, there are comprehension checkup questions, a pedagogical tool that enables readers to immediately know if they have mastered the key issues they have just encountered. In each chapter, there are also highlighted key terms that are defined in the Glossary of the book. Each chapter ends with a conclusion that brings together the key ideas and often offers a novel integrative insight. The summaries that follow the conclusions are comprehensive digests of the entire chapter in a bulleted format. Any students who can clearly recognize and elaborate on each bulleted point will have a good sense of how well they have mastered the chapter. Finally, at the end of each chapter, for more in-depth consideration of the material, there are sets of extended thought questions that challenge students to consider a problem more thoroughly.

Every chapter has a box that is concerned with a social policy issue connected to material in the chapter so that students can see how basic research can be linked to important and socially relevant real-world issues. A second box in each chapter is concerned with an example of an exciting new direction of developmental research so students can see how the field continues to evolve through innovative research initiatives. It is an important way of illustrating how developmental psychology is a dynamic, active field. A third box in each chapter illustrates in more detail the methodology of scientific research relevant to the topics of that chapter. The purpose here is to show in a manner closely analogous to posters at scientific conferences how an experiment is organized in terms of hypothesis, method, results, and conclusion, and to include illustrations of the experimental setup and results. These boxes are somewhat simpler than most posters at meetings, but they very much capture their spirit.

Throughout the book, there are brief historical discussions of research topics that make clear how current ideas and research emerged from older traditions. There is also careful documentation of cutting-edge research that serves not only to ground the research in particular studies but also serves as a rich source of references for further explorations by students, references that are also available on the instructor Web site and in prepared LMS materials available free of charge to every instructor using the book.

In the end, these pedagogical devices all serve the overarching goal of this book, which is to get to the heart of developmental psychology. My aim is to expose readers to developmental psychology's big questions in an engaging and compelling way that invites students to join researchers in one of the most lively and fascinating areas of intellectual inquiry that also has immense personal relevance and social importance.

Supplementary Materials

Our supplements package was developed based on data from a survey of 60 instructors currently teaching developmental psychology at a wide variety of schools. Our book-specific resources are easy to access in one place through wwnorton.com/instructors. They are also searchable on the *Interactive Instructor's Guide*, making lecture planning easy.

Presentation Tools

- *Lecture PowerPoints* offer images and instructor-only lecture notes that include additional examples and teaching suggestions, which will help ease the transition to using a new textbook. Each chapter also includes an optional set of slides that cover the research behind a concept covered in the chapter to illustrate how the science of developmental psychology leads to the theories students are learning about in class.

  The *Developmental Psychology Lecture PowerPoints* were written by David Barner and Jessica Sullivan, both of whom are at University of California, San Diego.
- All of the art in the book is available as PowerPoints and JPEGs to make creating custom presentation materials easy.
- Presentation tools are downloadable at wwnorton.com/instructors.

Videos

- Chapter Opening Videos from Frank Keil himself serve as an introduction to the chapter topics and help convey his enthusiasm and voice to the reader.
- Classroom Videos with discussion questions feature enactments of classic experiments and demonstrate a variety of characteristics from varying developmental periods, showing developmental psychology as a science in action. The *Developmental Psychology* videos were curated by Tasha Howe of Humboldt State University.
- Videos are available at wwnorton.com/instructors as part of the Interactive Instructor's Guide and as part of our LMS-ready materials.

Interactive Instructor's Guide

- The searchable *Interactive Instructor's Guide* offers classroom activity suggestions with print-ready handouts, chapter opening videos, and classroom videos with discussion questions. The *Developmental Psychology* videos were curated by Tasha Howe of Humboldt State University, and the activities were written by Melissa Barnett at the University of Arizona.
- The *Interactive Instructor's Guide* is downloadable from wwnorton.com/instructors.

Test Bank

- The *Test Bank* for *Developmental Psychology* is designed to help instructors prepare their exams. The *Test Bank* has been developed using the Norton Assessment Guidelines, and each chapter of the *Test Bank* consists of five question types classified according to the first five levels of Bloom's taxonomy of knowledge types: remembering, understanding, applying, analyzing, and evaluating. Questions are further classified by section and difficulty, making it easy to construct tests and quizzes that are meaningful and diagnostic.

- The *Test Bank* questions were written by Thompson Davis of Louisiana State University and Lisa Rosen of Texas Woman's University, with Tasha Howe of Humboldt State University.
- The *Test Bank* is available in paperback and on disk; it is also downloadable in PDF, RTF, or ExamView formats from wwnorton.com/instructors.

Norton Coursepacks: Our Content, Your Course

- Easily add high-quality Norton digital media to your online, hybrid, or lecture course—all at no cost. Norton Coursepacks work with and leverage your existing Learning Management System, so there's no new system to learn, and access is free and easy. Comprehensive coursepacks are ready to use, right from the start, but they are easy to customize, using the system you already know and understand. The *Developmental Psychology* Coursepack includes classroom videos with discussion questions, Quiz+ review questions, and flashcards available for the students (or assignable as instructors see fit), as well as the Test Bank.
- Quiz questions were written by Thompson Davis of Louisiana State University and Lisa Rosen of Texas Woman's University, with Tasha Howe of Humboldt State University.
- All of these materials are downloadable in Blackboard, Moodle, D2L, Angel, and Canvas formats.

eBook

- Same great book, a fraction of the price.
- An affordable and convenient alternative to the printed textbook, Norton eBooks retain the content and design of the print book and allow students to highlight and take notes with ease, print chapters as needed, and search the text. Norton eBooks are available online and as downloadable PDFs. They can be purchased directly from our Web site, or with a registration folder that can be sold in the bookstore.

Acknowledgments

My deepest debt goes to my wife Kristi Lockhart, who was assigned to the same office as me on our first day of graduate school and who has been my one true love and colleague ever since. Kristi has made major career sacrifices for the sake of our family and my career and has always done so with great generosity and good humor, spreading that spirit of generosity and good humor to our children as well. As a parent and partner she has been loving, supportive, and playful in ways that have sustained and inspired all of us. I am infinitely fortunate that she is the love of my life and marvel every day that she was willing to spend her life with me. She has taught me more about children, parenting, and family dynamics than all other sources combined and has been the best parent ever. Through countless discussions with her about almost all the topics in this book and through listening to her many observations about children, I have been a most grateful recipient of her wisdom. I owe her everything. I have also shared with Kristi in the delight of watching our three sons grow, each in their own ways, into remarkable young men. From their first moments as newborns to their lives as young adults, Derek, Dylan, and Martin have taught us both many volumes about development and continue to do so, as well as providing us with the most rewarding and meaningful experiences of our lives. Kristi, Derek, Dylan, and Martin have also been incredibly patient and tolerant of my obsession with this book and the ways it has hovered over all of us for decades. These two photos of our

family cover only part of the entire period of writing this book, but they show the passage of time during which I was writing it. The many hours I have spent working on this book have been all too evident to every member of my family, and they all have been tremendously gracious about its intrusions into their lives. I thank all of them from the bottom of my heart for their support, their inspiration, and their forbearance and I thank the heavens that I was lucky enough to be part of this family.

Certain people at W. W. Norton also deserve extraordinary thanks, starting with Don Lamm and Don Fusting, who originally signed me up to write the book years ago. I appreciate the support I have received from the Acquisitions Editors Sheri Shavely, Roby Harrington, Jon Durbin, Cathy Wick, and, especially recently, Aaron Javsicas, who made sure the whole project met critical deadlines and who has been very helpful in selecting art. I have also been blessed with brilliant copy editing by Janet Greenblatt and project editing by Rachel Mayer. I thank Vanessa Drake-Johnson, who served as an early Developmental Editor of the book, and Photo Editor Mike Fodera, Photo Researchers Donna Ranieri and Julie Tesser, Media Editor Callinda Taylor, Editorial Assistant Shira Averbuch, Production Manager Eric Pier-Hocking, and Marketing Manager Lauren Winkler. I also would like to thank Jonathan Kominsky who worked on the art manuscript in New Haven.

But I must especially acknowledge the massive contributions made by two Developmental Editors, Sarah Mann and Sandy Lifland. Sarah became involved in the project in 2007 and went through the entire text and asked me probing questions about what I really wanted to say and if I was saying it in the best and briefest ways possible. She helped enormously to shape what had become a far too long body of text into something much more workable. Even more critically, Sandy Lifland has had a profound influence. She is a legendary editor who early on gave me challenging feedback on the crude first drafts of this book and made me realize just how much more I had to do if I wanted to write the book I really envisioned. She then rejoined the project in 2011 and worked full time on the book until its publication. We studied, considered, and often extensively discussed every word of text, every line in every figure and graph for ways that they could be clearer, better connected to the big ideas of the book and to the basic scientific literature. Sandy herself read hundreds of original articles to understand more deeply what I had in mind and to ensure that I was getting across to the reader exactly what I really intended. She also kindly pointed out to me several cases where I still wasn't clear in my own head about what I actually wanted to say. I honestly cannot imagine a better editor who cared more about creating a product of real intellectual and aesthetic value.

This book has been reviewed through the years by many scholars who have been involved in all stages of its evolution, sometimes sending me extensive comments on earlier drafts, other times providing confirmatory reviews to Norton editors about the near final drafts. I have included the affiliations of the reviewers at the time that they wrote their reviews, and some may since have moved on to other colleges and universities. I deeply appreciate all the work that the reviewers have done and thank the following:

Joseph Allen, University of Virginia
Richard Aslin, University of Rochester
Terry Au, University of Hong Kong
Melissa Barnett, University of Arizona
Kymberley Bennett, Indiana State University
Paul Bloom, Yale University
Amanda Brandone, Lehigh University
Sara Broaders, Northwestern University
Gwen Broude, Vassar College
Jean Burr, Hamilton College
Joseph Campos, University of California, Berkeley
Carol Cheatham, University of North Carolina
Judith Danovitch, Michigan State University
Daniel Dickman, Ivy Tech Community College of Indiana
Ann Edworthy, Swansea Metropolitan University
Leanne Franklin, Cardiff Metropolitan University
Janet Frick, University of Georgia
Jeffrey Gagne, University of Texas at Arlington
Susan Gelman, University of Michigan
Gilbert Gottlieb, University of North Carolina, Chapel Hill
Joan Grusec, University of Toronto
Amy Halberstadt, North Carolina State University
Jacqui Harrison, University of Bolton
Brett Hayes, University of New South Wales
Fay Julal, Southampton Solent University
Robert Kavanaugh, Williams College
Rachel Keen, University of Massachusetts, Amherst
Debby Kemler Nelson, Swarthmore College
Susan Kemper, University of Kansas
Katherine Kinzler, University of Chicago
Kristin Lagattuta, University of California, Davis
Alan Leslie, Rutgers University
Robert Lickliter, Virginia Tech
Gary Marcus, New York University
Ellen Markman, Stanford University
Lori Markson, University of California, Berkeley
Carol Murphy, National University of Ireland, Maynooth
Simone Nguyen, University of North Carolina, Wilmington
Bjorn Nilsson, Skovde University College

- Experimental Studies
- Longitudinal Approaches
- Cross-Sectional Approaches
- Converging Methods
- Designing a Sound Study

Conclusions

Summary

A baby is born and seems totally helpless. He can't feed himself or warm himself or move to avoid danger. Does he know anything that will help him get what he needs? Can he do anything that will draw the attention of those who can help him?

Consider some of the perceptual challenges a baby faces in the first week of life (see Figure 1.1). It's the middle of winter, and a 3-day-old baby boy is leaving the hospital with his parents. In the morning, he is moved rapidly from the nursery, where he has been looking up at the white ceiling with its blinking red light and hearing the intermittent cries of other infants and the muffled conversations of nurses. He is wheeled in a nursery cart into a noisy hallway where many large people bustle past on both sides of him, occasionally looming over and cooing at him. On arrival in his mother's room, she scoops him up and embraces him, as she has many times in the past 3 days. As she nurses him, he feels her warmth and hears her voice as he tastes and smells sweetness. He is then rushed down the busy hall again, this time held in his mother's lap as she sits in a wheelchair—and outside into a blast of cold air and a 100-fold increase in brightness. He is buckled into an infant seat in a rumbling older car and driven home over bumpy roads, with trees and telephone poles whizzing by the windows. When the car stops, he is carried into a house where a dog is barking, two children are shouting excitedly, and a telephone is ringing. Finally, he is brought into a quiet, darkened bedroom and laid in a crib for a nap. All of this takes about 1 hour.

Many observers would consider this infant a completely helpless creature with no behavioral or perceptual abilities and a brain like a blank canvas, waiting for experiences to be painted on it in his encounters with a richly structured environment. This view is the basis for the seventeenth-century philosopher John Locke's famous statement that the child's mind is a tabula rasa, or "blank slate," upon which knowledge and perceptual skills will be "written" through experience (Locke, 1690/1964). The great psychologist and philosopher William James described this view more colorfully when, at the turn of the twentieth century, he wondered if all the newborn saw was a "blooming, buzzing confusion," a meaningless collage of fleeting images, colors and sounds (James, 1890).

Newborns' behaviors might seem to reinforce the notion that they are completely helpless and passive, waiting to gain understanding and meaning through experience. They sleep a great deal, and even when they are awake, they do not clearly attend to any one stimulus. In fact, their eye movements often seem uncoordinated, and they seem unable to track moving objects visually. In addition, there is no easy indication that they recognize anything they see. In casual observations of young infants, Locke's comparison of the newborn's mind to a blank slate appears to be warranted.

FIGURE 1.1 A newborn baby. William James, the philosopher/psychologist, described the newborn's first perception of the world as encountering a "blooming, buzzing confusion."

Moreover, when it comes to making sense of the world, the infant faces remarkable perceptual challenges. How could our 3-day-old boy possibly understand his trip home? He typically sees only the top half of people's bodies, and those people often appear and disappear too rapidly for him to recognize them as individuals. How could he form an impression of the body as a whole? As he is brought to his mother in her hospital room, how does he know that she is getting closer rather than staying the same distance away and blowing up in size like a balloon? And how does he link his experience of seeing her face as she approaches with his completely different experience of her when nursing? At home, when he hears a dog barking, children shouting, and a telephone ringing, how can he tell which sounds come from which objects?

If babies did not have any perceptual abilities to help them make sense of the world's patterns, these challenges might overwhelm them. In fact, they are born remarkably well equipped to begin making sense of the world they perceive. Indeed, even newborns make interpretations that go far beyond seeing the world as a blooming, buzzing confusion.

Understanding what newborns can see or hear or understand and how they add to their knowledge and abilities as they age is an area of great interest to developmental psychologists. Developmental psychology can be viewed as a scientific way to address our intrinsic fascination with similar developmental questions throughout the lifespan. It looks at the challenges that confront the growing child and asks how the child or adolescent or young adult is able to master these mental and physical challenges.

In this chapter, we will explore some of the strategies used in the scientific study of psychological development. We will present several reasons for examining development. We will then discuss the nature of development, looking first at periods of development (the child at different ages) and then at domains of development (the spheres in which development occurs, such as perception and cognition). We will briefly address some basic questions about development before going into different perspectives on development. Finally, we will consider how to study psychological development, discussing different kinds of studies and approaches and the criteria for sound studies that give us valid, reliable, and replicable results.

Why Study Development?

A child is born and grows from infant to toddler to school-age child to adolescent and to adult, regardless of where he is born or who his parents are. In the course of development, he acquires a wide range of perceptual and motor skills as well as cognitive and social abilities. Developmental patterns are intrinsically interesting, since we all have faced the challenges of acquiring skills and knowledge and fitting into a family, a peer group, and a community. These patterns are the key to understanding what changes over the course of development, what stimulates and what constrains development, and what problems may develop along the way. Knowing what occurs in infancy or early childhood or adolescence can give us clues to understanding adult mental states and behaviors as well. Finally, studying development can also give us insight as we make decisions and formulate social policies that affect children.

Development as a Key to Understanding Children's Capabilities

The process of psychological development is a remarkable story, informed by sophisticated scientific methods and theories. This story is animated by the problems that children confront at different ages and the ways they tend to solve them. Many of these problems are universal, faced by children in all cultures throughout the world, as in the perceptual challenges faced by a newborn, as described at the beginning of the chapter. For that reason, many aspects of the development story follow a similar arc regardless of where and how children live. All children, for example, must learn how to talk, to walk, to find their way home, to count, to catch an object, and to know when others are mistaken. Developmental psychologists ask how skills and knowledge are acquired by children. They look at how children master motor skills, cognitive skills, and social skills. They examine the universal commonalities that affect the development of children throughout the world. And they study how developmental constraints can affect the age at which particular skills and knowledge are acquired.

Consider two key components of this story in a bit more detail. For one, children throughout the world must learn to decode and respond to communication from others. In just a few short years, virtually all children master much of their culture's language, even though languages vary widely. As they come to understand and produce new and complex linguistic expressions, they must refine several skills—from decoding speech sounds to making inferences about a speaker's meaning. As a second example, all children must form a sense of themselves as individuals within their own family and community. Even very young children weave together several skills and forms of understanding in the course of developing a sense of self. As an adult, this self-knowledge—seeing yourself as distinct from others and possessed of particular abilities and traits, as well as having a sense of the choices and goals that direct your journey through life—is easy to take for granted. In fact, this kind of understanding depends on a rich array of early accomplishments, ranging from controlling the movement of your limbs to knowing which parts of your knowledge are private and unavailable to others. Over the course of childhood, these abilities and many others become integrated into a unified sense of self.

The problems facing the developing child require complex solutions far beyond the capacities of even the most advanced computers, yet all children either solve them completely or are well on their way to a solution within the first few years of life. The course of development is a fascinating story in which a limited range of abilities and behaviors starts the infant on a developmental pathway leading to a variety of remarkable achievements, including social collaborations, problem solving, and acquisition of specialized expertise. One major goal of this book is to explain how that success is possible.

As the story of development unfolds, parents do not simply mold their children into a desired form. Instead, if things go well, they work as mentors, coaches, and partners with their children, helping them develop in optimal ways. Studying development is one way to better understand children—to appreciate them as individuals in their own right and to see their nobler goals and beliefs. In addition, each child's development takes place within many different communities, including family, peers, school, town, and the entire culture, each of which exerts its own influences.

Understanding these developmental patterns can also grant each of us a new perspective on our own developmental journey. To appreciate these common developmental stories, as well as their individual variations, is to gain insight into a new world of remarkable complexity and wonder. Put differently, all the intriguing questions about the adult's mind and behavior apply to development as well; and in the field of development, these questions are enriched by a host of new ones about origins and changes. Successful psychological development is one of the great wonders of modern science.

Development as a Means for Insight into the Mature Form

At some point in our lives, almost all of us stumble across clues about what our parents were like as children or as much younger adults—an old photo album, a grainy home movie, a saved drawing from preschool, or a surprising story from someone who knew them many years ago. These records of the past seem to hold answers to all kinds of nagging questions: Was my mother always so outgoing and friendly? Was my father always so concerned about tidying up? Did something happen early in their lives that made both of my parents so thrifty? Knowledge about someone's origins and background often offers clues into that person's thoughts and behavior in the present.

Studying development offers unique insights into some of psychology's oldest and most intriguing questions. For example, are our personalities the same both as children and as adults? What are the roots of our moral intuitions? How does language change the nature of thought? And how does conscious experience differ from mental life that occurs outside of consciousness? Researchers in both biology and psychology are increasingly discovering that they can sometimes answer questions about mature organisms by considering how they emerge and change in the course of development.

A surprising discovery from the field of embryology helps to illustrate this principle, though the question that motivated the research might appear obviously—or even ridiculously—unanswerable: Are zebras white animals with black stripes or black animals with white stripes? Those who studied adult zebras for the answer concluded that zebras must be white with black stripes, because the adult underbelly was often white (see Figure 1.2). But a different answer emerges when considering how the stripes develop (Gould, 1983): zebras actually seem to be black animals with white stripes. Studies of the developing fetus revealed a process of inhibiting the skin's dark pigment in particular areas to lay down a series of white stripes on a black background (Bard, 1977). This example not only shows how studying development can sometimes resolve seemingly unanswerable questions; it also provides insights into why that coloring might have evolved, how skin patterns relate to embryonic growth, what might go wrong in deviant cases, and so on. The developmental context greatly enriches our understanding of the final form.

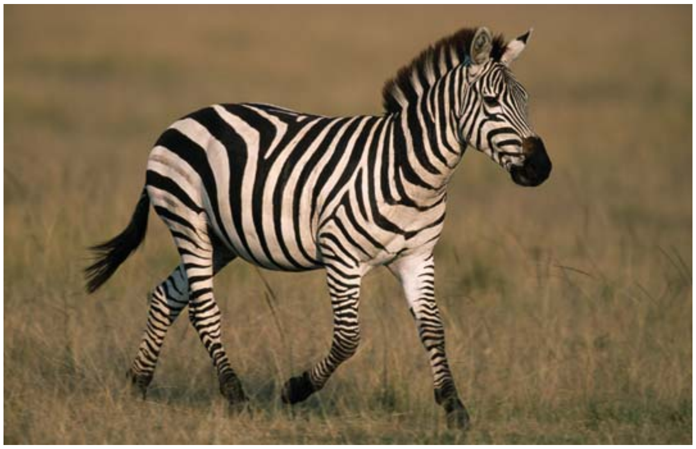

FIGURE 1.2 Studying development to understand adult structures. Even the closest examination of an adult zebra does not clarify whether it is a black animal with white stripes or a white one with black stripes. But prenatal developmental analyses suggest an answer to this question.

Leaving biology and returning to psychology offers many similar examples. Understanding how psychological skills develop—such as recognizing faces, handling threatening situations, or even understanding that a multicolored thing is one object rather than two—is central to understanding the mature form of these abilities in adults. Studying development can allow us to see subtle distinctions that become blurred in adults, but it can also allow us to see the foundational framework for a behavior as it emerges. For example, for hundreds of years, scholars have debated whether people are basically selfish but learn from society's constraints how to behave appropriately, or whether they are, at their core, caring and altruistic but become "corrupted by society." Developmental studies are enormously revealing here, as they can suggest whether one aspect of morality or the other is truly foundational. This particular developmental story is still unfolding, but recent work suggests that both facets of morality, self-interest and altruism, may appear very early as equally intrinsic components of human nature (Bloom, 2013; Warneken & Tomasello, 2009). These findings certainly do not mean that infants and young toddlers hold fully formed moral beliefs, but they make strong suggestions about the nature of humans' deepest moral impulses.

Q: Give an example of how patterns of development provide insight into a mature form.

Development and Social Policy

As citizens in a democracy and as decision-making adults and potential parents, we are also in a position to put developmental insights to practical use (see Figure 1.3). Just a sample of today's headlines shows that we will all need to make choices concerning children's education and welfare: When should a child be tried as an adult if he or she commits a crime? What is the appropriate age to start sex education? Are preschool programs for disadvantaged children effective? Is joint custody best for children of divorced parents? Should birth parents always have access to the adopted child? We owe it to the younger generations to make these decisions based on sound information.

Although we will not resolve these difficult questions in this book, we will see how developmental psychology bears on them and how to interpret and use information about these issues. This kind of critical thinking is one of the most valuable aspects of education—and one important way of putting this skill to use is in the decisions we make, as individuals and as a society, about our children. In that sense, studying development provides tools for evaluating the kind of nuanced information you will encounter, and often have to act on, for the rest of your life.

Knowledge of psychological development also affects how each of us relates to those who depart from behavioral norms, how we value them as individuals, and how we make decisions about their welfare. Some of the most challenging social policy decisions concern individuals with special needs. These include children with learning disabilities, social deficits, or emotional problems. All of us have encountered or heard about children who struggle with anxieties, ranging from a mild fear of dogs to paralyzing distress about almost everything outside the home. An understanding of anxieties and how they develop in children requires considering how the child perceives and thinks about the world and how these perceptions and thoughts change as the child matures. Knowing more about how thoughts and emotions interrelate in development can also help you understand children with emotional problems, such as depression or uncontrollable anger.

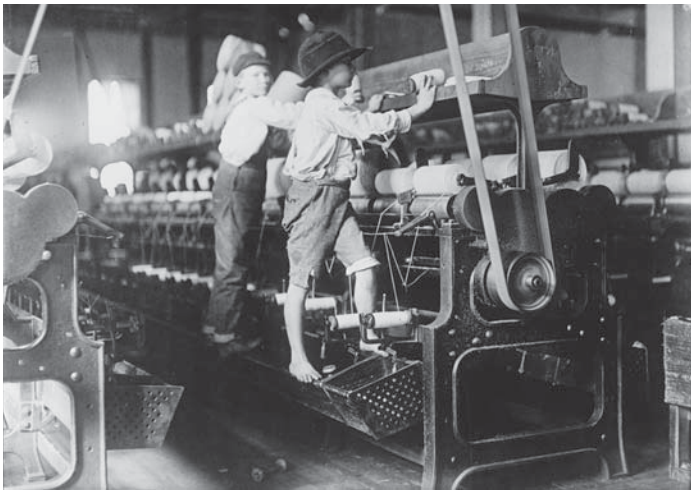

FIGURE 1.3 Child labor. Basic research in developmental psychology can have important implications for social policy. A better understanding of psychological development can help support arguments against the use of children as laborers. Although most people consider child labor a thing of the past, as depicted in this photo, the practice is still common in many parts of the world.

When a school district decides how to teach children with special needs, when there are debates about expanding children's health care coverage to include treatment for emotional difficulties, or when a community establishes a program to help children recover from a natural disaster, it is critical to understand the nature of both normal and abnormal psychological development. Without an appreciation of how both normal and abnormal thoughts, feelings, and behaviors develop, it is difficult to effectively support those who are affected by these decisions. Such an appreciation also reduces social stigma and prejudice, as it brings to light all that we have in common with those who are impaired.

Q: Name a social policy question involving children, and explain how basic research in developmental psychology might help to answer it.

The Nature of Development

When we study development, we are interested in the patterns of change that occur in an organism as it progresses through its lifespan. In this book, we will focus on patterns of change between birth and young adulthood, but it is possible to extend the idea of developmental change to include adulthood and older age. Indeed, midlife and later life changes—including some faculties that come only with advanced age, such as wisdom (Baltes & Staudinger, 2000)—are discussed in Chapter 17.

Psychological development includes patterns of change in mind and behavior that occur as an organism progresses through its lifespan. The mental changes involve the growth of processes such as perception and reasoning, as well as changes in emotion and motivation. Behavioral changes over the lifespan range from young children's toilet training or learning to avoid temper tantrums to adolescents beginning to date. Psychological development is one of the most challenging and rewarding areas of psychology because it explains how we come to be who we are. There is a popular misconception that studying young children might be simpler because young children have fewer abilities than adults. As we will see, however, understanding psychological development requires careful consideration of both the child's early abilities and the mature mind toward which a child is progressing.

Categorizing Developmental Phenomena

To study the rich, vast scope of a lifetime of changes, psychologists group developmental patterns in several ways. We will consider how development can be divided into periods and domains before turning to some of the broader questions that developmental psychologists ask and the diverse perspectives that inform their search for answers.

Periods of Development One way of categorizing developmental patterns involves dividing the lifespan into a series of developmental periods based on age—most commonly these are the *prenatal period*, *infancy*, the *preschool period*, *young school age*, *later school age*, and *adolescence*. Researchers who consider the entire lifespan would add *young adulthood*, *middle adulthood*, and *late adulthood* to this list (see Figure 1.4). One reason for dividing development into these periods is that each one shows unique patterns of change in mind and action, so it makes sense to treat each period as a distinct area of study. A second, more practical reason is that certain periods require their own specialized research methods. Most researchers who study infancy, for example, use the same set of techniques.

Considering these periods in a little more detail, the *prenatal period* covers development from the moment of conception to birth some 9½ months later. The study of early prenatal development focuses largely on anatomical and physiological development. Considerations of psychological development usually do not enter the picture until shortly before birth, at which point some researchers ask how experiences in the womb might influence behaviors after birth. As we will see, research in this area has revealed that infants prenatally develop a preference for some of the sounds of their mother's language such that, at birth, they already prefer to listen to her language over others. The developmental psychology of the prenatal period also involves understanding the psychological effects of substances that can harm the developing fetus. For example, children whose mothers drank excessive amounts of alcohol during pregnancy are more likely to have a host of cognitive and emotional problems.

FIGURE 1.4 Periods of development. The members of this extended family represent many developmental periods, from infancy and the preschool period through adolescence and late adulthood.

Infancy usually refers to the first year to year and a half of life. The most notable feature of this period is that infants are largely preverbal. The absence of language has led some researchers to propose that the infant's mind works differently from the minds of older children, hypothesizing that the infant may lack the ability to think about anything that is not present. Infants' behavior also shows many differences from the behavior of older children, ranging from young infants' sleep patterns, to crawling, to the pronounced fear of strangers that emerges at around 8 months of age. Studying infancy also requires a specialized set of research methods, since infants can't say in words what they like or dislike.

The *preschool period*, from roughly age 1½ to 4, includes changes on several fronts. Language appears and flourishes such that most 4-year-olds can chatter away on any number of topics. During this period, children clearly show the ability to think about things that are not present, and their memory skills often improve considerably. Socially, children improve in their ability to understand other people's minds, and they develop the capacity for much more complex social interactions.

Young school age, from roughly age 5 to 7, is a period in which children's social and cognitive skills expand considerably. Their memory strategies become much more effective, their mathematical skills become more sophisticated, and they usually learn to read. They can understand more complex discussions and seem to follow more elaborate lines of reasoning. Socially, one of their most significant changes is the child's experience in the world outside the family, most notably in school. Another major socialization tool in many cultures, the television, becomes ever more influential.

In *later school age*, from roughly age 8 to 12, children continue to make clear advancements as they improve their ability to express complicated thoughts and solve complex problems. As self-control improves, they appear increasingly able to inhibit impulses and delay gratification. Their real-world knowledge increases greatly as they come to understand their community and its place in the world. At the same time, their social networks expand and tend to focus on friendships with peers of the same sex.

Adolescence, from roughly age 13 to 20, is another period of salient changes. Some are physical, as the differences between the sexes become more distinct during puberty. At the cognitive level, adolescents are increasingly able to consider hypothetical situations and to see how two people can disagree without either being mistaken. There is also a surge of risk taking in this period that may involve underestimating some risks, thrill seeking, and difficulty in controlling impulses, representing both cognitive and emotional changes. Other more purely social and emotional hallmarks of adolescence involve entering romantic and sexual relationships and establishing independence from one's parents.

Young adulthood, from roughly age 21 to 30, is a period of consolidation of the many changes that have occurred in earlier years. The wildness or volatility of adolescence typically diminishes, and this period's cognitive changes may mostly involve gaining more detailed knowledge and applied skills. In most cultures, adults in this age group commit to a particular role in life, either in a career or as a homemaker.

Characteristics of *middle adulthood*, roughly age 31 to 60, vary considerably across cultures. It is important to keep in mind that a century ago, members of most communities in the world had an average lifespan of 40 years. Even today, the average lifespan of a man in Sierra Leone is 37 years, while that of a woman in Japan is 86 (CIA World Factbook, 2010). Given such an enormous range in life expectancies, it is difficult to generalize about experiences during this period. In specific cultures, such as the United States, more consistent patterns take shape. For example, most adults in the United States and other developed countries are likely to reach their career peak during this period and enter the period when their own children reach adulthood and leave home.

Late adulthood, from the late 60s onward, encompasses a gradually increasing age range in many cultures as lifespans increase. Like middle adulthood, late adulthood is characterized by huge individual variations. Some people show a substantial decline in cognitive and motor skills, whereas others show only modest changes even in very old age. Moreover, performance in some tasks that draw on large amounts of stored knowledge can continue to improve well into old age. In terms of social and emotional change, older adults show a strong tendency to experience the present and remember the past more positively than younger adults.

This brief chronology merely serves as a reminder of the enormous amount of change that occurs from birth through childhood and adulthood and into old age. These nine periods are also somewhat arbitrary; the lifespan could potentially be divided into either fewer periods or more, depending on what kind of developmental changes serve as a basis for the divisions.

Areas of Development Our overview of the hallmarks of different periods helps to illustrate the full sweep of development, but developmental psychologists usually pose specific questions, focusing on changes in particular kinds of psychological processes. Thus, besides dividing the lifespan into chronological periods, developmental psychologists also categorize developmental phenomena into the different types of psychological processes that undergo developmental changes—including *perception*, *action*, *cognition*, *morality*, *social behavior*, and *emotions* (see Figure 1.5).

Perceptual development involves the ways people grow in their ability to pick up information from the world by using their senses and by processing sensory information. We will see, for example, that infants may perceive faces and speech sounds in quite different ways from older children and adults, raising profound questions about how people transition from one way of perceiving to another. Perceptual development also involves changes in the ability to integrate information from different senses, such as hearing and vision, and to use that information to guide action.

Development of action is concerned with how people change in their ability to move about in the world and purposefully guide their bodies and limbs. It also includes the development of reflexes and conditioning, a particular type of learning that focuses on behavioral changes in response to positive and negative reinforcements. Developmental changes in this area are often most obvious among young children—for example, as a child progresses from crawling to walking or from being unable to catch a ball at age 2 to catching a ball while running at age 5.

The study of *cognitive development* focuses on how people change over the lifespan in the ways that they understand and use information. Research in this area usually involves observing changes in behavior in order to make inferences about the changes in a person's thoughts and beliefs. Thus, when a 7-year-old first demonstrates that she understands multiplication, researchers will ask how that child's mental representations of mathematical concepts have changed in accordance with her new understanding. Cognitive development includes not only gaining particular types of knowledge, such as understanding the characteristics of physical objects or the biological world, but also developing mental abilities such as memory and attention that support many kinds of thought and behavior.

The study of *moral development* asks how a child's sense of values emerges as well as how moral and immoral behaviors develop. Examining the development of values can include studying how children reason through moral decisions and also exploring their particular beliefs about whether behaviors like cheating or physical aggression are ethical under various circumstances.

The field of *social development* looks at how a wide range of relationships between people form and change. Psychologists in this area may investigate how an infant forms

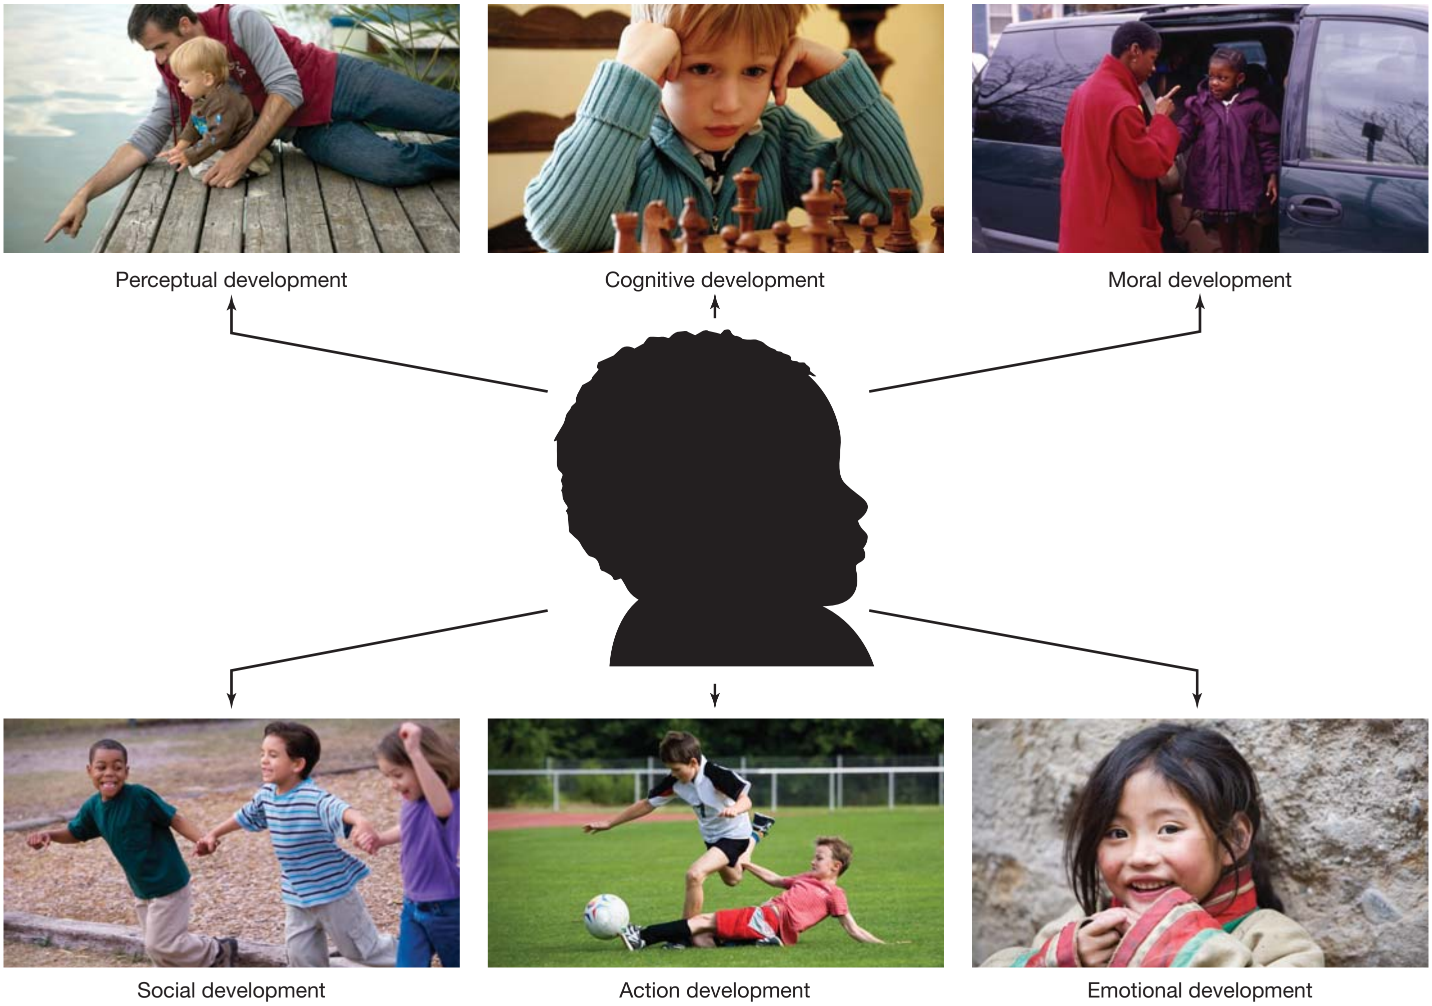

FIGURE 1.5 **Areas of development.** The different areas of development interact constantly throughout the lifespan. Nonetheless, researchers tend to focus on a particular areas—such as changes in perceptual, cognitive, action, social, moral, or emotional processes.

a special attachment to a caregiver and shows distress at separation. They may examine how teasing and bullying in middle school affect both the bullies and the victims. Studying social development in adolescence might focus on how teens' first romantic relationships differ from earlier close relationships. Other topics of interest within social development include how particular social qualities, such as shyness or leadership, emerge.

Research on *emotional development* examines how the full range of emotions takes shape, beginning in infancy. Its concerns range from which basic emotions are present in a newborn to the way complex emotions, such as guilt, emerge out of simpler ones, such as sadness and fear. Because psychologists often construe motivation in emotional terms—that is, behaving in a particular way to feel better (or to avoid negative feelings)—the field of emotional development may also study motivational changes that occur with increasing age. These include the disillusionment that often emerges in adolescence or the more positive outlook that can come with older age.

Basic Questions about Psychological Development

Clearly, psychological development is not a monolithic concept; changes over a lifetime happen in several different dimensions. Furthermore, specific periods and psychological processes show their own distinct patterns in the ways that developmental changes unfold. These differences lead to questions about which patterns happen in what circumstances. We will consider three broad questions about dimensions of development that pertain to many developmental periods and processes.

Is Development Stage-like or Continuous? Are there points in development when children gain a new capacity that is completely different from what they previously were able to do? Or is development more of a continuous process in which thoughts and behaviors slowly become more elaborate and complex? **Qualitative change** takes place when a new kind of structure or process emerges that was not present before. In developmental psychology, discussions of qualitative change often refer to different **stages of development**; a child is said to be in one stage before a qualitative change occurs and in a different stage after the change. Stages involve relatively discontinuous changes in thinking and behaving, resulting in new kinds of accomplishments and patterns of thought that were not present before that stage. This stands in contrast to **quantitative change**, in which the same structures and processes remain but show differences in their magnitude. Discussions of quantitative change focus on incremental expansions to a mental or physical process or capacity.

In physical development, we can easily see both qualitative and quantitative patterns of change. For example, a tadpole's body undergoes qualitative changes as it develops into a frog (Gilbert, 2010). A series of interactions between genes and hormones causes the tadpole's body to break down and resorb the tail that it used for swimming and then to use the resorbed material to generate new structures that distinguish the frog's body from the tadpole's. This tail resorption happens in the context of many related changes, including a reshaping of the head and massive development of the tongue, a shift from the tadpole's herbivorous digestive system to the frog's carnivorous one, and the development of a middle ear that allows the frog to hear in the air. Thus, a whole constellation of interconnected changes in structure and function serve the developing organism's needs. Each of these physical developments can be considered a qualitative change in its own right, as each bodily system has structurally and functionally distinct "before" and "after" states.

The difference between qualitative and quantitative changes is especially clear in the tadpole's case because we can contrast the qualitative changes that transform the tadpole into a frog with the very different outcome that results when a tadpole undergoes purely quantitative change: blocking the action of thyroid hormones can create a developmental path in which the tadpole can reach enormous dimensions (see Figure 1.6). When a tadpole retains its same basic structure and grows ever larger without undergoing the normal transformation of its anatomy or physiology, then it exhibits quantitative change.

In the course of normal development, we typically see a mix of qualitative and quantitative patterns of change in the same organism. Animals that undergo metamorphoses (for example, tadpole to frog, caterpillar to butterfly) exhibit especially dramatic qualitative changes, but more typically the two kinds of change are both apparent. Thus, when a deer grows its first set of antlers, it makes a clear qualitative transition from its earlier antler-free period; yet other aspects of its anatomy, such as its skeleton and muscles, grow larger in a more quantitative fashion at the same time.

In human development, the most obvious patterns of qualitative physical change occur during adolescence. After a period of relatively incremental change in childhood in which the body gradually increases in size on most dimensions, patterns of change during puberty take on a different character (see Figure 1.7). In girls, these changes include a broadening of the hips relative to the rest of the body and the development of breasts as new functional organs. The reproductive system changes as well. At the biochemical level, the onset of menses represents a major new hormonal cycle that was not taking place in the childhood years. For boys, a different set of qualitative changes occurs. The upper body develops more extensively relative to the lower body, and facial hair grows from previously hairless skin. The male reproductive system also changes substantially.

Keeping in mind the case of the supersized tadpoles, it is easy enough to picture how a pattern of exclusively quanti-

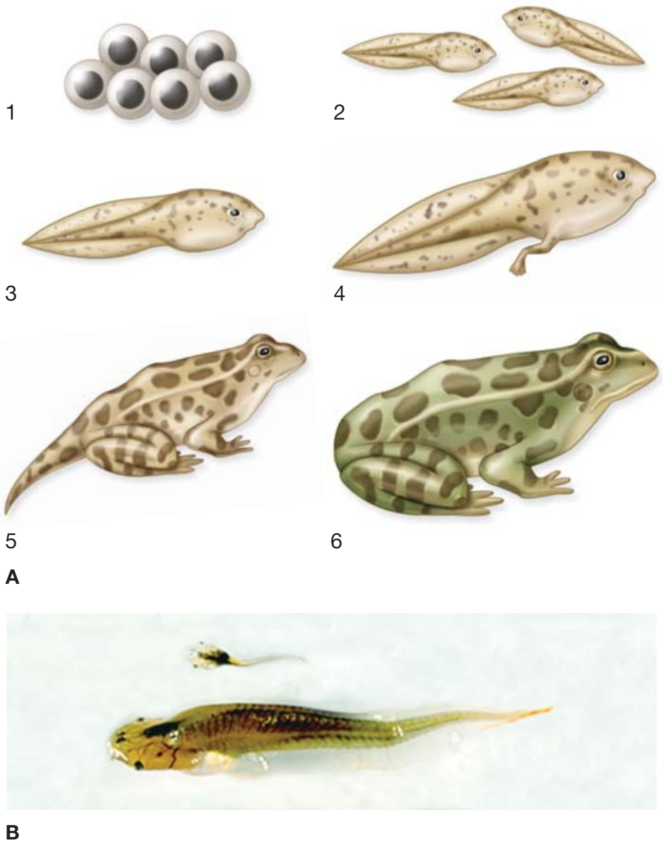

FIGURE 1.6 Qualitative versus quantitative development. It can be difficult to tell whether a pattern of psychological development is qualitative or quantitative, but the contrast is often clearer in biological change. **(A)** The tadpole's dramatic qualitative change into a frog (from eggs to tadpoles to adults) is caused by a rise in thyroid hormone production that occurs in the tadpole's normal development. **(B)** Quantitative change, but not qualitative change, occurs when a tadpole lacks thyroid glands and hence cannot produce thyroid hormones. As such, it cannot metamorphose from a tadpole into a frog (qualitative change). Instead, the tadpole continues to grow (quantitative change), resulting in a giant tadpole (bottom) compared to a normal tadpole (top).

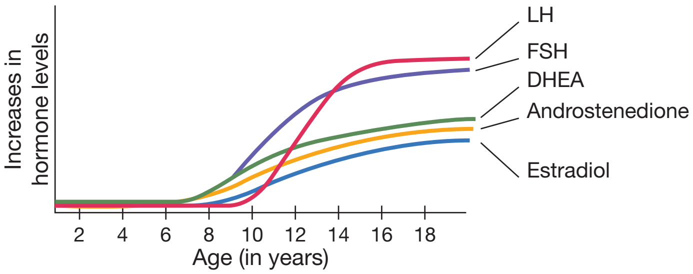

FIGURE 1.7 Increases in hormone levels and qualitative changes during puberty. There is a surge of blood hormone levels during puberty in both girls and boys that produces dramatic qualitative physical changes in their bodies. LH (luteinizing hormone) stimulates ovulation in girls and growth of testes in boys; FSH (follicle-stimulating hormone) stimulates the formation of ova in girls and sperm in boys; DHEA (dehydroepiandrosterone) and androstenedione are involved in the production of testosterone and estrogen; estradiol is produced as estrogen and affects breast development and body shape in girls and bone maturation and growth in boys. Adapted from Gordon and Laufer (2005).

tative changes would differ from one involving qualitative changes. Imagine a child who simply grows larger and larger, never changing in body proportions and never acquiring any of the secondary sex characteristics that develop during puberty. In an extreme case of purely quantitative change, this child would continue growing at the same rate throughout his lifespan and never show other signs of aging.

This distinction between qualitative and quantitative change also applies in the psychological realm. Consider, for example, the consistent finding that infants who are younger than 6 months old are unable to see the depth relations conveyed in pictures, but after the first 6 months of life, they perceive these relations easily (Yonas et al., 2002). Their visual systems change qualitatively at around 6 months of age, acquiring a whole new kind of functional capacity in a short period of time (see Figure 1.8). By contrast, the ability to see patterns in high resolution, which is called visual acuity, gradually sharpens from birth through the first year of life and seems to be a clear case of quantitative change.

As we consider developmental patterns during particular periods of life and within different domains, we will often ask if the changes seem to be continuous and quantitative or if they seem more qualitative and therefore suggestive of distinct developmental stages. In some cases, as you will see, experts disagree about which kind of change is occurring, and a series of experiments can often help us choose between the alternatives. These debates are important not just for understanding what kind of change is happening; they can also, for example, help teachers design strategies that suit children's emerging abilities.

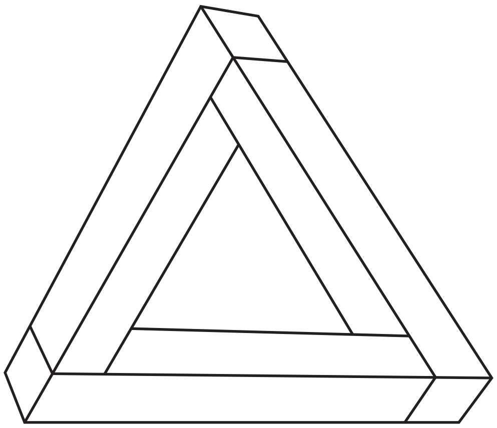

FIGURE 1.8 Qualitative change in depth perception. Because 3-month-old infants cannot yet see depth as it is depicted in two-dimensional pictures, they would not find this "impossible" figure troubling. In contrast, a 7-month-old can see depth in pictures and might well find this illustration odd.

Q: What is the difference between stage-like and continuous change?

Is Development Global or Local? In some cases, developmental change sweeps across many types of processes or abilities at once. When such **global changes** occur, similar developments occur at roughly the same time in very different areas of thought. Global changes are therefore general changes that apply across all situations or domains. For example, during middle childhood, children seem to show strong improvement in the ability to focus on the information most relevant to a task and ignore irrelevant or distracting information (Houde et al., 2010). This new ability to sustain attention could support improvements in a variety of areas where the ability to stay focused is critical. Thus, a child at this age might show gains in making moral judgments, reasoning about video game puzzles, and solving math problems.

Other times, particular skills and mental competencies each show their own unique sets of developmental changes. When development is characterized by such **local changes**, different kinds of psychological capacities develop relatively independently of each other. Local changes are therefore specific changes that occur in restricted areas or domains. In this case, a change in patterns of moral judgment would not necessarily coincide with or resemble a change in understanding mathematical concepts. Consider an example in which a researcher carefully tracks a child's patterns of both moral and mathematical reasoning from age 5 to 10. During this period, the child seems to undergo a major shift in how she thinks about moral dilemmas. Perhaps in the early years she has difficulty understanding immoral acts that cause no physical harm but may cause psychological harm, but in later years she becomes attuned to the psychological consequences as well. During this 5-year period, her mathematical skills also show great changes. Initially, she can only do the simplest addition, while by age 10, after some training with the researcher, she can easily do long division.

This child has shown strong changes in moral reasoning and mathematical skills during the same period, but these would still be considered *local changes* if there were no relationship between the two patterns of change. For example, by taking frequent measurements, the researcher might discover that the two domains showed different developmental trends (see Figure 1.9). Perhaps the improvements in moral judgment started off rapidly at age 5 and then gradually slowed down by age 10, while changes in mathematical ability showed the opposite pattern, changing slowly at first, then showing steep gains. We would have further evidence for local change if, after additional training in math, the child improved at solving a broad range of similar mathematics problems but showed no gains in moral reasoning. Taken together, these findings would clearly indicate that the changes in these domains took place independently of one another, in the form of local changes. By contrast, if the changes in both moral and mathematical reasoning seemed tightly linked in their patterns and timing, and if training in one of these areas also helped in the other, those results would suggest more global change.

In reality, global changes and local changes happen together and often affect the same processes and skills. Development in capacities such as memory, which contributes to a variety of psychological processes, can support broad, global changes that affect many different areas. At the same time, more specific, focused patterns of change can take shape within local areas. If, for example, general improvements in memory over the course of development affected every area of thought, those improvements would need to be taken into account in such diverse areas as language acquisition, mathematical reasoning, and conflict resolution skills—even as each one of these areas showed its own local patterns of change as well.

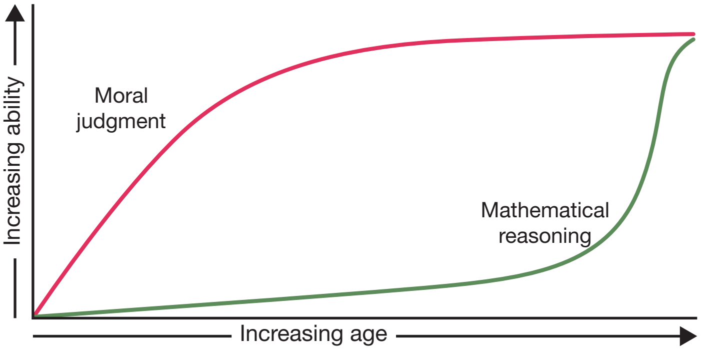

FIGURE 1.9 **Local developmental change.** If two developmental processes show their own distinct patterns of change, their development would be considered local rather than global. Here we see different developmental trends for two hypothetical processes. Note that both processes start at the same lower level and end up at the same higher level, but moral judgment changes rapidly at an early age and then levels off, while mathematical reasoning increases slowly at an early age but increases rapidly at an older age. It is implausible that these two processes would reflect different aspects of changes in the same underlying system.

Q: What are some domains of behavior that might be examined to determine if change is local or global?

How Do Nature and Nurture Shape Development?

Few aspects of developmental psychology are as prominent in popular culture as the "nature/nurture" debate. In these discussions, patterns of thought and behavior that emerge in much the same way regardless of experience are considered the results of "nature," whereas "nurture" is said to describe psychology and behavior that result from specific experiences. This basic "nature/nurture" distinction can be fruitful in discussing development—but it must be applied carefully. It makes little sense to talk about any behavior or psychological process as *exclusively* a product of either nature or nurture.

Consider two physical developments that might seem to illustrate either pure nature or pure nurture. Beard growth in men seems like a development rooted completely in "nature," the unfolding of a genetically predetermined process. In reality, however, the environment is also important, as an extreme environment that disrupts hormonal output can prevent beard growth. Hundreds of years ago in Italy, preadolescent boys who were talented singers were sometimes castrated to preserve their high voices (Peschel & Peschel, 1986). Castration is obviously an extreme circumstance, but strictly speaking, it involves an environmental, or "nurture"-related, influence. Similarly, although a person becomes sunburned from exposure to ultraviolet light, the influence of "nature" also plays a role. Different individuals burn to differing degrees in the same sunlight in the same environment because of genetic differences in pigmentation and other light-sensitive molecules in the skin. Thus, even traits subject to very strong and specific genetic influences cannot emerge without the support of a particular range of environments. And even the most experience-associated traits can develop only within constraints that are heavily influenced by genes.

Because all development, whether physical or psychological, involves an interplay of nature and nurture, it can be tempting to assume that the entire nature/nurture debate is misguided—an argument about a dichotomy that does not really exist. According to such accounts, all development is a mixture of both, and it makes no sense to ask how a particular trait, behavior, or psychological process is influenced by nature or nurture. There are, however, good reasons why the debate has been a topic of fascination for millennia.

While it is true that all psychological development involves interactions between nature and nurture, there are real differences in developmental patterns that can be understood by asking about the relative influences of genes and environment. For example, we can ask if across a wide range of "normal" environments (that is, environments that do not involve such unusual occurrences as brain surgery, hormone disruption, or extreme trauma and deprivation) a child will develop the ability to mentally fuse the separate images seen by the right and left eyes. This capacity for binocular vision requires repeated experiences in a lighted environment with both eyes at the same time; if such environmental conditions are met over time, the vast majority of children will acquire binocular vision in essentially the same manner. In contrast, quite specific environmental experiences are needed to be able to learn how to read—for example, being taught to recognize groups of letters and to associate them with what they represent. This ability does not develop automatically in any environment.

In this book, we will consider the nature/nurture question in many different contexts and at several periods in development. We will see that scientists have disagreed about the roles of nature and nurture in areas ranging from language, to morality, to spatial navigation. These debates are worthwhile, and they can often be illuminated by the data patterns produced by careful research. For example, if some aspects of language development happen in the same way worldwide, regardless of the particular language spoken and regardless of whether parents speak to their children often or just a little, those linguistic developments might be considered more a function of nature than a function of nurture. If, however, those same aspects of language are closely linked to the particular language a child is exposed to, and if they vary greatly, depending on how parents speak to their children, nurture would seem to be more central. Even in cases like these, however, it is important not to oversimplify the question into a matter of "either/or," in which one kind of influence completely excludes the other. We will see that carefully designed studies can be essential to disentangling the relative contributions of nature and nurture to many aspects of development.

One way of thinking about how nature and nurture contribute to some aspect of development involves imagining how a range of different environments might affect these developmental changes (Chomsky, 1975, 1988). Figure 1.10 depicts a situation in which a particular initial state (say, the way a newborn mentally represents human faces) develops in different environmental conditions, shown in the figure as different colored lines. The upper panel represents a more nature-biased account, where environmental variations have little effect on the development of face perception. The outcomes at the right fall quite close together, signifying, in this scenario, that the mind comes to represent faces in much the same way, regardless of the environment an individual experiences. On the other hand, the lower panel represents a nurture-biased account. Here, the triangles representing outcomes are widely dispersed, signifying that quite different ways of representing faces develop, depending on differences in the environment.

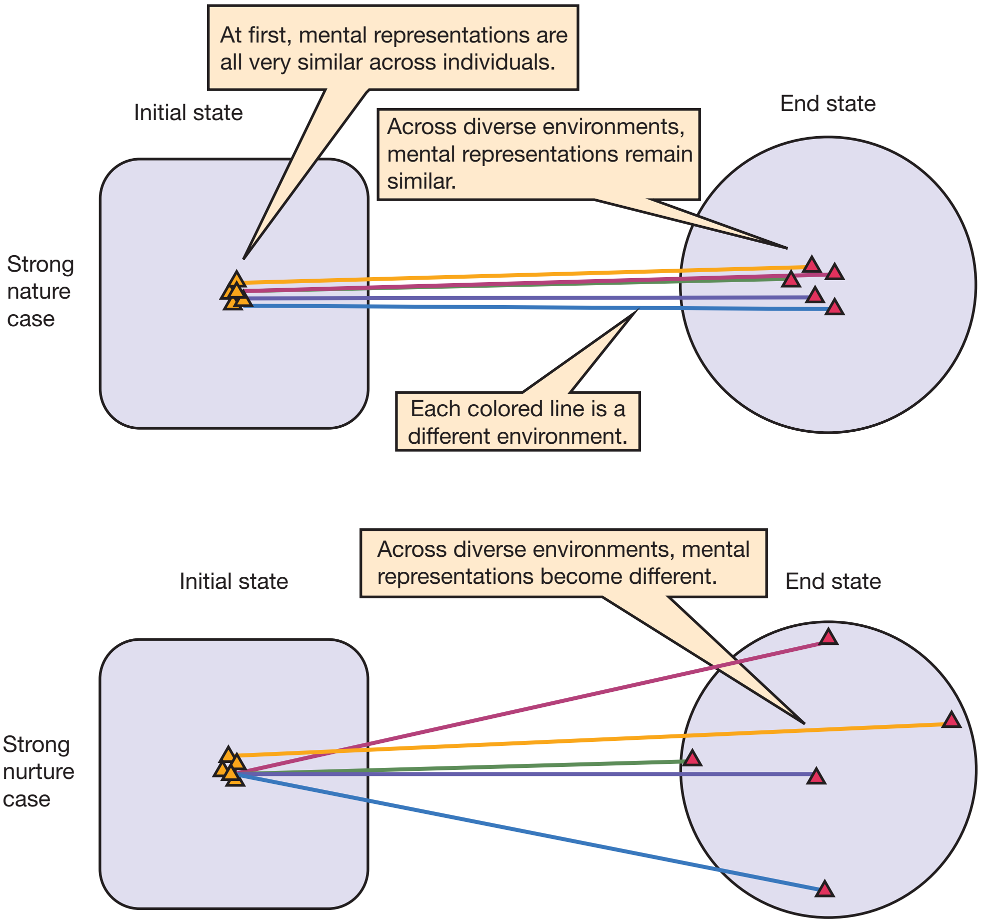
Of course, Figure 1.10 is an idealized representation; in practice, it is much more challenging to determine how the influences of nature and nurture affect development. Moreover, individuals do not really begin life at exactly the same "initial state." Nonetheless, this illustration helps to convey what is often at stake in nature/nurture debates; accounts of development may predict different patterns of change, and even different outcomes, depending on which kind of influences they emphasize.

Up to this point, we have considered nature and nurture largely in terms of whether a particular psychological process or structure tends to develop in the same way regardless of the environments experienced or whether the developmental outcomes vary widely, depending on particular kinds of experiences. A different angle on nature/nurture tends to focus less on such qualitatively different outcomes and instead looks at how genes and the environment each contribute to individual differences (Plomin, 1989). For example, there are intense debates about the extent to which an individual's intelligence is more a product of nurture (including education) as opposed to nature (including genes). It is important to keep in mind that even if the *qualitative aspects* of a skill emerge the same way in most environments, individual differences in the *degree* of the skill could still depend on how the environments differed. For example, in humans, the anatomy and structure of particular muscles develop in the same way across most environments—but when we compare two individuals, the strength of each muscle is significantly related to experience. We will need to keep in mind these different ways of framing nature/nurture discussions as we explore psychological development.

Q: What are some ways in which scholars might disagree about the initial mental state of the newborn infant?

The three questions that we posed in this section—concerning qualitative and quantitative change, global and local change, and nature and nurture—are relevant in each

FIGURE 1.10 Envisioning the "nature versus nurture" debate. This diagram shows one way of depicting the differences between developmental accounts that emphasize nature's influences and those that emphasize nurture. Think of tracing developmental changes from an initial state, as shown on the left, across a range of different environments. (These developmental paths are shown as different colored lines.) In the strong nature account at the top, development that takes place in a wide range of environments results in very similar outcomes. In the strong nurture account, development that takes place in different environments leads to quite different outcomes due to the influences of distinct environmental factors and experiences.



At first, mental representations are all very similar across individuals.

and every chapter that follows. In studying development, it is always useful to consider how these three questions reflect on a particular aspect of development. The answers are not always easy to determine, but just posing these questions can guide further exploration of developmental phenomena.

Perspectives on Development

The fundamental questions just described are usually posed within a particular psychological perspective on the process of development. These different perspectives—which include *comparative and evolutionary perspectives*, *cross-cultural perspectives*, *neuroscience perspectives*, *behaviorist perspectives*, *psychoanalytic perspectives*, *cognitive science perspectives*, and more broadly *empiricist* and *nativist* perspectives—are each based on specific intellectual traditions. They are each associated with certain research methods, styles of argument, and theoretical positions. Thus, each perspective tends to approach developmental questions somewhat differently.

Rather than contradicting each other, these perspectives usually offer complementary approaches. Each one helps to frame a set of phenomena in a manner that emphasizes some aspects over others. When different perspectives are applied to the same phenomena, they often raise different kinds of questions and therefore yield different answers. Because each perspective invariably leaves out some aspects of a problem and emphasizes others, you might think of them as different lenses for examining patterns of change, each one bringing certain issues into sharp focus. For these reasons, we will often find it useful to consider how multiple perspectives provide their own unique insights into a developmental pattern. It is also important to keep in mind which perspectives are in play as you pose questions about psychological development. We start by considering a pair of broad philosophical perspectives on development commonly known as empiricism and nativism.

Empiricist and Nativist Perspectives

By the time psychology emerged as a separate discipline in the late nineteenth century, philosophers, biologists, and others had been actively discussing many of its central issues for centuries, and some of the most persistent, intriguing questions focused on the origins of human perceptions and knowledge. Two philosophical perspectives on development, empiricism and nativism, helped to shape these discussions, which often led to inquiries about how knowledge originates and takes shape in the mind of an infant or child (Spelke & Newport, 1998).

Empiricism **Empiricism** is a view of development that emphasizes the idea that a general, all-purpose learning system, with few or no biases toward acquiring particular kinds of information, is present at birth. Empiricists' proposals and speculations can be traced back thousands of years, but they are best exemplified by three remarkable seventeenth- and eighteenth-century philosophers (see Figure 1.11). John Locke (1632–1704) laid out the general idea that all human knowledge is built up by forming links, or mental associations, between the phenomena we experience. George Berkeley (1685–1753) incorporated this idea of association-based knowledge in his explanation of how we perceive and interpret the visual world. And David Hume (1711–1776) used this same association-based view of knowledge to develop a theory about how complex mental processes work, including how humans understand cause-and-effect relationships.

"All knowledge through the senses" is perhaps the best-known slogan associated with the empiricist movement. It simply means that the content of all knowledge and thought—an elaborate web of learned associations—could only be gained from experience. This slogan, however, hardly does justice to the empiricist position. The empiricists were committed to the idea that the mind (and the brain) made sense of the world by linking together any bits of information that co-occurred frequently enough in experience. Any piece of information, such as the sound of the word "no," could become associated with any other, such as an angry facial expression, provided that an individual experienced that particular combination—in this case, a word and an expression—sufficiently often. In this way, the empiricists argued, sensory experiences that were relatively meaningless on their own became meaningful over time through learned associations.

Nativism **Nativism** is a view of development that emphasizes the idea that a set of different learning systems is present at birth, in which each system is biased to acquire particular kinds of information better than others. The roots of nativist philosophies go at least as far back as the ancient Greek philosopher Plato, and their influence continued into the sixteenth and seventeenth centuries with scholars such as René Descartes and Gottfried Leibniz. Unlike the empiricists, nativists believed that human knowledge could never be understood solely in terms of an increasingly complex web of associations. Their early discomfort with the empiricists' view arose from the observation that different breeds of domesticated animals, such as dogs, showed distinct dispositions and abilities; for example, Labrador retrievers retrieve and sheepdogs herd (see Figure 1.12). Since empiricism could not explain these differences in other species, the nativists asked, why should it be considered plausible for explaining differences in humans? Other arguments against empiricism arose from the sense that it

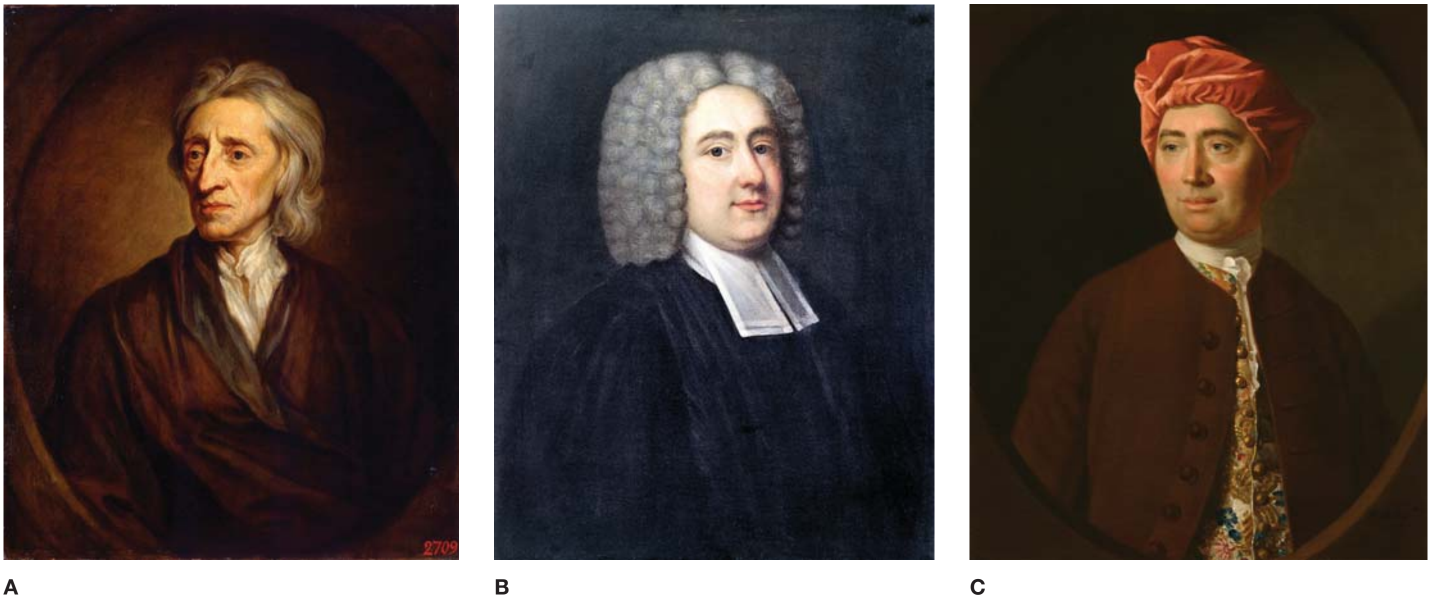

FIGURE 1.11 The early empiricists. Empiricist philosophers **(A)** John Locke, **(B)** George Berkeley, and **(C)** David Hume supported the idea that all knowledge is based on learned associations. This view of how the human mind comes to perceive the world, understand causality, and have new ideas is still with us today.

was impossible to account for the enormous differences in people's specific talents, like musical talent, mathematical ability, or athleticism, only in terms of their prior "associative" experiences.

Instead, the nativists held that certain aspects of mental life were intrinsic to being human and that these capacities were present at birth. The nativists also agreed that these inborn capacities were more specialized and more complex than the general associative mechanism proposed by the empiricists. Beyond these points of agreement, however, there was—for good reason—enormous diversity among the nativists about the nature of the human mind. Without the insights of modern experimental psychology and cognitive science, they could only speculate based on dissatisfaction with the empiricists' much simpler model.

The empiricist and nativist perspectives still influence the study of development today, but at a much more sophisticated level (Carruthers et al., 2007; Pinker, 2002, 2004). The nativists no longer have to rely on intuitions that certain kinds of knowledge—of God, or morals, or mathematics—seem inborn. Instead, they now have experimental data that they can analyze. They propose specific models of mind that make different predictions about such experimental data than do the models proposed by the empiricists.

Empiricist models of psychological development typically involve general learning mechanisms that apply in pretty much the same way to all sorts of content and experience. In these models, the mind's only specializations for handling different kinds of information occur at early stages in the process, such as in the way we perceive the initial input from our different sense organs. Nativist approaches, on the other hand, focus on learning mechanisms tailored for processing particular kinds of information, such as learning language or retaining a mental map of your neighborhood in memory. These nativist approaches suggest that we use specialized capacities for processing much more than just sensory input and that these specializations may include higher mental functions that are far "downstream" from the perceptual system.

Nativism is commonly focused on the influences of "nature" on development, while empiricism is linked to "nurture" (Cowie, 1999), but these links can be misleading. In fact, both empiricism and nativism are based on the idea that organisms must be born with initial capacities that help them perceive and understand their physical and social environment (see Figure 1.13). Sensory organs such as the eyes and ears gather and process information right from birth, and they relay that information about the world to the brain, which processes and interprets that information. Thus, both traditions emphasize that nature endows the newborn with sensory organs and a brain with the capacity to process information from the start.

Empiricists and nativists disagree, however, on the relative roles of nature and nurture in the particular ways we process and interpret information as it moves "downstream" from the sensory organs to the highest levels of thought. For empiricists, once sensory information has undergone some initial perceptual processing, nature's only role is to provide for a general, all-purpose associative mechanism that allows the mind to link together any kind of inputs—whether they are visual or auditory, social or physical, or of any other sort—based on how often they co-occur.

In contrast, a nativist perspective tends to favor preexisting specializations not just for the simplest processing of incoming information but for all levels of the mind. Nativists believe that infants come into the world with mental structures tailored for learning specific kinds of information, such as language, moral principles, or number concepts. These theories consider the brain's specializations

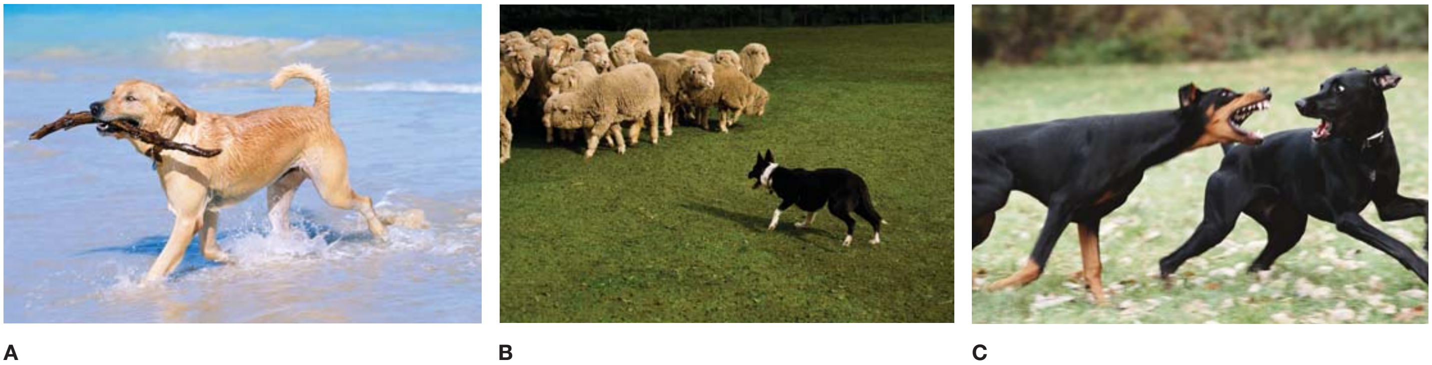

FIGURE 1.12 **Intrinsic behavioral tendencies.** People have recognized for centuries that different dog breeds can have distinct dispositions and reasoning capacities in areas like **(A)** retrieving (as in this Labrador retriever), **(B)** herding (as in this sheepdog), and **(C)** attacking (as in this Doberman). These kinds of strong, intrinsic behavioral differences among animals provided early support for a nativist view of development.

FIGURE 1.13 The initial state. Watching a newborn observe the world immediately raises questions about the human mind's initial state. Clearly, the newborn's brain already differs in important ways from those of other creatures, yet the newborn also clearly has a great deal to learn through experience. Developmental psychologists are intimately concerned with questions about how a baby's biological nature interacts with input from the environment.

for capacities like language use and social interactions to be "built in" or heavily influenced by nature in much the same way that particular parts of the brain are specialized to process visual input from the eyes and other parts of the brain process auditory information from the ears. It is important, however, to remember that just because a particular specialization is strongly influenced by nature does not necessarily mean that it is evident at birth. Remember that male facial hair, which is largely driven by nature, usually doesn't manifest until after puberty. If a particular specialized mechanism is typically present at birth, that often suggests a dominant role for nature in the mechanism's development; but later developments (for example, the growth of a beard) can still be more a product of nature than of nurture.

We will often find it more useful to consider whether a line of experimental research fits better with a nativist or an empiricist view rather than thinking in terms of a simple nature-versus-nurture dichotomy. These debates between empiricist and nativist views are less about whether or not something "built in" or something "learned" enables perception or cognition to develop. Instead, they focus on whether the mind is initially specialized only at the lowest levels of processing different types of sensory information or whether specialized mechanisms exist at all levels of information processing. Nature and nurture are part of this story, but they are not enough on their own.

Comparative and Evolutionary Perspectives

Questions about developmental psychology have never been confined to humans. Many other species have offspring that grow and develop more elaborate behaviors. Indeed, more than most psychological questions, inquiries about development naturally seem to lead to comparisons across species, which are the main focus of the *comparative perspective*. Even a casual observer of a dog nuzzling her puppies or a baby monkey clinging to its mother cannot help but be struck by the close bonds between parents and offspring and wonder why they exist, how they came about, and what they mean to the animals (see Figure 1.14). In fact, an extraordinary diversity of organisms seems to confront similar challenges during development, such as coordinating visual and motor skills with changing body size and ensuring that

FIGURE 1.14 Comparative and evolutionary perspectives. These perspectives often examine a comparable developmental process across several species, as shown in these examples of mothers caring for their young. Researchers may then ask if these behaviors are alike at a deeper psychological level—perhaps because they have evolved to serve similar functions.

FIGURE 1.15 Cross-cultural perspectives. Developmental researchers often ask if developmental patterns unfold in the same ways across cultures. For example, do friendships form in similar ways in all these groups of children? Are the roles of boys and girls the same in all cultures?

fragile young survive to an age of self-sufficiency. A true appreciation and a genuine understanding of developmental psychology must keep in mind the common problems that many organisms confront, even as they sometimes solve them quite differently.

Closely related to comparative perspectives, *evolutionary perspectives* ask how and why a particular trait, whether it is a body part or a behavior, emerged over successive generations of a population through the process of natural selection. **Ethology** is the study of traits from an adaptive evolutionary perspective that usually involves comparisons across species. Thus, ethologists examine how certain traits improve a species' fitness within its specific environment, conferring advantages that make members of the species that have these traits more likely to survive and produce viable offspring. Understanding how particular traits affect a species' ability to reproduce in its environment also requires closely analyzing the local environment itself in terms of its physical features and the other organisms that inhabit it.

Evolutionary and comparative perspectives, however, do far more than describe the range of patterns of development and how they relate to a population's particular environment. Using these perspectives, we can pose specific questions about the origins of various psychological capacities, including our earliest emotions. For example, feelings of disgust at bodily excretions do not seem to be present at birth, but they emerge in all cultures during the third year of life. From an evolutionary perspective, minimizing contact with bodily excretions makes sense, since this would reduce the spread of disease. But perhaps there are also evolutionary reasons that disgust doesn't appear until an age when the child is actually able to do something to avoid the contamination by means of toilet training and hygiene. Researchers are currently trying to learn whether both factors—the desire to avoid contamination and the inability to do so before about the age of 3—affect the way the emotion of disgust develops. Comparative analyses often pose similar questions about the roots of particular human tendencies, such as the tendency to value things you already own more than things you are about to acquire, a bias known as the endowment effect. Comparative research has demonstrated that monkeys show similar biases even without observing similar behaviors in others (Lakshminaryanan et al., 2008). Those results suggest that future developmental studies of the endowment effect in humans may find its earliest traces even before culture has much of an influence.

Cross-Cultural Perspectives

Before making general statements about the development of any process, whether it is a child's attachment to a parent, the concept of self, or almost any other aspect of psychological development, it is crucial to gain a sense of how that process develops in different cultures (see Figure 1.15). All too often, we take our own culture's patterns as the obvious default options, only to be surprised that these familiar tendencies actually may be quite rare in other cultures.

The *cross-cultural perspective* on development focuses on two main issues. First, how do cultural variations influence patterns of development? Research addressing this question has become increasingly sophisticated in recent years, demonstrating how development in such diverse areas as moral reasoning, folk biology (intuitive patterns of reasoning about the living world), and religious beliefs differ between cultures. The most insightful approaches have developed models in which specific aspects of cultures, such as cultural values or norms, are thought to have distinct psychological outcomes. For example, some cross-cultural researchers have argued that growing up in a collectivist culture, where the group is considered more important than the individual, results in different patterns of reasoning than growing up in a more individualist culture (Nisbett et al., 2001).

The cross-cultural perspective's second main concern is with consistency across cultures: What aspects of behavior or mind, if any, develop in the same way throughout the world? Whereas some kinds of psychological development differ systematically across cultures, others show little variation and reflect universal patterns of psychological development. For example, the way children come to learn about rules of etiquette or religious practices may vary dramatically as a function of culture, but the way they learn to walk or to perceive visual depth develops in much the same way regardless of culture. Some of the more interesting and controversial questions within cross-cultural perspectives involve how culture contributes to the development of morality, spatial abilities, and interpretations of events.

Neuroscience Perspectives

Neuroscience perspectives focus primarily on the neurobiological systems that give rise to psychological development. One way to do this is to consider the maturation of the brain. For example, between birth and age 2, extensive changes occur in brain size and physiology, raising questions about how those changes relate to the psychological developments taking place during these years. Thus, the hippocampus, a brain structure centrally involved in forming new memories, was once thought to be fully mature late in infancy—so that older infants would likely form memories in similar ways to older children and adults. However, more recent work suggests that between birth and 3 years, hippocampal structure changes substantially at the neural level, and these changes may help explain how memory abilities change in the first 3 years of life (Ghetti et al., 2010). Because of this neuroanatomical research, psychological views of early memory are changing. In recent years, neuroscience researchers have claimed similar linkages between specific aspects of brain development and the emergence of various capacities, such as learning language, delaying gratification, searching for hidden objects, and perceiving faces. As the methods of measuring the developing brain's structures and patterns of activity become more refined, it will be possible to study how brain growth influences psychological development in greater detail (see Figure 1.16).

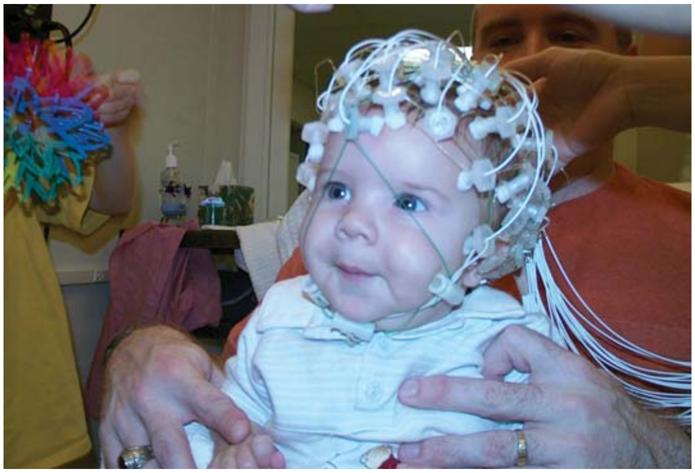

FIGURE 1.16 Neuroscience perspectives. This infant is hooked up to an EEG (electroencephalogram). Neuroscience perspectives on psychological development ask how biological changes in the brain (here measured as electrical waves picked up on the head's surface) relate to psychological changes over the course of development.

A second way the neuroscience perspective informs the field of psychological development has to do with how the nervous system changes as a result of experience. Experience modifies the brain in many different species, and it is essential to keep in mind that the causal relationships between changes in the brain and psychological development run in both directions: brain development can cause psychological changes, and experiences—including their psychological components—can also change the brain. For example, as mentioned earlier, experience with visual information that reaches both eyes simultaneously is essential to the development of normal binocular vision, raising the question of how early visual experiences cause changes to individual brain cells.

Behaviorist Perspectives

In the history of psychology, the great challenge of studying internal events and mental states in a scientific, unambiguous way has fueled some major disputes. In the last few decades, some researchers have developed innovative and increasingly precise techniques for inferring mental states. Others, however, find it more prudent to focus on observable behaviors and how they are shaped by external factors over the course of development. Proponents of this behavior-focused approach favor *behaviorist perspectives*, which have a long history in North American psychology (Watson, 1913). As we will see in Chapter 4, behaviorists developed particular methods that enabled researchers and animal trainers to shape behaviors through carefully controlled patterns of reinforcement (Skinner, 1938). Despite severe limitations to behaviorism that emerged in the 1960s, some of its techniques for modifying behavior are still commonly used with both humans and nonhuman animals. A behaviorist perspective can be helpful in some clinical situations, as in modifying the behavior of an aggressive child who is hurting others in the classroom. Because the child's aggression may arise from several factors that are difficult to tease apart, a clinical psychologist might focus initially on trying to change the child's behavior through positive, and possibly negative, reinforcements (see Figure 1.17). Behaviorist perspectives can have severe limitations when they deliberately ignore all information about mental states and processes, but by emphasizing relationships between changes in the environment and changes in behavior, they can bring into sharp focus aspects of psychological development that might otherwise be neglected.

FIGURE 1.17 Behaviorist perspectives. Behaviorist perspectives on development ask how various external reinforcements, such as rewards and punishments, can shape a child's behavior. Here, stickers seem to be a strong reward for a recent behavior.

FIGURE 1.18 Psychoanalytic perspectives. Psychoanalytic perspectives often ask how an emotionally powerful early experience, such as toilet training, might relate to later personality development.

Psychoanalytic Perspectives

In contrast to behaviorism, *psychoanalytic perspectives* focus on understanding internal mental states and processes. Psychoanalytic perspectives, which originated from Sigmund Freud's psychoanalytic theory, cover several different ways of talking about mental life, but they tend to share a few key features. Their proponents see the mind as having distinct components that exert different kinds of influences on behavior. Among these components, they emphasize the power of the unconscious—thoughts and emotions occurring outside awareness—to affect behavior. They also view many kinds of psychological problems as a result of conflicts between different components of the mind, such as between conscious and unconscious desires.

Psychoanalytic views of development tend to see early childhood experiences as having important and lasting influences later in life (see Figure 1.18). Sometimes those early experiences are thought to set up internal conflicts or provoke strong emotional reactions that can stay unresolved and outside of awareness until a skilled therapist unearths them. Most psychoanalytic perspectives also view development as a series of stages, thereby emphasizing patterns of apparent qualitative change. The process of moving through those stages could also give rise to unresolved internal conflicts. In this view, if a child fails to make a complete transition from one developmental stage to the next, he can remain partially "trapped" in a psychological stage that conflicts with other, more mature aspects of himself.

Many aspects of psychoanalytic perspectives have been criticized in recent years, including psychoanalytic accounts of infants' attachments to their parents, the development of moral beliefs and behaviors, and the nature of toilet training, among many others. These challenges often seek to refute specific psychoanalytic proposals, very often those of Freud himself, which seem to make incorrect predictions about parent-child relations or to propose developmental psychological processes for which there is no evidence. It can therefore be tempting to dismiss all psychoanalytic perspectives as quaint historical curiosities. Yet, in a broad sense, these perspectives highlight several important aspects of psychological development that are still of great interest, such as the influence of processes outside of consciousness, the role of early experiences, the idea that the mind develops distinct components with different characteristics, and the presence of developmental stages.

Cognitive Science Perspectives

Late in the twentieth century, the *cognitive science perspective* on studying the mind emerged in universities and research centers. This approach to developmental psychology draws on methods and models from several disciplines—psychology, computer science, philosophy, neuroscience, and linguistics—to ask how specific skills or kinds of knowledge emerge and change. These perspectives involve more than just embracing different fields' approaches, however. In particular, cognitive science perspectives focus on questions about how our ways of representing and using information

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Measuring Infants' Brain Function: Near-Infrared Spectroscopy (NIRS)

Across fields of psychology, researchers are studying brain activity to shed light on the processes underlying thought and action. One commonly used set of techniques, called functional neuroimaging, involves taking precise measurements of neuronal activity and representing them as images that show different levels of activation in specific brain regions. In studies of older children or adults, a technique known as functional magnetic resonance imaging (fMRI) has become the dominant method of brain imaging. This method takes advantage of the finding that when neurons in a specific area of the brain are active, the amount of oxygenated blood flowing to that area increases. Thus, fMRI scanners work on the principle that at a molecular level, oxygenated blood reacts differently in a magnetic field than deoxygenated blood. By measuring this difference in the brain of a volunteer while he performs a particular mental task, researchers are able to see which brain areas receive greater blood flow—and to infer that those areas are the most active. This kind of neuroimaging can capture detailed images of activity in particular brain areas, but it requires that the participant be very still inside a scanner, usually for 15 minutes or longer. During the scan, the machine's powerful magnets also cause sudden, loud pulsing noises. For these reasons, the technique is difficult to use with young infants.

Recently, a new silent brain-scanning technique known as near-infrared spectroscopy (NIRS) has been developed that can tolerate substantial head movements without compromising the resulting images, and it seems to be safe for use with infants (see Figure 1.19). NIRS involves shining a low-energy band of near-infrared light through the infant's scalp and skull and measuring the infrared light that is reflected back. Based on the reflection patterns, researchers can determine blood oxygenation levels in different areas of the brain (Aslin & Mehler, 2005; Hoshi, 2007; Meek, 2002; Sakatani et al., 1999; Villringer & Chance, 1997). Thus, like fMRI, NIRS is a way of measuring which brain regions are more active based on the increased flow of oxygenated blood to those areas. Using precise sensors, these measurements can be taken with relatively low levels of infrared light, comparable to a few minutes of bright sunlight. This technique offers an important new way of addressing critical questions about early changes in brain functions and psychological processes (Minagawa-Kawai et al., 2011; Wilcox et al., 2005).

One interesting use of NIRS has been to explore whether infants' brains have regions specialized for processing numbers long before the child can speak. Researchers monitored infants' brain activity with NIRS as the infants repeatedly viewed groups of objects. Most of these groupings had 16 items, but occasionally the infants saw an "oddball" array with a different number. Intriguingly, 6-month-olds reliably showed increased activation of a particular region of the brain's right hemisphere when a deviant number appeared in the display (Hyde et al., 2010). Further research will be needed to determine whether this pattern of results is specific to observing a change in number. By helping researchers to address questions like this and to make inferences about the mental capacities of preverbal infants, NIRS is likely to be an especially useful tool for studying early brain development.

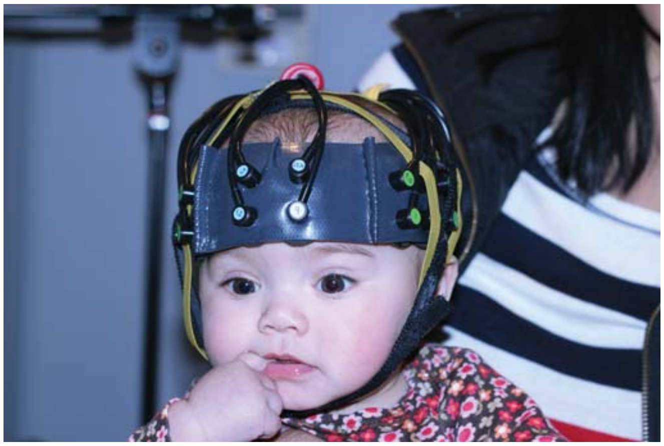

FIGURE 1.19 Near-infrared spectroscopy (NIRS) and brain activity. This infant's brain activity is being measured with NIRS. Low-energy near-infrared pulses of light are transmitted through the scalp and skull onto brain regions, then reflected back onto sensors near the light transmission points. This procedure, which is as harmless as a few minutes of bright sunlight, allows researchers to measure blood flow changes in various parts of the infant's brain.

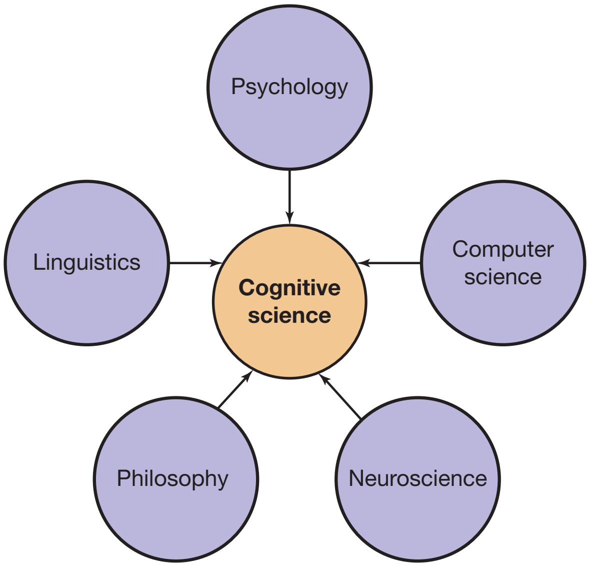

FIGURE 1.20 **Cognitive science perspectives.** Cognitive science perspectives often ask about how people represent and use information. Cognitive scientists draw on the theories and methods of several disciplines to see how each one offers unique insights into common questions.

change over the course of development (see Figure 1.20). To fully address these questions, they seek to integrate many ways of studying information processing, including formal computation (computer science), biological bases (neuroscience), logical consistency (philosophy), expression in language (linguistics), and the way these different types of information processing take place in a real organism in real time (psychology).

In practice, a cognitive science researcher may focus within one discipline, but will nonetheless consider how the progress in other relevant disciplines informs her work. For example, a cognitive scientist interested in how language is acquired might conduct experiments on language acquisition in children (psychology), but when designing experiments, she might also look at formal descriptions of language capacity (linguistics), conceptual analyses of the relationship between language and thought (philosophy), models of language acquisition in computer systems (computer science), and relations between brain development and language development (neuroscience). In the study of development, questions about the origins of thought and knowledge and about the ways that skills and abilities change over time naturally lead to considerations of what kinds of information processing the developing organism is doing.

We will frequently consider the cognitive science approach in this book—not only in areas of development traditionally associated with it, such as visual perception and logical reasoning, but also in areas such as social and emotional development. In almost all areas of psychology, it is useful to consider how people represent and use relevant information.

Studying Psychological Development

Not surprisingly, it takes a wide range of approaches to study topics as diverse as a newborn infant's ability to see color and an adolescent's ways of relating to her peers. Throughout this book, we will encounter various methods of investigating particular questions about development. At the outset, it is useful to survey the range of research techniques that we'll encounter to provide a methodological road map and to explain some key terms.

Observational Studies

The oldest, and seemingly simplest, method of research is the **observational study**, in which children are simply observed in a natural setting and their behaviors are carefully recorded (see Figure 1.21). These records may take the form of trained observers' written notes or collections of audio or video recordings. But this method is not always as simple as it sounds. Suppose you are interested in researching how children's personalities develop between ages 3 and 5. Perhaps you plan to observe a classroom of 20 preschoolers to test some ideas about how the traits of shyness, aggression, and leadership develop and how they relate to the child's preschool experiences. (For example, shy children may seek out different environments within the classroom than extroverted children.) What observational data would you collect? You could potentially measure thousands of different variables: the number of seconds between each conversation for each child, the direction and duration of each eye gaze, a vast array of facial expressions or body postures, the objects a child

FIGURE 1.21 **Observational studies.** Videos of children in everyday settings offer rich opportunities for data collection, but coding and interpreting the footage also create challenges.

holds, the size of the group a child is in, each child's proximity to the teacher, and so on.

To focus on their research questions and keep from being overwhelmed by information, observational researchers must decide which variables to measure among a vast set of possibilities and how frequently to measure them. Suppose, for example, that a theory of emerging friendships suggests that shy children take longer to establish friendships than outgoing children because the shy children make less eye contact with peers whom they have just met. A researcher might measure durations of eye contact every 5 minutes after some shy children and some outgoing children first meet other new children. Later on, when analyzing the data, the researcher would see whether the amount of early eye contact was systematically related to later measurements of the time required for a friendship to develop. In addition, the observational setting itself may be critical. Perhaps a key aspect of personality must be examined across several situations to be understood. Thus, the researcher must decide whether to observe the children in the preschool classroom, in the home (at a particular time or day of the week), or in a less familiar setting, such as a new mall. Observational studies require a specific model or theory to help guide these decisions, specifying which variables should be of interest and why.

New observational technologies open exciting possibilities for observational research, but these developments may also muddy the research issues at stake. When tape recorders became commonplace, they were soon used in many studies. Video recording represented the next major change, and soon researchers were collecting thousands of hours of videos of children in a wide range of situations. Today, the decreasing cost of digital video and increasing computational abilities to automatically search video frames will likely contribute in important ways to developmental research. Another exciting technological innovation allows some aspects of video scenes to be automatically coded based on researchers' specifications, making it quicker and easier to analyze very large data sets of children's behaviors in natural settings (Roy et al., 2009). But these technologies are valuable only when researchers use them carefully and strategically to zero in on critical variables. Researchers must decide which recorded behaviors to observe and how to categorize and quantify them.

Observational studies play an indispensable role in developmental research despite their limitations. In many situations, they allow researchers to assess children's behavior under natural, normal circumstances—without the distortions caused by bringing children into a lab to study their behavior under carefully controlled conditions. In addition, observational studies allow for the possibility of unexpected discoveries outside the immediate research question. Such surprises are a common source of inspiration in scientific research, and observational studies can suggest many new possibilities to pursue.

One intrinsic limitation to observational studies is that they uncover correlational patterns, not causal ones. This limitation is important to keep in mind because the goal of most scientific research is to identify causal relationships. For example, if a researcher wants to know whether children play more aggressively after watching violent cartoons, she is asking whether the cartoon violence somehow *causes* the kids to treat each other more aggressively. An observational study might show a strong correlation between these behaviors, such that children who watch more violent shows also favor more aggressive play. But these observations would not help the researcher determine whether one of these behaviors caused the other. It might be true that watching violent cartoons makes children more likely to play rough, but the correlation could also be driven by a different causal relationship. One possibility is that children who are aggressive choose to watch more violent cartoons. In that case, being aggressive would cause the television watching, rather than the other way around. Another possibility is that a third variable, such as lack of parental control, could cause children to both behave aggressively and watch more violent television. In this case, aggression and viewing violent TV could be closely correlated, even without being directly linked.

Some scientists use complex statistical techniques to try to infer causality from observational data (MacKinnon, 2006). While such approaches can strengthen a particular causal interpretation of the data, it remains difficult to rule out the possibility of other influences on the data (Pearl, 2010). We will see, in contrast, that well-designed experimental studies can clearly demonstrate specific causal relations. This is just one example of the tradeoffs involved in choosing between research methods. Observational studies may often yield exciting new ideas, but they typically do not produce firm conclusions about cause and effect.

Q: What are some strengths of observational studies?

Experimental Studies

To answer developmental questions about cause and effect—such as whether watching violent cartoons *causes* aggressive behavior or whether participating in after-school programs *causes* better academic performance—researchers often design an **experimental study**. The goal of these studies is to manipulate a single variable while holding all other aspects of the experimental situation constant. By changing only one variable at a time in the course of an experiment, researchers are better able to pinpoint exactly which change caused any differences they observe in the experiment's outcome.

To return to our earlier example, if a researcher wanted to determine whether watching violent cartoons *causes* aggressive behavior, she might recruit two groups of children for a study in which she would manipulate the amount of time the children spent watching violent cartoons. She would be careful to randomly assign children to each group to ensure there were no initial differences between the groups. If the children who watched the cartoons for many more hours subsequently showed an increase in aggression while the other children did not, this would support the claim that watching violent television can cause children to behave more aggressively.

In most developmental psychology experiments, a researcher presents some sort of stimulus or event to a participant (usually a child or nonhuman animal) and then measures the participant's pattern of behavior. It is common to speak of the **independent variable**, which is the variable manipulated by the experimenter, and the **dependent variable**, which is the variable being measured to see whether or how it changed in response to manipulation of the independent variable. For example, in an experiment designed to test children's verbal memory, you might be interested in finding out how the child's age (the independent variable) affects the percentage of words from a list the child can recall correctly (the dependent variable). In this scenario, age would be the independent variable because you are interested in the way differences in age affect another measure (memory). In this case, you would "manipulate" age by presenting the memory task to children of different age groups. To be sure that any differences in performance were due to the children's ages and not to some other aspect of the testing situation, it would be crucial to carefully control, or hold constant, all other variables. Thus, you would want to make sure that all the children were tested in equally quiet environments that were free of distractions, and at the same time of day so that they would be equally alert. Finally, you would want to ensure that all the children were similar to each other in terms of socioeconomic status, cultural background, and other possible differences and that they were drawn from the same broader group, or population, that you wish to study, such as middle-class elementary school students.

One advantage of experiments is that they allow researchers to examine highly specific effects of stimuli and events on participants. For example, suppose a researcher wanted to know if kindergartners were able to use transitive reasoning—that is, if stick A is longer than stick B, and if stick B is longer than stick C, do kindergartners realize that stick A must be longer than stick C? It is unlikely that kindergartners do much observable transitive reasoning in their daily lives. Some aspects of everyday situations may involve this kind of thought, but all the complexity and variety of these real-life problems would make it impossible to tell for sure whether a child is using transitive reasoning to solve them.

But when an experimenter poses carefully designed, age-appropriate questions that require transitive reasoning, he is able to assess the children's abilities more clearly. In the context of an experiment, the researcher could present transitive reasoning problems of various difficulty that deal with some topics familiar to kindergartners (such as comparing the heights of children) and some topics that are unfamiliar to them (such as comparing the costs of hotel rooms). Those systematic manipulations would help the researcher determine whether young children failed at certain transitive reasoning tasks primarily because of a difficulty with this type of reasoning or whether their failures were actually due to other factors (such as difficulty remembering all the components of the problems or unfamiliarity with the material used in the problems).

Of course, experimental approaches also have their limitations. Perhaps the biggest challenge is **ecological validity**—whether a study faithfully captures a pattern of behavior that would occur in the normal circumstances of childhood. An experiment that lacks ecological validity may be elegantly designed and carefully controlled, but its results may be irrelevant to the real world. To take an extreme case, imagine that you wanted to experimentally examine the development of sharing in children between the ages of 5 and 10. In your experiment, a group of children are brought to the lab—where digital cameras and note-taking researchers will record how often they share—and put in pairs. One child in each pair is shown a basket of several types of candy and asked to point out her favorite. An assistant then gives many pieces of that same candy to the other child in the pair, who is sitting across the table. As the cameras record and the experimenters take notes, the children with candy almost always share it with the other child, regardless of their age. You could hastily conclude that there are no developmental changes in sharing between ages 5 and 10, but there would be clear problems with this conclusion. Surrounded by adult observers and confronted with a blatantly unfair distribution of candy, almost any child would be compelled to share. In a more natural setting, children might behave very differently, depending on their age. Although the problems are clear in this example, similar issues lurk in most experimental studies. The more a study departs from everyday situations, the more it risks failing to measure variables of real interest. Yet, such departures from real-life circumstances can also confer great advantages by allowing researchers to elicit specific behaviors and closely control their measurements.

More broadly, experimental research requires certain idealizations from real-world settings (Strevens, 2009). All scientists try to isolate the phenomena they study—which is why physicists think about "frictionless" inclined planes and "ideal" gases and biologists think about hypothetical,

DEVELOPMENT AND SOCIAL POLICY

What Kinds of Experimental Research Are Justified?

Experimental techniques are invaluable in developmental research, but unlike observational studies, experiments bring children and infants into environments they would not otherwise encounter. How do researchers justify manipulating children's experience?

Clearly, not all experiments are justified. Few would approve of an experiment that caused children to feel intense shame and discomfort in order to study their coping strategies. It strikes us as simply wrong to purposely upset children or make them uncomfortable, regardless of the value of the scientific insights that such an experiment might yield. But what about a more benign experiment in which an infant stares at a stimulus for 10 minutes until he is bored? And is it acceptable to pay a 6-year-old a large sum of money to participate in an extremely tedious task? Researchers must carefully consider the risks and benefits for participants in their studies—especially when working with children and infants, since they are much less able to advocate for themselves than are most adults. The researcher's goal, as in all research on humans, is to minimize any risks to participants and to directly benefit both society at large and the participants themselves to the greatest extent possible.

In most countries with large-scale human research programs, every university, hospital, or other institution that undertakes such research is legally required to have an institutional review board, commonly called an IRB. An IRB typically consists of researchers from a wide range of fields who are engaged in studies of humans, and it often also includes members of the community outside the research institution. On behalf of the research institution, IRB members scrutinize all research proposals that involve human subjects to ensure that the planned studies do not pose unreasonable or unnecessary risks for those who participate.

Ideally, researchers should always analyze the costs and benefits of their own studies and strive to ensure that their benefits outweigh their potential risks. Risks to participants might range from discomfort in doing an experimental task to self-esteem problems if a child finds out that her peers outperformed her. On the other hand, participants can also benefit from taking part; in fact, some tasks might be intensely engaging for young participants. More broadly, a study's benefits to society include any information the research yields that furthers understanding of development, so as to better inform decisions about children's education, care, and welfare.

Another critical issue in the IRB's review, and one that is especially important in studies involving infants or children, is the participants' ability to consent to take part. Before they consent, potential participants should be told as much about the experimental procedures and goals as possible without compromising the research. The researcher must also be sure that all participants understand that they are free to discontinue the study at any time and are under no obligation to finish a session or a task. In the United States, a child under age 18 is not considered fully capable of consenting to participate in research. Along with the child's own consent, a parent or legal guardian must give written consent as well. In addition, researchers who work with children must watch them carefully throughout the experiment for any signs that they would like to discontinue the study, and their wishes must be honored. During and after a study, researchers typically are also obligated to protect participants' privacy, and the records are usually coded to make sure no one reading about the research can identify the participants.

Because experiments involve studying people outside of normal daily circumstances, they often raise the clearest questions about potential risks, but concerns about costs and benefits to participants are also relevant to observational studies. Many observational studies risk intruding in children's lives, as the observers may be in plain view, unintentionally influencing the children just by being present. Even so, most researchers assume that children who have (with parental approval) consented to participate will fairly quickly become accustomed to being observed and will behave normally. Concerns about confidentiality are as important in observational studies as they are in experimental studies—maybe more so, since the natural behavior being observed may be more revealing of the child's true nature. A child who cheats in a contrived laboratory card game may not be nearly as stigmatized as one observed cheating in the classroom. For all these reasons, observational studies usually require participants' consent, but researchers may opt not to reveal the focus of their research until after the observation is complete to avoid influencing children's behavior.

Many important research questions in developmental psychology, such as how children deal with failure, are particularly difficult to study because of ethical concerns. Children are an especially vulnerable group, so it is only reasonable that developmental research should be conducted extremely carefully.

simplified ecological systems. Likewise, psychologists sometimes focus on individuals without accounting for all the social influences that affect each person. But does the effect of isolation from a normal, social context undermine conclusions about the individual? This question—how much are you influencing the processes you're researching just by isolating them?—is important to keep in mind for all psychological research, but many contend that it is especially relevant to questions of development.

There are certainly tradeoffs between focusing on the developing organism outside the context in which development takes place, as experiments typically do, and accounting for the developing child's many complex interactions with other people and the broader culture. Developmental researchers think carefully when designing their studies about which emphasis is best for the question they are addressing. In some cases, often in the initial stages of exploring a topic, observational studies may be more appropriate. In other cases, such as pinning down cause-and-effect relationships more precisely, experimental designs may provide more insight. Experimental researchers therefore constantly attempt to simplify the situations that they study in ways that allow them to understand what is going on without distorting the circumstances too much from everyday experiences. Psychologists continue to wrestle with questions about which aspects of psychological development can be studied with relatively little attention to such contextual issues and which ones are inextricably linked to those issues.

Q: What are some of the tradeoffs between naturalistic-observational methods and experimental methods when asking research questions about psychological development?

Longitudinal Approaches

In choosing between observational and experimental studies, all research psychologists must consider their available resources, their research questions, and the advantages and drawbacks of different types of study. When developmental researchers are interested in how children change over time, they typically must decide between two different approaches to studying change over time—namely, longitudinal and cross-sectional approaches. Each of these approaches has its own strengths and weaknesses, and each can be used in designing either an observational or an experimental study.

One appealing way to learn about a developmental pattern is to study a single group of children repeatedly, over a time period that includes the aspects of development you wish to research. This method of measuring the same children's abilities or behavior on a regular basis over time is known as a **longitudinal approach**. For example, you might want to study how children come to understand the concept of fractions by looking at how their ability to solve various fraction-based math problems changes from ages 5 to 15. Taking a longitudinal approach to this study would involve tracking the progress of the same group of children over this 10-year period, perhaps assessing each child's understanding of fractions at the beginning of every school year (see Figure 1.22A).

Longitudinal approaches are well suited to uncovering developmental differences between individuals. By taking repeated measures of each individual child over time, the researcher essentially documents each participant's specific developmental trajectory—which can then be compared with those of other participants. Thus, if some children first understand fractions by visualizing sections of a figure, while others begin to learn about them by following steps in a calculation, a longitudinal study might reveal how these different patterns unfold. Longitudinal studies can also help researchers ensure that many of the variables that could influence their results are held constant. There is no need to worry about whether separate groups of participants are truly comparable, since the same set of participants is studied over the course of developmental change; whatever is distinctive about a child at one age will tend to remain distinctive at later ages. Finally, longitudinal studies allow a special kind of research known as **microgenetic analysis**, in which the researchers assess participants every few days or weeks rather than every few years (Cheshire et al., 2007; Siegler, 1995). This approach documents the details of developmental transitions at a scale much closer to real-time change in skill or cognitive structure. For example, one might do a microgenetic analysis of a child overcoming an error in mathematical calculation.

Longitudinal studies also have several drawbacks. A major limitation is that they often require an enormous commitment of time and expense. Some studies can take 15 to 20 years to complete. If, for example, you wanted to test a theory about whether the strength of infants' bonds with their mothers predicted their romantic relationship styles as adults, you would have to wait for the infants to reach young adulthood. Such long time frames cause additional problems beyond the research team's extended commitment to a single study. Because of the need to maintain consistency throughout the study, a researcher can get stuck asking participants the same questions in the same way for many years, even if advances in the field suggest new, preferable approaches. Likewise, in long-term longitudinal studies, researchers run the risk that their measures may seem

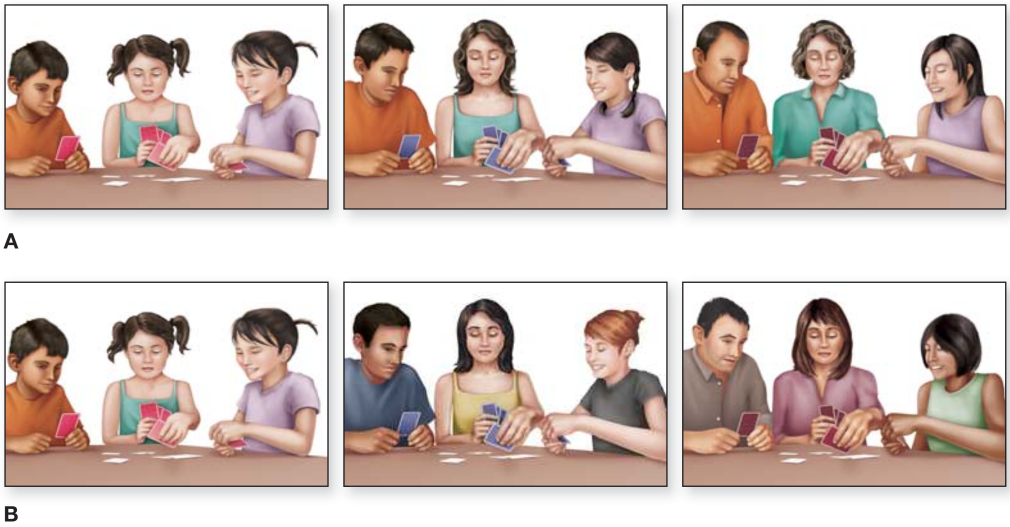

FIGURE 1.22 Longitudinal versus cross-sectional approaches. (A) In a longitudinal study, the same group of people is studied at various time intervals. **(B)** In a cross-sectional study, a different group of people is studied at each age of interest to the researchers.

outdated or flawed by the time the study is over. Retaining a large enough group of participants over time is also challenging, as families move or no longer want to participate.

Finally, a subtle problem can confound the more experimental longitudinal studies. Suppose you assessed understanding of fractions by repeatedly presenting children with a series of problems to answer. If you do this every 6 months for 6 years, the experimental assessments themselves can become a form of training that affects how the participants' understanding of fractions develops. In this case, you would be studying the *effects of participating in the experiment* rather than the natural course of development. For that reason, experimental longitudinal studies are often used to study the effects of training on the development of particular skills or capacities.

Q: What are some drawbacks of longitudinal studies?

Cross-Sectional Approaches

A study that examines developmental change by comparing groups of children at different ages is known as a **cross-sectional approach** (Figure 1.22B). To use this approach to study how children learn fractions, you might select six groups of 20 children each, taking a group of kindergartners, a group of second-graders, and so on, through a group of tenth-graders, and then test each group's abilities to solve problems using fractions. With sufficient research staff, the entire study could be conducted in just a few weeks, rather than the 10 years that a longitudinal design would require. The cross-sectional approach provides another advantage when it comes to experimental studies. Unlike the longitudinal approach, which requires the same participants to repeat the experimental tasks at different ages, the cross-sectional approach involves studying a different group of children in each age group. As a result, each child is assessed only once, and there is no need to worry about the experimental tasks accidentally becoming a form of training. Most of the experimental studies discussed in the chapters that follow will be cross-sectional.

The largest drawback of cross-sectional studies concerns their inability to follow specific individuals' development over time, which makes them much less sensitive than longitudinal studies to individual differences in developmental paths. For that reason, psychologists who are interested in how individual differences develop over time, such as how personality traits emerge, tend to use longitudinal approaches. Nonetheless, cross-sectional studies can shed light on other kinds of individual differences, such as how a behavior manifests at particular points in development. For example, a researcher might be interested in how shy children cope with large groups at the ages of 5, 10, and 15. A cross-sectional observational study could enroll 20 shy children at each of these ages and then observe the children's interactions within large groups to see how the behaviors of each age group differed. By comparing the coping methods of the 5-year-olds, the 10-year-olds, and the 15-year-olds, the researchers could learn how those behaviors varied with age.

Aside from these specific strengths and weaknesses, a different sort of factor related to broad historical patterns can also influence whether a researcher uses a cross-sectional or longitudinal design. If the changes within a culture over time significantly alter children's experiences, research that compares children of different ages can be subject to **cohort effects**, in which a given age group (or cohort) might differ in important ways from people in the same culture who are somewhat older or younger. Suppose you were interested in how and when children first become aware of their peers' interests and activities. If you simply used a cross-sectional design to examine four different groups of children, in grades 4, 6, 8, and 10, you would likely get distorted results. With the rapid rise of online social networks, today's fourth-graders probably know more details about the daily activities of distant acquaintances than their older siblings did at the same age. This cohort effect might suggest another approach and a slightly different research question—perhaps a longitudinal study of how the increasing availability of social networking sites influences what children know about their peers over the course of childhood and adolescence.

Q: What are some drawbacks of cross-sectional studies?

Converging Methods

Developmental psychologists, like other psychologists, often use several different ways to explore a particular problem. As we have seen, each method has its own advantages and limitations. As researchers apply more methods to the same problem, the different approaches tend to complement each other in ways that create a more accurate overall picture. This process is known as using **converging methods**. As researchers use various approaches to probe a phenomenon from different vantage points, the results of the different types of studies tend to converge on a more accurate, objective answer than any single method could produce. For example, we might observe that certain forms of parent-child interactions are correlated with the children having earlier autobiographical memories when they grow up. But to be more confident that the interaction is having a causal effect on earliest memories, we might also conduct an experimental study in which we taught randomly assigned parents to interact in a particular way with their young children and then later asked those children if they had earlier memories than those of the children in a control group whose parents had not been taught to interact in this particular way. Similarly, if we perform a cross-sectional study of children between the ages of 2 and 7 who are sampled 1 year apart and observe that the correlation emerges at around age 7, we might then do a longitudinal study to see how early parent training has to occur to have a maximal effect. Consider, therefore, the ways in which the advantages and disadvantages of observational and experimental studies and longitudinal and cross-sectional approaches overlap. Table 1.1 illustrates the main strengths and weaknesses of each and how they intersect in different types of studies. These tradeoffs illustrate the importance of using converging methods.

Throughout this book, we will see how converging methods can give rise to new insights into specific developmental questions. For example, researchers who study infants' understanding of physical objects use a number of different methods to figure out what is happening in babies' minds. Some measure how infants react when their expectations are violated; others examine infants' reaching patterns in response to different objects; and still others study the details of infants' eye movements as they examine an object or event. When these different methods all tend to tell the same story, their separate measures tend to support one another. On the other hand, when various methods tell very different stories, this raises important questions for researchers about how to interpret each measure.

Q: What is the value of using converging methods?

Designing a Sound Study

Beyond the tradeoffs involved in different types of developmental studies, several concerns about research methods apply to almost all psychological studies. These concerns are relevant regardless of whether the research participants are adults or children. At the most general level, researchers need to make sure their findings are as *reliable*, *valid*, and *replicable* as possible.

Reliability and Validity The issue of **reliability** refers to whether researchers would obtain consistent results if they or others repeated the research study in the future using the same types of participants. More precisely, researchers often talk about the reliability of a specific way of measuring behavior, such as a test or an experimental task, rather than the study as a whole. A highly reliable measure will consistently yield the same pattern of results, as long as investigators have controlled for other possible influences. Such a measure is analogous to a tool that works the same way every time rather than working only sometimes.

Suppose researchers are testing a theory that young children remember events they see in videos more accurately than events described in words. The researchers develop a way of testing both kinds of memory, and they design a study using this memory test at several different ages. The measure has reliability problems if it yields different results when repeatedly used with children in the same age group who have the same demographic characteristics.

There are two forms of reliability: test-retest reliability and interrater reliability. *Test-retest reliability* is an indica-

		Longitudinal Approaches	Cross-Sectional Approaches
		+ Document individuals' developmental transitions. – Participants may drop out as study progresses.	+ Easier to ensure that the same number of participants take part at all ages. – Do not track individuals' developmental trajectories.
Observational Studies	+ Rich data may allow for unanticipated insights. – Support correlational arguments but cannot determine causal relationships. – Behaviors of interest may not appear without experimenter intervention.	+ May uncover long-term patterns of change in individuals. – Require a long time commitment from research staff.	+ Reveal distinctive patterns for each age group. – Questions about individual differences are more difficult to address.
Experimental Studies	+ Allow exploration of cause-and-effect relationships. + Researchers can design focused assessments of specific variables. – Create possibilities of ecologically invalid measures.	+ Good for studying long-term effects of training. – Repeated assessments may become an unwanted form of training.	+ Enable quick assessment of hypothesized differences between age groups. – May miss key transitions as well as individual developmental patterns.

TABLE 1.1 Tradeoffs of different developmental research methods. The advantages (+) and disadvantages (–) of each kind of study and each kind of approach are shown here, as well as the advantages (+) and disadvantages (–) of using converging methods—longitudinal observational studies, cross-sectional observational studies, longitudinal experimental studies, and cross-sectional experimental studies.

tion of how consistently a measure yields the same result when it is used by the same researcher. If a given researcher finds large variability in results when repeatedly measuring the quality of children's memories, that would be a case of low test-retest reliability. *Interrater reliability* describes how consistently two different researchers get the same results when they use the same measure with the same child. To have high interrater reliability on a test of children's memories of videos and verbal descriptions, it would be important for the test to provide scoring guidelines describing how much detail is required to consider a child's recall fully "accurate." Otherwise, individual researchers could make different judgments of what constitutes an "accurate" memory. In a well-designed study, the measures should show both test-retest reliability and interrater reliability.

Reliability is a necessary part of research in developmental psychology, but reliability alone is not enough to conclude that research findings are sound. Even highly reliable measurements can be misleading if it turns out that you are not really measuring what you intended to measure. The criterion of **validity** refers to whether measurements accurately reflect what a researcher means to study. Returning to the example that compared visual and verbal memory, suppose the researcher develops a set of measures showing very high test-retest and interrater reliability. Thus, different researchers using these methods to test the accuracy of children's verbal and visual memories could easily get consistent results, which would also closely resemble the results obtained from using the same methods with new groups of similar children. Nonetheless, these highly reliable measures may be assessing something very different from what the investigators intended to measure—if the measures themselves are flawed. That is, children's memory scores may not really reflect their ability to recall the videos and verbal descriptions. Perhaps the younger children are more easily distracted, which causes them to underperform unless they are tested in an especially quiet, focused setting. In this case, this particular memory measure would consistently suggest that young children have poorer memories than they actually do. The study would have reliability, but it would not be valid for the skill that the researchers intended to measure.

Like reliability, validity comes in different forms: internal validity and external validity. *Internal validity* is especially relevant to experimental studies. It concerns whether the changes observed in the dependent variable are really due to the experimenter's manipulation of the independent variable or whether the changes are caused by other extraneous influences. If, for example, a young child performed poorly on a memory test because she was distracted (rather than due to an inability to remember), the study would lack internal validity. *External validity* refers to whether the research findings are truly generalizable, or broadly relevant, to a wide range of situations. Perhaps children from particular backgrounds or cultures are more accustomed to remembering events seen on video and therefore are better able to recall them. If so, this would represent a limit on the study's external validity. Issues related to validity can be subtle and complex, but they are extremely important to consider.

We will see that the most compelling and exciting studies are those that carefully consider both internal and external validity while also achieving high reliability. Studies with reliable and valid measures also tend to have high **replicability**, which is simply the ability for others to easily reproduce the study and find the same results. Replicability is ultimately the hallmark of all good studies. Even if a study uncovers an interesting developmental phenomenon, if its measures are too difficult or intricate for most researchers to use, the usefulness of the research might be quite limited. Scientists want their pioneering studies to be easily replicated in other laboratories so that the findings can serve as a solid foundation for follow-up studies.

Q: How can a study have high reliability but low validity?

Within-Subjects and Between-Subjects Designs In designing a developmental study, researchers must make one last major decision: whether to assess all children in a study in the same way or whether to divide children into groups and assess each group in a different way. In studies that use a **within-subjects design**, each child participates in all experimental conditions, and therefore all children are assessed in the same manner. This design allows researchers to compare the same subjects' responses to each experimental condition. For example, suppose you wanted to know whether children are more likely to believe a new piece of surprising information when they hear it from an adult or when it comes from a peer. In a within-subjects design, you might show each child in the study two videos: one in which a child of their same age describes a remarkable fact (for example, "Did you know that kangaroos can't walk backward?") and another in which an adult relays another equally remarkable fact (for example, "Did you know that some fish can live for more than 200 years?"). Each child would then be asked to rate the likelihood that each piece of information was true, perhaps on a 5-point scale. In contrast to this setup, a **between-subjects design** would involve assessing a different group of children in each experimental condition. You might divide the children into two equivalent groups. One group would watch the video of the child and then rate its truthfulness, while the other group would do the same with the video of the adult.

Both kinds of designs involve tradeoffs that must be taken into account when choosing which one to use in a specific study. Within-subjects designs have the benefit of requiring fewer children, since each child takes part in all experimental conditions. On the other hand, between-subjects designs have the strong advantage of ruling out any unintentional effects of assessing each child more than once. For example, if children become more skeptical about unusual facts the more often they hear them, a within-subjects design might not be well suited to the study just described. The children might give a harsher judgment of whichever video they viewed second. (This effect can be partially controlled by showing half the children the video of the adult relaying the fact first, while the other half sees the video of the child relaying the fact first, but it would still be a concern.) In addition, being presented with the two different videos and asked to evaluate each one could subtly suggest to participants that they should rate the facts differently, even if they seem about equally believable. In designing a study, an experimenter needs to keep these kinds of concerns in mind. In the spirit of using converging methods, some investigators will examine a single research question using a series of studies that includes both within- and between-subjects designs in an attempt to benefit from the strengths of both.

In summary, developmental psychology uses a wide array of methods to highlight many aspects of how people's minds and their behavior change over time. Choosing the best methods for investigating a particular problem requires careful consideration, and throughout this book we'll see how these issues play out in many areas of developmental research. Moreover, when it comes to studying certain kinds of abilities, the specific methods that researchers choose can affect how capable children seem to be, creating controversies about how to interpret the measurements (Cohen & Cashon, 2003). Taken together, however, the wide variety of methods now available allows researchers to discover and verify fascinating developmental patterns that would have been impossible to study even a few decades earlier.

Conclusions

A full explanation of the child's developing mind easily rivals the complexity and beauty of the cellular machinery explored by molecular biologists or the origins of the universe investigated by astrophysicists. Developmental researchers strive to build coherent models and theories of psychological development and then test them in rigorous ways, using both experimental and observational studies. Together, these theories and research methods enhance our understanding of the growing and changing mind.

Some of psychology's most challenging and fascinating problems focus on development—and their answers promise deep insights into who we are. Questions about the nature of developmental change have fascinated laypeople and researchers alike for thousands of years. In the last few decades, developmental psychologists have begun to address these millennia-old questions in a much more focused manner, as new methods and techniques have given researchers clearer insights into what develops and how. Patterns in the development of perception, cognition, and social skills are among the most complex in the natural sciences, and the details of these processes are often breathtaking in their elegance and beauty. The study of developmental psychology becomes ever more fascinating as research continues to reveal richer interrelations between the theories and the evidence. Just like reading an intricate mystery novel or appreciating a beautiful piece of art, studying development helps us all appreciate the wonder of what it means to become fully human.

STUDY AND REVIEW

SUMMARY

Why Study Development?

- Developmental psychology is a complex, elegant, and intrinsically fascinating scientific study of how children's minds and behaviors grow over time.
- Studying development offers insights into psychological structures and processes in adults by describing how those processes originate and take shape.
- An understanding of psychological development is critically relevant to many decisions about social policy, ranging from changes to local elementary schools to questions concerning children's legal rights.

The Nature of Development

- In considering the nature of developmental change, we want to know whether a developmental change is stage-like or continuous and whether change occurs globally or in a more local manner.
- Nature and nurture always work together to shape development. In looking more closely at interactions between nature and nurture, we can consider which kinds of development are more heavily influenced by nature and which are more influenced by nurture.

Perspectives on Development

- The various perspectives employed by researchers in developmental psychology function much like different lenses on development: each one brings certain issues and questions into sharp focus and de-emphasizes or even ignores others.
- Empiricist and nativist perspectives propose different models of how the mind processes information once that information has passed through our sensory and perceptual systems. Empiricist views emphasize the idea that a general system for learning associations based on experience is present at birth. Nativist views emphasize the idea that various learning systems are present at birth and that each system acquires particular kinds of information more readily than others.
- Evolutionary and comparative perspectives start with the premise that many organisms other than humans confront similar challenges in development. These perspectives use cross-species comparisons, as well as long-term historical considerations, to ask about how and why humans develop as they do.
- Cross-cultural perspectives compare patterns of developmental change across several different cultures; they ask which aspects of development remain relatively consistent across cultures and which ones vary dramatically.
- Neuroscience perspectives ask how brain development guides or constrains psychological development.
- Behaviorist perspectives focus on observable behaviors and ask how they are shaped by reinforcement over the course of development.
- Psychoanalytic perspectives are concerned with internal states and processes and their influences on behavior. They also focus on early experiences and unresolved conflicts and their effects later in life.
- Cognitive science perspectives consider how developmental changes in the mind relate to ways of acquiring, representing, and using information. These perspectives draw on

several different disciplines, including psychology, linguistics, philosophy, computer science, and neuroscience.

Studying Psychological Development

- Developmental psychologists take advantage of a rich array of research methods, each of which has advantages and drawbacks. Collectively, these methods can be used to gain objective views of what develops and how.
- In observational studies, researchers track developmental patterns over time by documenting various aspects of behavior, often in a naturalistic setting. In experimental studies, researchers manipulate variables to see how those changes affect specific behaviors.
- Longitudinal and cross-sectional approaches are two ways of studying developmental change over time. Using a longitudinal approach involves studying the same children at repeated intervals over the course of their development. Using a cross-sectional approach involves studying separate groups of children at different ages—for example, a group of 7-year-olds, a group of 9-year-olds, and a group of 11-year-olds.
- Reliability measures the degree to which a pattern of results would be consistently found when the same assessments are done in the same way with similar participants.
- Validity refers to the extent to which a set of measures actually reflects what the researcher is interested in studying and the extent to which that measure will continue to reflect that phenomenon in other settings.
- Replicability refers to the ability for other researchers to reproduce a previously documented pattern of results when they perform the same study with similar participants.
- In between-subjects designs, researchers assign separate (but equivalent) groups of children to different experimental conditions to compare the effects of the different conditions. In within-subjects designs, researchers assign all children to the same set of tasks to compare individual participants' performance across the different tasks.

THOUGHT QUESTIONS

1. It has been argued that just as people need to take driving lessons before learning how to drive a car, future parents should be required to take courses in developmental psychology so that they might be better equipped to make decisions about raising their children. Discuss the appropriateness and feasibility of such a view.
2. Design a study to explore the effects of violent video games on children's behavior, using three distinct converging methods. Discuss the tradeoffs of each method and how, in the aggregate, they offer insights that go beyond the benefits of any one study.

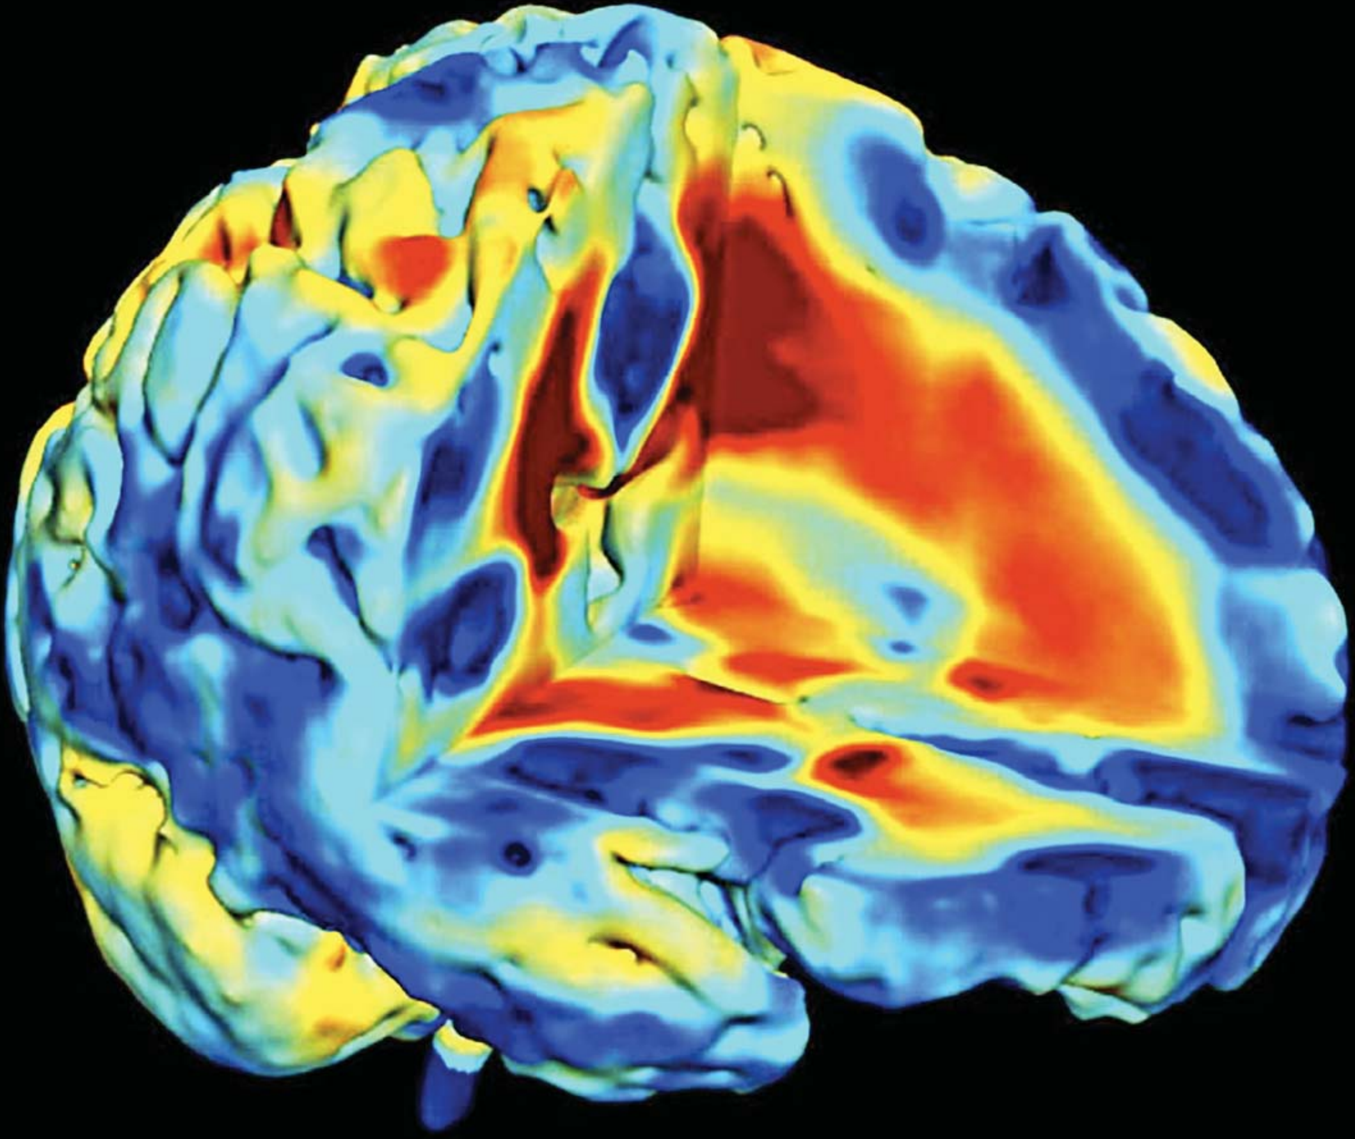
Conclusions

Summary



In 1989, a girl named Madeline Mann was born severely premature. Her gestational age was only 27 weeks, and she weighed only 280 grams (9.9 ounces); at that time, she was the smallest baby ever to survive a premature birth. There are only 110 recorded cases of newborns who weigh less than 400 grams, and the vast majority of these have serious medical complications. In fact, of all the newborns born weighing less than 500 grams, fewer than 1 percent reached 18 months without some kind of complication, often quite serious brain impairment (Muraskas et al., 2012). Yet, because of extraordinary medical care and some unique biological features relating to her situation, 22 years later, in 2012, Madeline was a senior honors student in a liberal arts college.

As seen in Figure 2.1, an almost impossibly small baby became an accomplished adult. These two photos vividly illustrate the biology of development and the extraordinary changes that occur. They also illustrate how normal development is a complex interplay of biological programming and environmental support. Just a decade earlier, Madeline would have been very unlikely to survive. She had to be mechanically ventilated for 65 days and could not leave the hospital until 122 days after her birth. She had some bleeding in the ventricles of her brain and immune system problems, both of which could have caused massive complications or death without constant vigilance and superb medical attention. Madeline may also have done so well because of a phenomenon in which the fetus, when it senses environmental stresses and drops in nutrition (as happened in Madeline's case), is sometimes able to slow down the rate of growth until the stresses are removed. This "thrifty phenotype hypothesis" may be a form of evolved adaptation for fetuses in times of famine or other stresses that might impair maternal nutrient support (Hales & Barker, 2001). When those stressors are removed, the newborn baby can display rapid "catch up" in terms of physical and behavioral growth, apparently because of some genetic signaling that accelerates rates of growth once the child is in a more benign environment. In addition, whatever damage Madeline's young body did suffer early on, it was able to recover from those early insults, showing an important flexibility to the developmental process.

As impressive as our technology is in many areas of biology, it is remarkable how difficult it is to mimic the natural support of a mother's womb. Despite heroic technological efforts, the vast majority of extremely premature infants experience complications. Thus, the wonder of all development starts with biological development, which will illustrate several important themes for understanding psychological development.

In this chapter, we will consider how biological changes, including genetic and environmental influences, prenatal development, and brain development, bear on the study of developmental psychology. We will survey the biology of development, looking for principles and patterns that will help us understand psychological development—for example, how orderly patterns of change, involving precise timing and sequencing, are necessary for normal adult forms.

A closer look at development from the moment of conception onward reveals breathtaking patterns of change. From an initial cluster of seemingly identical cells, there emerges an organism with thousands of different cell types. From that initial ball of cells, a rich array of structures devel-

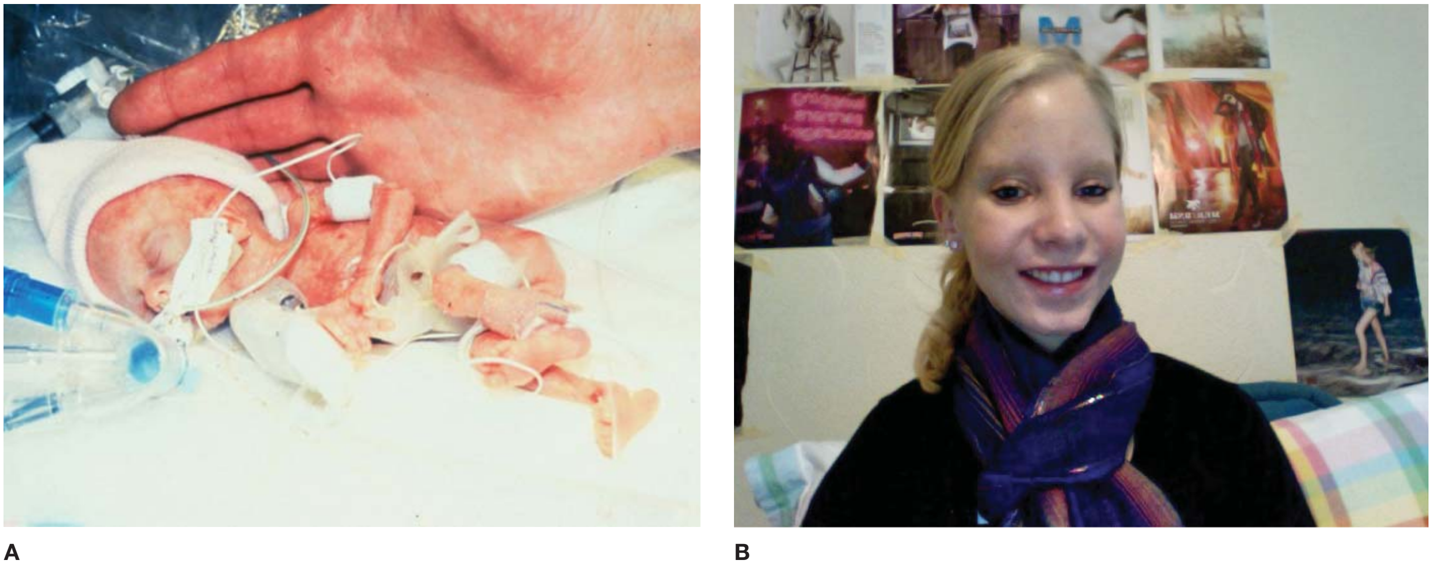


FIGURE 2.1 **Extreme premature birth and development.** **(A)** Madeline Mann was born at 27 weeks and had an extremely low birth weight because of complications of her mother's pregnancy. After her birth, she was hooked up to a breathing tube and kept alive through extraordinary measures. **(B)** Madeline survived and today is a college student without the physical or neurological impairments suffered by most infants born at extremely low birth weights.

ops, forming the organs and the general body shape. Limbs sprout and continue to grow for years; bodily structures change their size, shape, and proportions. All these changes must occur in an ordered sequence and at appropriate times for normal development to take place.

This chapter has two goals. First, it aims to examine the biological underpinnings of psychological development. How are developmental changes in the brain and other body systems related to psychological changes? Are children's brains physically immature in ways that limit their capacities to perceive, think, or feel? How do physiological changes, such as those that occur during puberty, influence thoughts and feelings? This chapter explores these issues by considering biological development both in the womb and after birth.

We will consider how relatively unspecialized cells develop into brain cells prenatally—that is, before birth—and how these cells grow and interconnect, giving rise to the brain's major anatomical structures. In studying postnatal development—that is, development that occurs after birth—we will focus on how aspects of the environment (such as various forms of deprivation) and major physiological changes (such as those that happen during puberty) exert distinct influences on brain function. Examining some key anatomical and physiological changes to the brain helps us see how neural development supports the psychological changes described in later chapters.

We will end by discussing a different kind of link between biology and behavior, that of behavioral genetics. Rather than asking how brain maturation influences psychological functioning and behavior, behavioral genetics asks how differences in the genes relate to variations in behavior. Researchers are beginning to understand how variations in genetic information are linked to differences in brain structure and function and how those neurological features are in turn linked to behavior.

The second goal of this chapter is to characterize some of the patterns common to both biological and psychological development. For example, both types of development involve **critical periods**, time frames in which certain kinds of experiences are essential for normal development. At the biological level, for example, a fetus develops normal sex organs only if it is exposed to particular hormones at a specific point in prenatal development. Similarly, at the psychological level, which is grounded in biological mechanisms, an infant's early visual experiences are crucial to developing the mental ability to fuse the separate images seen by each eye into one integrated visual experience.

Another developmental pattern in both the body and the mind is the tendency for vital systems to develop earlier than those that are less important for survival. In biological terms, the organs necessary for breathing and eating are functional at birth, whereas those supporting reproduction are not functional until puberty. Psychologically, infants learn to avoid dangerous ledges to keep from falling long before they can tell whether an object is balanced. Thus, development at any level of analysis, from individual cells to cognitive processes, shows some common patterns. This chapter offers just a brief glimpse into the rich fields of developmental biology and neurobiological development, but even this brief glimpse will yield powerful insights in later chapters.

The Basis of Development

Virtually every complex organism begins life as a single fertilized egg and develops into a creature with interacting anatomical systems and a broad range of behaviors. Starting before birth and continuing over the lifespan, the organism's environment exerts a critical influence on the way that it develops. At the same time, environmental influences interact continuously with the organism's biological makeup. As the organism matures, these interactions must allow it to progress toward the adult state in a way that supports its survival at every point in its development.

To understand how these complex processes take place, it is useful to think about development as a systems problem in the sense that developmental changes to the biological system must interact and build on one another in a way that supports the organism's needs at every stage. Imagine for a moment what the adult members of a new species would look like, but also the processes that would give rise to all their properties over the course of the lifespan. There would need to be a sequence of emerging structures and processes to yield the largest number of healthy, mature members of the species.

Examining an organism's needs in its environment and the developmental challenges it faces often suggests why that organism's development unfolds as it does. For example, newborn kangaroos, which are born blind, would have little use for functional eyes during the first days in the mother's pouch. But to get from the birth canal to the pouch, where its physical development continues, it needs forelimbs strong enough to crawl up its mother's belly on its own. Similarly, it is far more important for human newborns to have a functional sucking system for nursing than to be skilled at recognizing faces. Development proceeds as an ordered sequence of interdependent events, in which the more complex aspects of an organism depend on the essential, simpler systems that emerge earlier.

Considering the process as a systems problem leads us to focus on two main influences on development: the inputs that influence the process and the constraints that both limit and channel how development occurs (Newell, 1986). The *inputs* consist of an organism's genes, its environment, and the resulting patterns of gene-environment interactions. The *constraints* consist of the need for viability throughout development, the need for specialized cells to serve particular functions in the body, and the need for certain sequential processes to occur at just the right times.

Inputs to the Biological System

The interacting influences of genes and environment vary considerably across different kinds of organisms. Some animals are able to function in a nearly mature way from the moment they are born, while others mature gradually, developing systems that depend heavily on environmental inputs after birth. Such variations can happen even between relatively similar organisms. Thus, Australian brush turkeys are completely functional and self-sufficient right after birth, while many kinds of songbirds are born with closed eyes, without feathers or down, and lacking the ability to eat on their own. These sorts of differences arise because of the different local environments, or **environmental niches**, into which these birds are born and for which these birds have evolved special adaptations. Brush turkeys are born on the ground and must immediately fend for themselves, while songbirds are born in nests in trees and can safely remain helpless for quite some time after birth. These variations reflect the ways in which the different species' genetic codes were modified through natural selection, resulting in organisms adapted to their particular environmental niches.

The Genes **Genes** are the inherited instructions for producing the proteins that make up cells or for regulating whether other genes will be turned on or off. A gene is made up of a section of **DNA** (deoxyribonucleic acid), a long, double-stranded molecule consisting of specific sequences of just four different chemical bases (adenine, thymine, guanine, and cytosine—abbreviated as A, T, G, and C) that encode the specific instructions for cellular construction and development. The molecular structure of these four chemicals allows them to link up as **base pairs** (A with T, and C with G) to attach the two strands of the DNA molecule together in a twisting structure called a double helix, much like the way the rungs of a ladder link the two sides of the frame (see Figure 2.2). Because of these base-pairing rules, every occurrence of C on one strand of DNA corresponds to the site of a G on the other strand, and every A corresponds to a T. Thus, the two strands are said to be complementary.

Molecular biologists refer to the sequence of bases that makes up a gene as having two main parts. The *structural sequence* directs the assembly of particular proteins (or parts of proteins), which can then give rise to traits in several ways. For example, the proteins may become body structures, such as muscle, or they may become enzymes that trigger chemical reactions, like the digestive chemicals in saliva. Adjacent to the structural sequence, most genes also have a *regulatory sequence* that acts like a switch to determine whether (and how much) the protein-coding genes will be active. Entire genes can also serve a regulatory function by coding for a type of protein that can "flip the switch" in the regulatory sequence that adjusts another gene's activity level. It is estimated that well over 95 percent of human DNA sequences is nonstructural and probably regulatory.

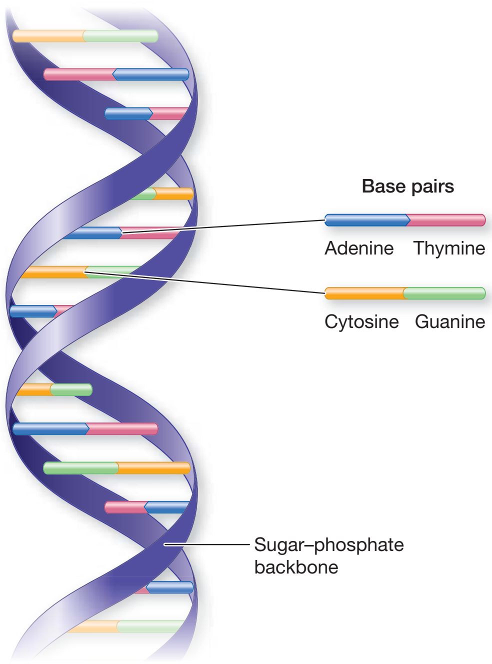

FIGURE 2.2 **The double helix.** The genetic material of all animals shares the same fundamental structure, a sequence of pairs of four chemical bases: adenine paired with thymine, and guanine paired with cytosine. These pairs are linked in a twisting structure called a double helix. The order in which these pairs occur on the double helix is the basis for all genetic differences between animals.

Sometimes, news reports or magazine articles describe genes "for" language, leadership, or aggression, suggesting that there is a single biological unit of information that directly and specifically produces these traits or behaviors. The reality is more complex and far more interesting. Instead of a simple link from one gene to a single trait or behavior, a complex web of interactions take place between multiple genes and environmental factors that together give rise to traits and behaviors.

In most organisms, the long DNA molecules are stored in the cell nucleus as tightly wound, highly compact **chromosomes**. In this form, roughly 3 billion DNA base pairs can fit inside a cell nucleus only 6 millionths of a meter across. The entire set of chromosomes in an individual organism is sometimes known as its **genome**. But the term can also be used to describe the typical genetic profile for a species or subspecies. Estimates of the precise number of genes in the human genome vary considerably, but at least 20,000 genes are packed inside our 46 chromosomes (Pennisi, 2007). Some have argued that this relatively low number means that most human brain structures, which involve trillions of cells, are too complex to be specified by genes. But this argument overlooks the power of gene interactions and the ways in which the interplay of a relatively smaller number of genes can yield many distinct proteins (Marcus, 2004).

Chromosomes normally occur in pairs, with each of the individual's parents contributing one chromosome in each pair. The two chromosomes in each pair contain corresponding genetic information about the same overall bodily structures or functions, but each chromosome may contain different variants of those genes, depending on the genes of the contributing parent. Biologists use the term **alleles** to talk about all the variations of a particular gene that can exist at a particular location on a chromosome. Thus, a single gene is said to be associated with a set of alleles.

For example, in humans, the ABO gene for blood type has several different alleles—for blood types A, B, AB, and O. Each individual receives two alleles for blood type—one from each parent—and the relations between those alleles then determine the child's blood type. When both parents contribute the same allele of a particular gene, the individual is said to be **homozygous** for that gene. If both parents contribute a type A allele, the child is homozygous (*AA*) and will have type A blood.

When each parent contributes a different allele of a particular gene, the individual is considered **heterozygous** for the gene. In these cases, the interactions between the alleles determine the outcome. Often one allele in a heterozygous pair is **dominant** over the other, meaning that its properties will be expressed preferentially over the properties of the other allele. For example, if a woman inherited one allele for type A and one allele for type O (*AO*), she would have type A blood because the allele for type A is dominant. The allele that is not expressed is known as the **recessive** allele. In this case, *O* is the recessive allele. (Recessive alleles are not expressed unless the individual is *homozygous recessive*, having received the recessive allele of that gene from both parents.) In other heterozygous cases, the alleles may be **codominant**, in which case both alleles are expressed simultaneously. This is the case when a person inherits one allele for type A and one for type B (*AB*), resulting in type AB blood. Blood type provides an unusually straightforward example of how traits are inherited, but most traits result from the interactions of multiple genes, contributing to the complex patterns of inheritance we see between parents and offspring.

Although most chromosomes come in pairs that contain matching genes, one important exception concerns the sex chromosomes, a special pair of chromosomes that determines the sex of many animals. In most mammals, there are two types of sex chromosomes: X chromosomes and Y chromosomes. Females have two X chromosomes, while males have an X and a Y chromosome. Females can therefore contribute only X chromosomes to their offspring, while males can contribute either an X or a Y chromosome. Thus, in humans, the sex chromosome contributed by the father determines the sex of the child.

The Environment Along with genes, the other main inputs to the biological system are the influences of all the environments in which an organism develops. Here, too, a seemingly simple concept can be examined at many levels. We often think of the environment as the physical world in which an organism develops, and although this is an important source of environmental influences, there are many other components of the environment to consider. In the first moments after conception, for example, the fertilized egg is bathed in a rich mixture of chemicals, including hormones secreted by the mother and, before long, additional hormones produced by the developing fetus. A male fetus experiences a very different hormonal environment than a female fetus, largely due to the fetus's own genetically triggered biochemical outputs. This sort of interaction of genetic and environmental influences—in this case, a genetic influence on the prenatal environment, which then triggers additional interactions—illustrates a complex relationship between genes and the environment.

The prenatal environment is also influenced by the mother's external environment, as it includes chemicals that the mother has ingested and passed on to the developing fetus. These might include chemicals that the mother has intentionally consumed, such as nutrients, caffeine, or alcohol, as well as chemicals that have entered her body without her knowledge, such as food additives or contaminants, air pollution, or compounds that contact her skin. Other aspects of the biological environment within the mother's body can also affect the fertilized egg. For example, when the mother contracts an illness that causes a high fever, her increased body temperature has the potential to cause birth defects (Czeizel et al., 2007; Hashmi et al., 2010). As we will see later in this chapter, the effects of each of these kinds of environmental influences also depend on the point in the developmental timeline when the fetus is exposed to them.

As the developing fetus approaches birth, other environmental factors can have an influence as well. These can include sounds in the outside world, as well as tactile sensations created when the mother's abdomen is touched. After birth, environmental influences proliferate as the baby experiences the world through all the senses, through the nutritional content of new foods, and through early social interactions. Through their behavior, babies also shape certain environmental influences. Thus, a baby who frequently cries and shows distress receives different environmental inputs, in terms of parental behavior, than a calm baby.

Interactions between Genes and Environment We have seen that genes and the environment constantly interact in complex ways, such that it rarely makes sense to consider them as completely separate inputs to the biological system. At the broadest level, environmental influences help us understand why differences may arise between the genotype of an organism and its phenotype. The **genotype** is the genetic information encoded as particular alleles in an organism's DNA (in contrast, the term *genome* is more often used for the genetic information that typifies a whole species). The organism's **phenotype** refers to the ways that the genetic information is expressed or manifested in an organism, including its anatomical structures, its biochemical processes, and its behaviors.

Environmental influences are an important clue to explain differences between genotype and phenotype because a particular allele's unique characteristics may only be expressed in certain contexts. For example, a child might inherit a genotype that predisposes him toward obesity, but he may only become overweight if he grows up in an environment with abundant food. Likewise, certain genetic variations related to lighter skin pigmentation can make an individual more vulnerable to skin cancer—but this increased susceptibility would be dangerous only in relatively sunny climates. Thus, a person with this genetic vulnerability who grows up in cloudy Astoria, Oregon, might not be any more likely to get skin cancer than other people from Astoria. But growing up in the desert sun of Tucson, Arizona, may make that same person much more likely to get skin cancer than other people in Tucson.

Other genes that have harmful effects in most environments can be rendered harmless in highly specialized environments. For example, some children are born with an allele that makes them unable to break down the amino acid phenylalanine, which is found in artificial sweeteners and other foods. If these children eat foods that contain phenylalanine, they will develop phenylketonuria (PKU), a condition in which phenylalanine builds up in their bloodstream, causing severe brain damage if left untreated. But if the same children grow up on a special diet without phenylalanine, they develop normally.

Different environments not only influence phenotypic features; they can also affect the activity levels of genes. It became clear only about 50 years ago that aspects of the environment could change genes' activities in this way (Jacob & Monod, 1961). Since that discovery, researchers have found that much of the information in the human genome is regulatory—that is, affecting when other genes are expressed and which genes can be activated by environmental factors such as hormones. Moreover, genes' intricate interaction patterns can form elaborate branching chains known as **regulatory cascades**. In these series of interactions, small changes in the activity of one gene can influence several other genes, which in turn can influence many more genes (see Figure 2.3). At the same time, these genes continue to be subject to environmental influences—from the biochemical surroundings of a particular cell to the features of the organism's external world.

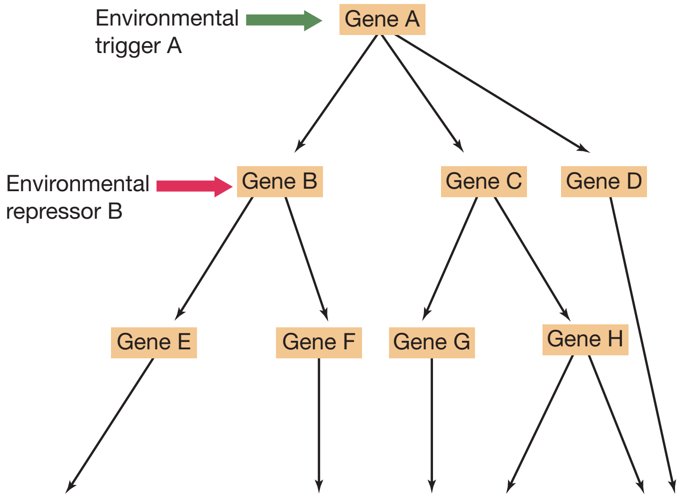

FIGURE 2.3 Regulatory cascades. This simplified diagram illustrates how genes can interact in complex patterns, where turning on one gene creates the products that turn on several other genes in a cascade. Environmental factors can also affect these cascades by turning genes on or off. (Real gene regulatory cascades involve many more interactions between intermediate stages and higher stages and between genes and their products.)

Constraints on Development

We have seen how genes, the environment, and their interactions act as inputs that influence development. Development is also shaped by three key constraints: the *viability* of the developing organism, the *differentiation* of cell types and anatomical structures, and the *timing and sequencing* of developmental events. These factors interact in crucial ways during biological development. Here we consider each factor in turn.

Viability From the moment an egg is fertilized until the baby is born, that rapidly growing and changing mass of cells must stay alive by metabolizing nutrients and eliminating wastes. It must have some way of circulating nutrients, and to do so, it needs muscle activity, such as the heartbeat. By contrast, a complex machine like a passenger jet might not have a functional engine system until other critical control mechanisms are installed, moments before completion. Thus, the need for viability in living organisms places constraints on development, requiring that certain essential structures and functions develop before others, but such constraints do not necessarily apply to nonliving entities.

What does the constraint of viability require of the developing organism? The answer depends on the environment in which the organism must survive. Thus, a fetus receiving oxygen via its umbilical cord is a very different being from the breathing newborn it becomes. This remarkable transformation occurs by means of an intricate set of triggers, including constricted blood flow in the umbilical cord, the physical pressures of contraction during birth, and changing maternal hormones. These events empty the baby's lungs of fluid before birth, changing the circulatory path of blood flow to take in oxygen from the lungs (rather than via the placenta) and activating the breathing reflex (Wyllie, 2006). Despite the complexity of this near-instantaneous transition, only a small percentage of newborns need resuscitation. Thus, over the course of development, both prenatally and postnatally, the constraint of viability can impose radically different requirements.

Differentiation of Cells and Structures The fertilized egg splits into two cells, then each of those cells divides, yielding four, then those four become eight. Though the eight cells seem identical, each will become specialized for a different function. What controls this differentiation into cell types, and what patterns does the process follow? Many researchers have devoted their careers to these questions, since cell differentiation is the key to understanding how the complexity of an organism emerges.

The biologist Conrad Waddington (1957) vividly depicted the process of specialization during development using the visual representation of a landscape (see Figure 2.4). He described changing cells undergoing a process of **canalization** through which they get committed to becoming certain types (Salathia & Queitsch, 2007). He compared the differentiating cell to a ball rolling down a surface with ever-deepening valleys and ridges, which represent different cell outcomes. As the valleys deepen and the ridges grow higher, the likelihood of the ball "jumping" to another valley diminishes. Likewise, after a cell begins a particular developmental path, it will be increasingly difficult for it to change course and become a completely different cell type. Several researchers have used this concept of canalization to describe how behaviors and abilities develop (Bishop, 2009; Gottlieb, 2007). Some scholars focus on the initial possibilities of many alternative developmental paths, while others focus on the valleys and ridges that represent increasingly limiting constraints on what develops.

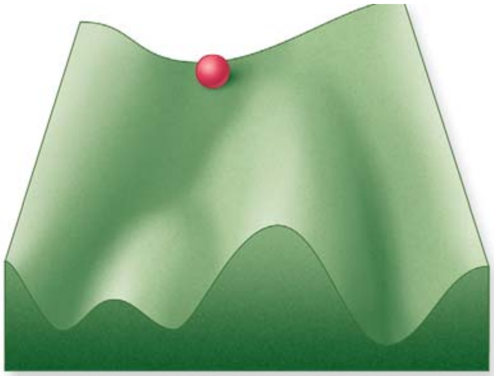

FIGURE 2.4 The landscape of canalization. Conrad Waddington envisioned the canalization process as a terrain with ever-deepening valleys and ridges. Like a ball rolling down this landscape, a developing cell becomes ever more entrenched in a certain fate. Adapted from Waddington (1957).

These complementary views of the developmental process emerge frequently in later chapters as we consider aspects of behavioral and cognitive development. When we examine perceptual development in Chapter 3, we will see how certain cells become attuned to receiving simultaneous visual input from both eyes and how after starting down that path, it is ever more difficult to reverse course and become responsive to input from only one eye. When we consider social development in Chapter 6, we will see how children's early parental attachments become ever deeper and stronger, making these attachments difficult to extinguish even in abusive situations. This pattern of increasing commitment to a particular developmental path pervades biological and psychological development.

Cell differentiation is controlled by an intricate set of genetic interactions that specify how and when cells specialize. One striking process involves **epigenetic regulation**, which leads to changes in gene expression without changes to DNA sequences (Dolinoy, 2007). Epigenetic regulation occurs when a particular cell type has some genes turned off and others turned on by its surrounding chemical environment and then "freezes" that pattern of on-and-off genes. When the cell divides, the genes of all the cells that it creates have the same on-and-off pattern. Thus, environmental influences can fix cells to be of a certain type, so that when they divide, they will produce cells of that same type. One of the most common mechanisms for epigenetic regulation involves **methylation**, in which methyl groups (specific carbon-hydrogen configurations) become attached to certain DNA base pairs, usually with the result of turning off the activity level of a gene or affecting other genes that follow that gene in a regulatory sequence.

Even the kinds of foods that a pregnant woman eats may influence the activity of the fetus's genes and in turn affect the way its cells differentiate. This phenomenon is the focus of a rapidly growing field known as *nutrigenomics* (Ross, 2010; Waterland & Jirtle, 2004). It is thought that certain effects of dietary variation in the pregnant woman are linked to high levels of certain maternal hormones in the womb, causing changes in gene regulation that may contribute to diabetes (Drake et al., 2005). Low-protein diets during pregnancy have also been associated with changes in fetal gene regulation that may lead to diabetes later in life (Burdge et al., 2007; Langley-Evans, 2007; Lillycrop & Burdge, 2011). As one researcher put it, it now appears that "you are not only what you eat, but what your mother and grandparents ate as well" (Dolinoy, 2007, p. 7).

Timing and Sequencing In biological systems, changes in timing can have major effects on what develops. We have seen that genes turn on and off in response to regulatory signals; in addition, some genes are active only during certain periods in an organism's development. How does the timing of gene activation influence development? More generally, when the timing of an important event—like activating a gene or forming an anatomical structure—changes, how does the change influence other developing structures and patterns of genetic regulation?

It appears that the timing of major anatomical developments is governed by the same set of genes in all species. They are known as **heterochronic genes**, and they seem to operate by regulating the activity of other genes (Banerjee & Slack, 2002; Hada et al., 2010; Pasquinelli & Ruvkun, 2002). In humans, errors in the timing of when specific genes turn on and off may result in anatomical defects, such as the abdominal cavity being unable to enclose the internal organs (Brewer & Williams, 2004). During normal development, the thin film of cells that initially covers the abdominal cavity is later replaced by thicker layers of skin and muscle cells. If this secondary set of layers doesn't develop at the right time, the organs may push out of the cavity, stretching the thin film into a large bulge. If the secondary layers of skin and muscle then start growing in after this delay, some of the organs may be trapped outside the body (Beckett & Baylies, 2007; Rochlin et al., 2010; Sun et al., 2007).

Closely related to timing is the issue of the sequence in which structural developments take place. For example, to build a house, some structures, like the foundation, must be completed before others, such as the walls—and those, in turn, must precede the roof. For other structures, sequencing is less important: the wiring can go in either before or after the plumbing. In a developing person, some structures or processes sequentially depend on others, and some can proceed independently. We will see several cases where cor-

SCIENTIFIC METHOD: Diet and Methylation

Hypothesis:

Paternal diets in mice can cause epigenetic changes, via methylation, that are inherited.

Method:

1. Male mice were fed control (20 percent protein) or low-protein (11 percent protein) diets, with the remaining mass of food made up of sucrose, from weaning until sexual maturity.
2. Mice on either diet were then mated with females reared on the control diet.
3. Twenty-six pairs of offspring (an offspring of a control mother and a control father paired with an offspring of a control mother and a low-protein father) were reared with their mothers until 3 weeks, when their livers were analyzed for gene expression.
4. DNA microarrays were used to explore global gene expression differences in the offspring from the two kinds of matings.

No increase in activation levels of genes involved in cholesterol synthesis.
Marked increase in activation levels of genes involved in cholesterol synthesis.

Results:

There was an extensive increase in activation levels of genes related to cholesterol synthesis in the offspring of males fed a low-protein diet. In general, there was more methylation of many genes in the low-protein groups, especially of a gene that regulated fatty acid synthesis. When methylation led this gene to be turned off, it may in turn have led to the increased levels of activity of cholesterol synthesis genes, which might possibly be related to increases in heart disease.

Conclusion:

Feeding males a low-protein diet from birth to maturity can result in gene-regulated metabolic changes in their offspring.

rect sequencing is vital. In the developing brain, for example, some kinds of nerve cells can develop only within a framework of other kinds of cells. These framework cells emit chemical signals that guide the growing nerve cells to their correct locations.

The Beginnings of Development

Considering development in detail reveals how the main inputs (genes and the environment) and the key constraints (viability, differentiation, and timing) interact throughout the process. In this section, we start with the processes that generate egg and sperm cells for reproduction and follow those cells from conception to the beginnings of differentiation.

Meiosis and Fertilization

Every human being starts with the fusion of two cells. The mother's egg and the father's sperm combine physically and genetically to create the new individual. We therefore start our discussion with **meiosis**, the unique process of cell division that produces the egg and sperm cells (see Figure 2.5A). We'll also see how meiosis differs from another type of cell division called mitosis, which gives rise to other kinds of cells throughout the body.

Meiosis and Mitosis In adults, most cells have two of each type of chromosome, with one chromosome in each

FIGURE 2.5 Meiosis and mitosis. (A) Meiosis is a special kind of cell division that prepares cells for sexual recombination. Normal human cells have 23 pairs of chromosomes. One chromosome of each parent goes to the sperm and egg cells that will be part of reproduction. **(B)** Mitosis is the process in which cell division occurs, but the chromosomes from both parents are copied and appear in all the new cells.

pair contributed by each parent. (The exception is the sex chromosomes: recall that males have an X and a Y chromosome, and females have two X chromosomes.) Typically when a cell divides, all of its genetic material—two copies of each type of chromosome—is reproduced in the new cells through the process of **mitosis** (see Figure 2.5B). However, the specialized **sperm cells** of the father and the **egg cells** of the mother are produced by meiosis. These specialized cells, known as **gametes**, have only one of each type of chromosome, or half the genetic material contained in the body's other cells. As a result, when the egg and sperm fuse during fertilization, the new cell has the normal, complete number of chromosomes—half from the egg and half from the sperm.

Q: How is meiosis different from mitosis? What functional role does meiosis serve?

The process of meiosis also serves the valuable function of greatly increasing the genetic diversity of offspring. During an early stage of meiosis, complementary pairs of chromosomes are next to each other and can swap parts of their genetic material, as shown in the mixing of the "blue" and "red" elements in Figure 2.5A. As a result of this **crossing-over**, each gamete is genetically unique, and offspring can have a sequence of alleles that differs from that seen in either the mother or the father. Thus, crossing-over creates more genetic diversity in offspring than was present in the parents. This diversity is advantageous, as it increases the odds that the offspring's genotypes will make them well suited for new environmental challenges.

Yet, meiosis may not proceed correctly; imperfect crossing-over may result in genetic disorders, including a genetic condition known as **trisomy 21**. A child with trisomy 21 has three chromosomes rather than two in what is normally the twenty-first chromosome pair (see Figure 2.6A). This anomaly is easy to see when a biologist constructs a *karyotype* in which all the chromosomes in an individual's genotype are stained with dye and the chromosome pairs are aligned and photographed through a microscope. When it isn't lethal, trisomy 21 leads to the most common form of Down syndrome, a disorder whose effects include delays in cognitive functioning and motor skills. In addition, people with Down syndrome tend to have distinctive facial features (see Figure 2.6B) and are at high risk for certain heart defects.

The problems that occur in cases of trisomy 21 reveal the subtleties of both genetic and environmental effects on development. In terms of genetic effects, it is striking that an extra chromosome at the twenty-first location can have such dramatic and widespread effects on development. At the same time, Down syndrome also illustrates how the environment can influence a phenotype. In recent years, improvements in special education for children with Down syndrome have resulted in impressive gains, with some children with Down syndrome growing up to be college graduates with successful careers. Such outcomes are rare even in the best environments, but researchers are now realizing that some environments

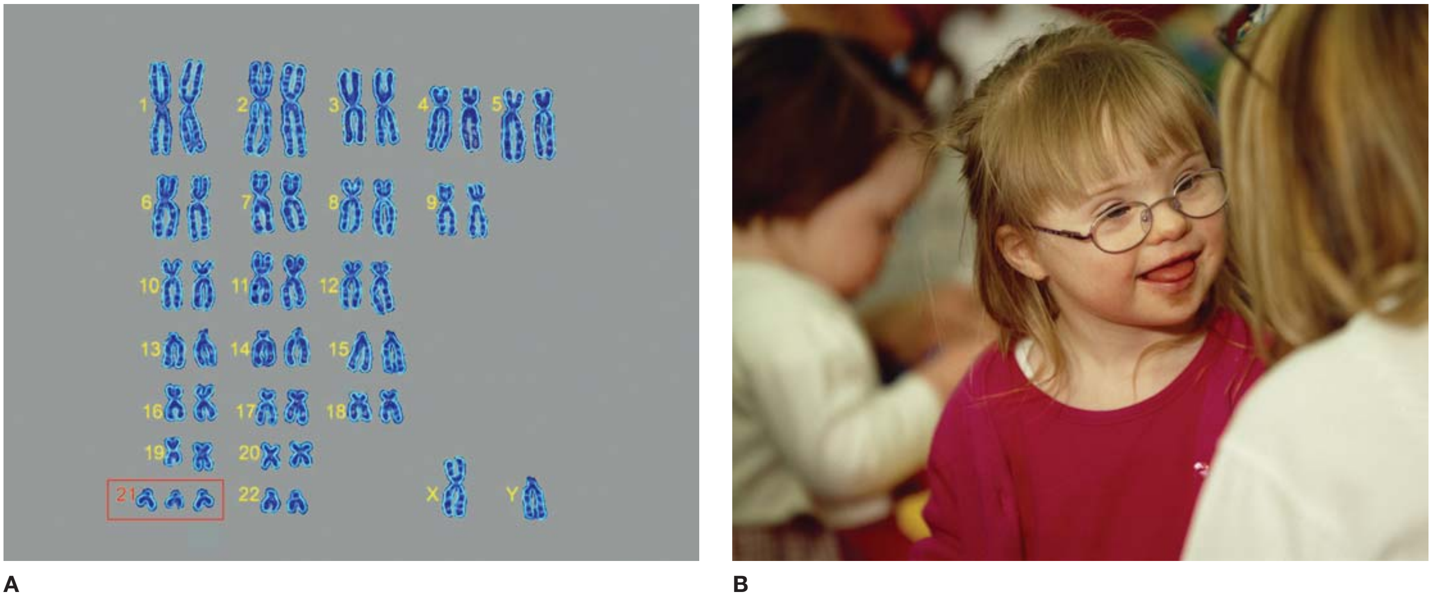

FIGURE 2.6 Trisomy 21 and Down syndrome. (A) A normal karyotype and a trisomy 21 karyotype. The upper panel shows a karyotype in which there is a pair for each of the 23 chromosomes. The lower panel shows a karyotype leading to Down syndrome, in which there are three copies of chromosome 21. **(B)** People with Down syndrome often have characteristic facial features that make them visually identifiable. A small amount of extra genetic material in part of the twenty-first chromosome causes a large set of effects, ranging from these facial features to heart defects and a variety of cognitive problems.

clearly can improve the future of such children far more than was thought possible a few decades ago (Pueschel, 2001).

Other errors during meiosis may result in extra or missing sex chromosomes. These anomalies can cause a number of problems involving sex-specific characteristics, such as breasts or facial hair, as well as other problems unrelated to sex differences. For example, women with Turner syndrome, which occurs in roughly 1 in 3,000 live births, have only one X chromosome (a condition known as monosomy X), and they are infertile. In addition to having reduced (or absent) female sex characteristics, individuals with Turner syndrome often are quite short, and they have webbed skin at the neck and drooping eyelids. Men with the rare condition of Klinefelter syndrome (roughly 1 in 1,000 live births) have an extra X chromosome (XXY). In addition to reduced male sex characteristics, they may also have abnormally long legs and show language impairments and excessive shyness.

Q: What are some examples of the effects of having extra or missing genetic material in the human genome?

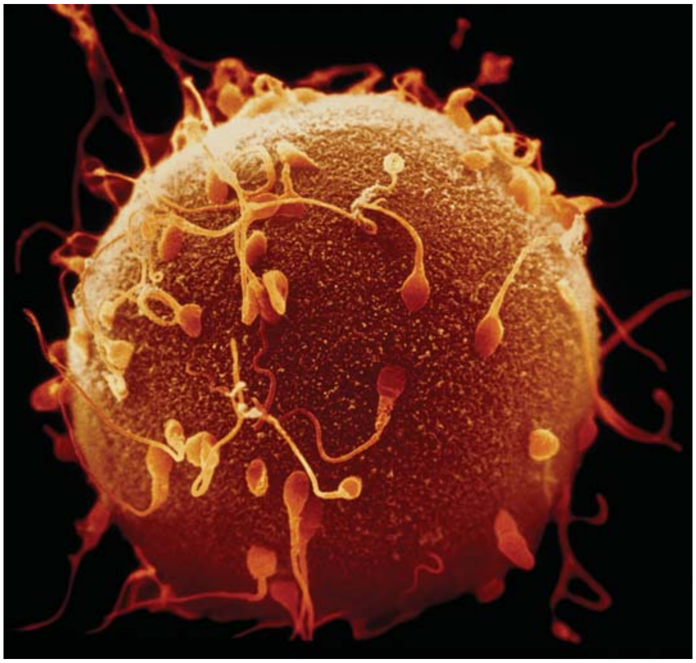

FIGURE 2.7 Fertilization. In the process of fertilization, 50 to 100 sperm, out of an original group of millions, finally reach the egg. The thread-like projections are the tails of sperm trying to enter the large, spherical egg.

Fertilization During sexual intercourse, many millions of sperm are released and swim in search of an egg to fertilize. Out of the millions that start the journey, only 50 to 100 sperm reach the egg and attempt to penetrate it (see Figure 2.7). When one sperm finally penetrates the egg, it triggers a series of chemical events that prevent all other sperm from entering, as well as allowing the penetrating sperm to move farther into the egg and fuse with the egg's genetic material (Gilbert, 2010). At this point, the fertilized egg is known as the **zygote**. If the zygote has an X chromosome and a Y chromosome, a male is created; if the zygote has two X chromosomes, a female is created.

Conception can result in twins or other kinds of multiple births. If the fertilized egg splits into two separate cells, each of which continues to develop into individuals, identical twins result. They are also known as **monozygotic (MZ) twins** because the two babies came from the same zygote, which is also the reason for their nearly identical genotypes. Biologists used to think that MZ twins had exactly the same genotype, but it turns out that subtle epigenetic effects can arise during in utero development and affect one or more sections of DNA, which can cause differences in the twins' susceptibility to certain diseases or subtle physical differences (Bruder et al., 2008; Ollikainen & Craig, 2011). By contrast, when two different sperm fertilize two different eggs, **dizygotic (DZ) twins** (or twins from two zygotes; also called *fraternal* twins) result. Because DZ twins develop from two separate conceptions involving genetically different sperm and eggs, they are only as genetically similar as any two siblings—that is, they have half their genes in common.

The First Patterns of Differentiation

Around 2 hours after fertilization, the zygote makes the first of many cell divisions. Initially, as the cells divide rapidly by mitosis, they get smaller with each division, such that the overall mass of the zygote does not increase. When the cell divisions result in a 16-cell body at day 4, this compact, solid ball of cells is known as a *morula*, and it shows the first signs of cell differentiation: its outer cells are larger than its inner ones. At around day 5, the larger outer cells of the morula become clearly distinct from the inner ones. These outer cells (the *trophoblast*) will eventually become part of the **placenta** (an organ that will make possible the transfer of nutrients and oxygen from the mother and wastes and carbon dioxide from the fetus). The encircling outer cells trigger a group of the smaller inner cells to cluster in a ball-like structure, which eventually will become the embryo (see Figure 2.8). This overall structure—the outer ring of cells and the inner cell mass—is known as the *blastocyst*.

In humans, about 16 days after fertilization, the blastocyst's inner cell mass undergoes an important cell differentiation process known as **gastrulation**, which is oriented relative to the point where the sperm entered the egg. During

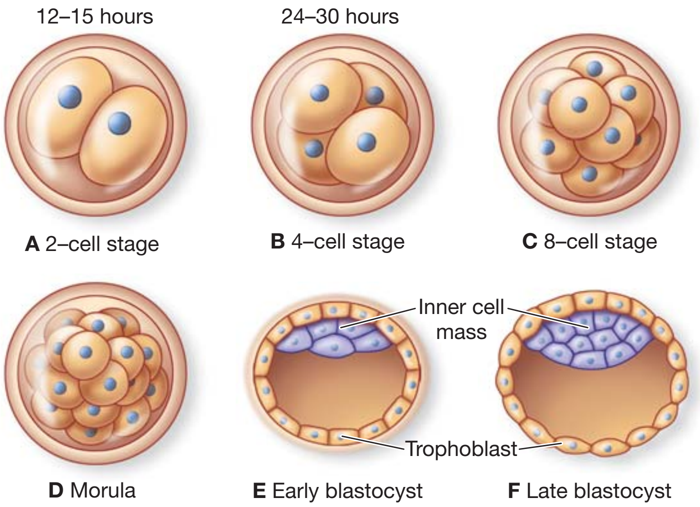

FIGURE 2.8 The formation of the blastocyst. In the earliest stages of growth, the fertilized egg progresses from apparently undifferentiated cells to the beginnings of specialization.

gastrulation, a cascade of changes in chemical concentrations relative to this orientation point soon leads to **bilateral symmetry**, a hallmark of most complex organisms. An organism that shows bilateral symmetry has identical structures on both sides of a center line (right and left kidneys, arms, legs, eyes, ears, and so on).

In the process of gastrulation, cells and cell clusters move within the blastocyst to form three distinct layers (see Figure 2.9). The outermost layer of cells, the **ectoderm**, eventually forms the skin and, perhaps more surprisingly, the nervous system. The middle layer, the **mesoderm**, becomes internal tissues, such as the skeleton, internal organs, and muscles. And the blastocyst's innermost cell layer, the **endoderm**, develops into some of the glands, such as the thyroid, and the specialized tissues lining organs such as the lungs. A matrix of fine fibers within the blastocyst directs the cells' migrations, much like a set of guide rails along which the cells move. A great deal is happening during these migrations. Specific sequences of genes become activated and deactivated as cells in the different layers start to develop specialized features. The identities of these cells soon become nearly irreversible (Cyranoski, 2007; Jackson et al., 2010; Verfaillie, 2002).

How do the cells on the inside of the blastocyst, which eventually become parts of the embryo, differentiate from the blastocyst's external cells, which will form the placenta? The relative positions of these cells in the blastocyst seem to trigger different sets of genes within them, leading the cells to specialize for different functions. Presumably, the cells in the inner layer and outer layer receive different kinds of chemical signals (Surani et al., 2007; Thomas et al., 2004). If an outer-layer cell is moved to an inner position at an early enough point, it will genetically and functionally develop like an inner-layer cell, becoming part of the embryo rather than the placenta. The same kind of functional transformation happens if an inner cell is relocated to an external position (Hillman et al., 1972).

Anatomical Development

So far, we have focused on changes at the cellular level, many of which are visible only with a microscope. Within just a few weeks after conception, however, noticeable anatomical features start to appear, and they change very rapidly in the following months.

Structures and Systems in the Embryo and Fetus

After fertilization and cell divisions that make the zygote into a multicelled organism, rudimentary nervous and circulatory systems and body structures appear and grow rapidly, becoming specialized for particular functions (see Table 2.1). We will briefly discuss the development of systems and structures from 2 to 8 weeks after conception (during the embryonic period) and from 9 to 36 weeks after conception (during the fetal period).

The Embryonic Period At about 2 weeks after conception, the fertilized egg attaches to the uterine wall (see Figure 2.10). After this implantation, it becomes more common to refer to the fertilized egg as an **embryo** (the embryonic period lasts from the middle of the second week until the end of the eighth week after conception). The first signs of legs and arms are visible at about the third week. The heart starts to beat at around 18 days, pumping blood around a rapidly expanding circulatory system. Limb buds appear as small bumps in the arm region, and similar buds emerge later in the leg region, following the head-to-toe principle of development in which structures tend to develop earlier in the more anterior regions of the embryo (situated toward the head or front). Development in which the more anterior structures of an organism mature earlier than structures in the posterior sections is known as **cephalocaudal development** (cephalo = head, caudal = tail).

In humans and all other mammals, as well as birds and other reptiles, the key event in gastrulation, during which the blastocyst starts to develop distinct layers of cells, is the formation of the **primitive streak**, which occurs at the end of week 2 in humans. The primitive streak is a ridge on one side of the blastocyst through which cells pass to become the mesoderm and endoderm. Where and when they pass through the streak influences whether the cells in each layer will become part of the head, the gut, or the tail (if the species has a tail). Cells within the streak itself appear to produce chemical signals that guide other

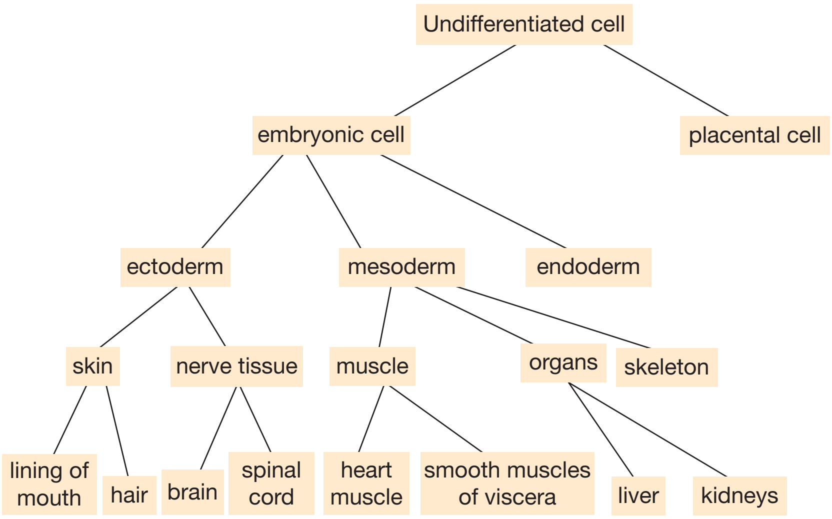

FIGURE 2.9 Cell differentiation. Cells differentiate in a pattern of hierarchical specialization, starting with cells that can become any sort of cell at all. Once a cell has progressed far enough down one path, it becomes extremely difficult to go back and revert to a less differentiated state.

cells to migrate toward the streak (Alev et al., 2010; Keller, 2005; Spagnoli & Hemmati-Brivanlou, 2008). Early-entering cells migrate toward one end of the streak, which may produce stronger signals, and become the head. Later-entering cells, as well as those that pass through the streak farther down, become other types of structures. Thus, the streak, which is one of the first signs of bilateral symmetry, also triggers a very early bias toward development in the head (see Figure 2.11). This head-to-toe progression is a powerful organizing principle of embryonic development.

Some cells that migrate into the streak end up forming the *notochord*, which signals ectodermal cells above it to form the *neural plate*, which lengthens and drops down into the surface to form a *neural groove* (at around day 18 in humans) with ridges on the sides. Eventually, these grooves fold in toward each other, join, and form a hollow **neural tube**.

Weeks after conception	Size (inches)	Weight	Hallmarks
2	0.01	< 0.25 oz	Embryo is soundly implanted on uterine wall.
4	0.125	< 0.25 oz	Limb buds appear; heart starts to beat.
6	0.5	< 0.25 oz	Fingers start to appear; some neural activity occurs; four-chambered heart is present.
8	1	0.5 oz	First elements of most body parts—for example, ears, fingers, toes—are present.
10	2.5	1.5 oz	Some movement occurs; fingernails appear.
12	3.5	2 oz	Kidneys start to make urine; blood is now made in bone marrow.
14	4.5	4 oz	Fetus may suck thumb; begins to make larger movements.
16	5.25	6 oz	Mother feels movements; some hair may be present.
20	10	1 lb	Fetus may hear sounds.
24	12	2 lb	If born at this time, 50 percent of babies survive with intensive care.
28	15	3 lb	Lungs can breathe air; eyes are open.
32	17	4.5 lb	Sleep and waking states are observed.
36	19	6.5 lb	Lungs are fully mature.
38	20	7.5 lb	Baby is full term.

TABLE 2.1 Milestones of prenatal development. The timetable of gross anatomical and physiological development of the human embryo and fetus is highly regular in normal cases. Although many structures are present in the first 5 months, not until well into the sixth month are babies at all likely to survive birth.

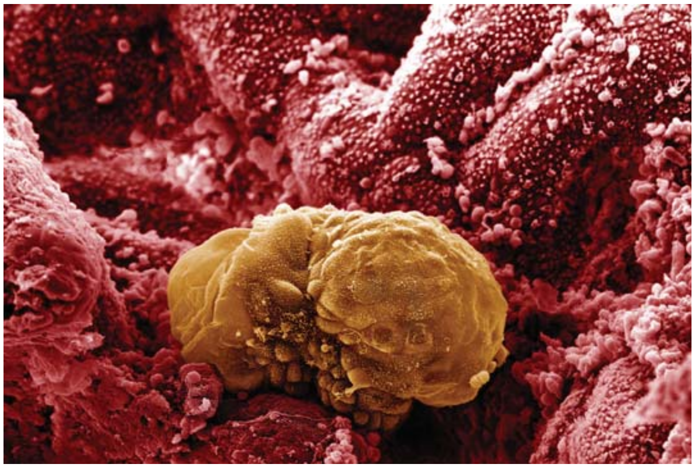

FIGURE 2.10 **Implantation of the embryo.** At 6 days, the blastocyst starts to implant on the uterine wall, as shown in this image. By 2 weeks, it is fully implanted and is about 0.01 inch long and is now known as the embryo.

This process of initial brain formation, called **neurulation**, is completed in week 4. The neural tube eventually becomes both the brain and the spinal cord. The notochord acts as a guiding framework for the spinal cord, with its cells eventually becoming parts of the vertebrae of the spinal column in humans. If the neural tube does not close properly, however, neural tube defects (for example, spina bifida, in which part of the spinal cord protrudes) will result.

After 3 weeks, the embryo's cells begin to differentiate. Cells that have identical genetic material take on different roles that support the development of a well-formed body. How can cells with the same genetic sequence become fingers, kidneys, brain cells, and muscles?

One key principle is that of successive differentiation. As specific cells develop, they narrow down their functional specialization in a step-by-step fashion, as shown in Figure 2.9. Thus, certain cells might first differentiate into three general groups: cells that can form muscles, organs, or the skeleton (bones). At first, the cells in the muscle group can become any kind of muscle, but at a later stage, most of those cells further differentiate into one of two main types of muscle. At an even later point, they specialize to form particular parts of specific muscles.

Dramatic changes in body structure occur between 4 and 8 weeks. At 4 weeks, the embryo is about 3 millimeters (about 0.125 inch) long. By the end of week 8, the embryo is well over 25 millimeters (about 1 inch) long. Even though it is only a little over an inch long, it already can be clearly seen as having human form.

The Fetal Period From the ninth week until birth, the growing human organism is referred to as the **fetus**. Over the next several weeks, the fetus changes dramatically (see Figure 2.12). It shows increasingly well-articulated fingers and toes. At 9 weeks, its four-chambered heart is clearly seen

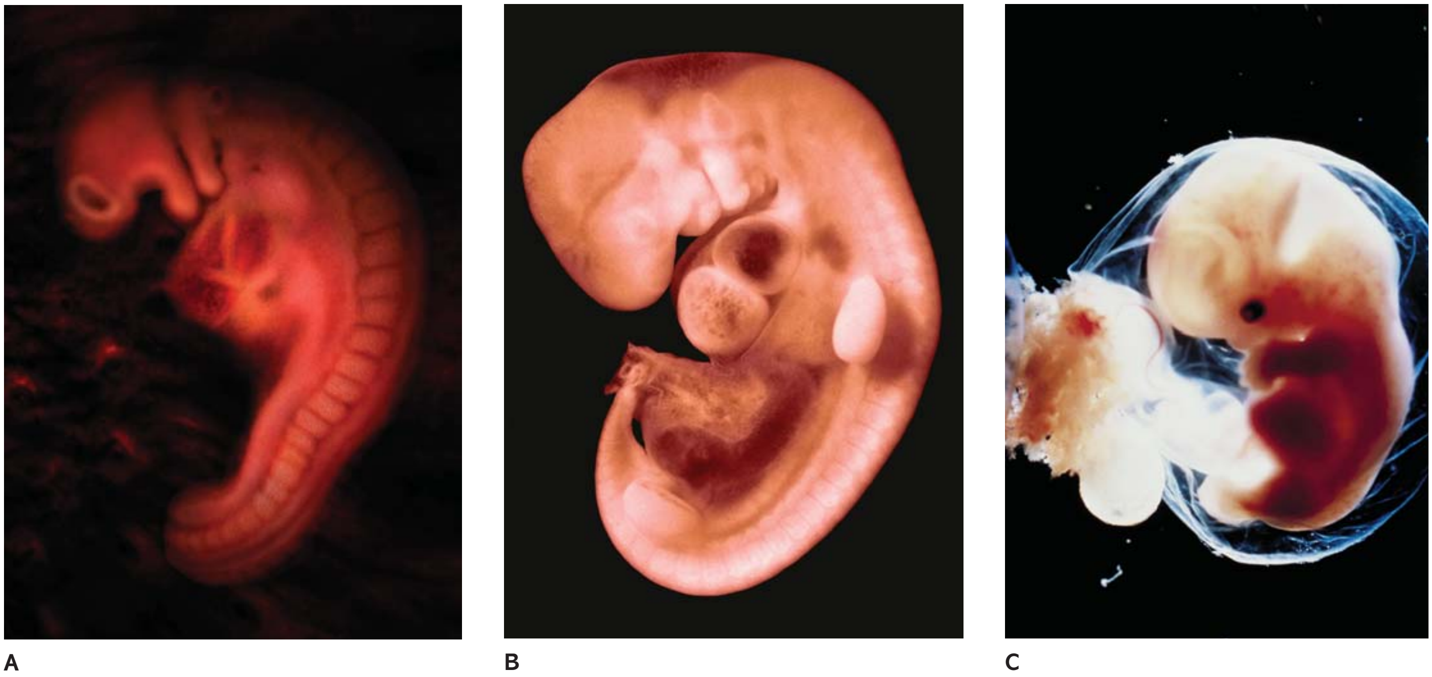

FIGURE 2.11 **The embryonic period.** **(A)** A 3-week-old embryo. The embryo's anterior structures, such as the head, tend to develop sooner than the posterior areas. **(B)** A 4-week-old embryo. By 4 weeks of age, the human embryo has a visible beating heart and the beginnings of limb buds, as well as a distinct head region. The heartbeat can be detected through ultrasound. **(C)** A 6-week-old embryo. The principle that structures near the head develop before those near the tail is complemented by the principle that structures near the body's midline tend to develop before those farther out to the sides.

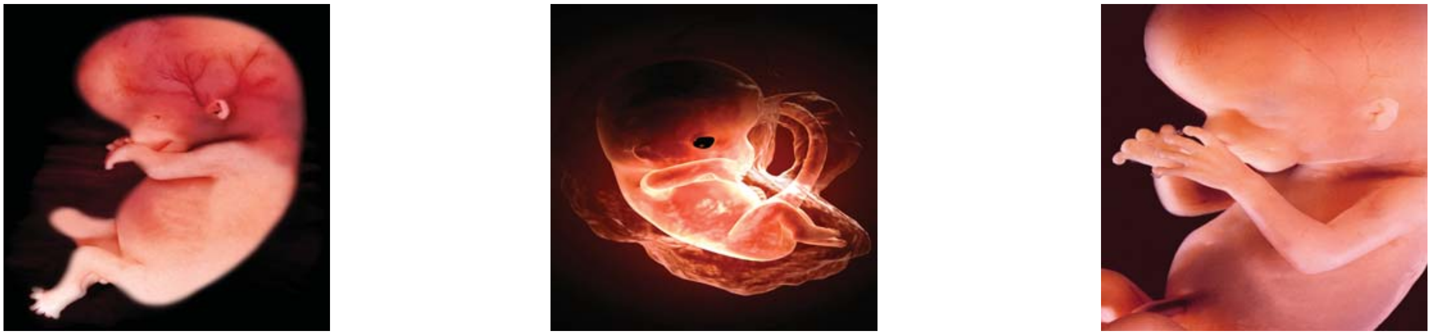
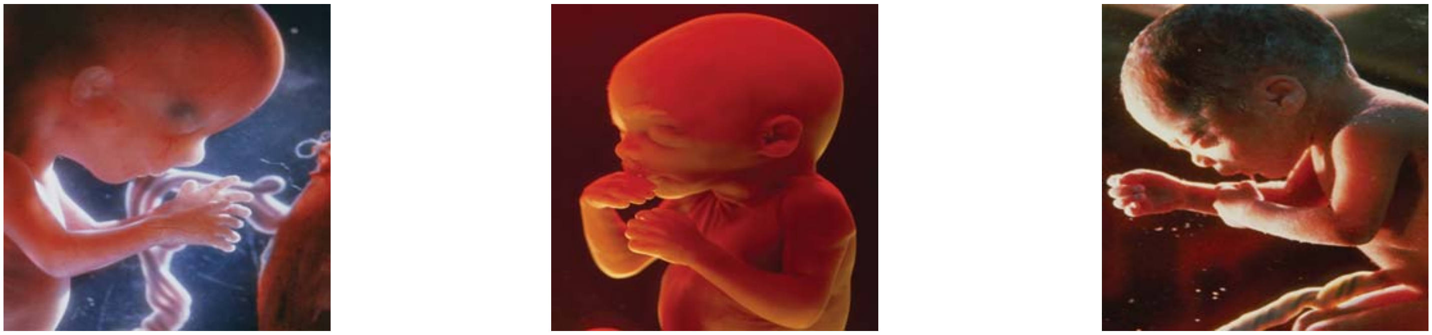


8 weeks 10 weeks 12 weeks



16 weeks 20 weeks 36 weeks

FIGURE 2.12 Prenatal development from 8 weeks to 36 weeks. From 8 weeks, both external and internal anatomical structures become further differentiated and more human in appearance. Development typically occurs earlier in the head region than in regions closer to the toes.

in ultrasound, as are visible facial features. Some of its neural connections are functioning, allowing it to show some reflexes.

By 12 weeks, it is quite easy to see most of the same anatomical features in the fetus that are visible in newborns. The fetus at this point is physiologically much more sophisticated than it was as an embryo, and most of its major bodily systems are partially functional. The fetus swallows, its muscles cause joint movements, and its kidneys now make urine. After 16 weeks, the fetus weighs 6 ounces and its external body parts are much more distinct. At 20 weeks, the fetus weighs about 1 pound, its hair is more evident, and its heartbeat can be detected with a stethoscope.

At 22 weeks, the fetus weighs about 1.25 pounds; this is the earliest stage at which a small number of premature newborns may survive birth, although this is possible only with the intensive medical care available at major hospitals, and the child is still likely to face many long-term disabilities. At 28 weeks, the fetus weighs close to 3 pounds. Its lungs typically have developed enough to be able to breathe air if birth is premature. By 6 months, the fetus is sufficiently well formed and physiologically mature that roughly 50 percent of infants born at that stage will survive if given intensive medical care. By 8 months, most infants will survive birth without major medical interventions. Once the fetus can survive on its own in the outside world, it is often called a baby.

At 36 weeks, the baby weighs about 6.5 pounds and is nearly full term. At this point, its movement in the womb is restricted because the baby is so tightly packed into the space. After its birth at 38 weeks of development, a newborn baby immediately breathes, cries, shows a range of behaviors and reflexes . . . and starts to learn about the world.

Preterm Births

A significant number of babies are born less than 38 weeks after conception. When babies are born 3 or more weeks early, they are known as **preterm** (or premature) **infants** and typically weigh less than 5.5 pounds, or 2.5 kilograms (see Figure 2.13). In the United States, roughly 12.5 percent of births are preterm, while in Europe, the rate is approximately 7 percent (Goldenberg et al., 2008). About 5 percent of preterm births occur before 28 weeks gestational age and are known as extremely preterm births.

Several forms of physical and psychological stress can increase the likelihood of a preterm birth. One major cause appears to be infections in either the mother or the fetus, which can indirectly cause either the onset of early labor or breaks in the membranes protecting the fetus (Goldenberg et al., 2008). Even infections far removed from the uterus, such as dental and gum infections, can increase the chances

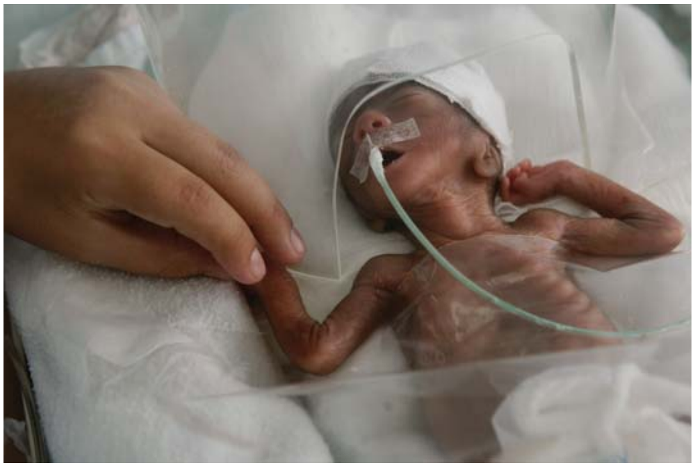


FIGURE 2.13 Extremely premature infant. Recent medical advances have made it possible for premature infants to survive at ages considered impossible a few decades ago. As younger and younger babies are able to survive, however, the incidence of severe, lifelong complications rises.

of a premature birth (Jeffcoat et al., 2001). Smoking, alcohol, and illicit drugs also increase the chances, and in combination they raise the odds still further (Dew et al., 2007). In addition to possible toxic effects, smoking, drinking, and drug abuse may put infants more at risk simply by exposing them to the increased odds of being born very early. Along the same lines as these physical stressors, mothers who experience intense stress and hardship are more likely to have preterm infants. Psychological stress may cause inflammation and immune responses, which in turn increase the odds of preterm birth (Wadhwa et al., 2001).

Preterm infants, and especially those that are extremely premature, are a cause of concern for physicians and psychologists because these infants are at increased risk for a host of complications later in development. As we consider the consequences of preterm birth, however, it is critical to keep in mind that these problems take the form of increased risks—not certainties. Preterm infants may have no negative medical or psychological conditions at any point in their lives, as we saw in the unusual case we described at the beginning of the chapter, but the closer to full term an infant is at birth, the smaller the chances of these kinds of problems occurring.

The more immature the preterm infant is at birth, the higher the risk of medical and psychological problems, not just in infancy but also in childhood and beyond (Korvenranta et al., 2010). At the level of neuroanatomy, preterm birth is associated with greater risk of a number of irregularities in brain development (Allen, 2008; Chuang et al., 2007; Volpe, 2009). This damage appears to happen in two ways: (1) premature birth seems to disrupt patterns of neural growth that normally occur in the last few months before birth, and (2) the problem that may have triggered a premature birth, such as an infection, can damage the brain directly (Volpe, 2009). The many mechanisms of damage are not well understood, making it difficult for physicians to reduce the rate of complications associated with extreme preterm births, even as infants are increasingly able to survive them.

Preterm births are also associated with a range of cognitive difficulties in memory, attention, and language skills, as well as with mental retardation in very severe cases (Allen, 2008; Anderson & Doyle, 2008; Rijken et al., 2007). These problems can persist long after infancy. School-age children who were born extremely preterm show a higher incidence of mild or severe cognitive impairments (Anderson & Doyle, 2008). Even among adults, those born extremely preterm show, on average, lower rates of school completion, lower levels of employment, and greater difficulty living independently (Allen, 2008; Moster et al., 2008).

How can the negative effects associated with preterm births be reduced? Interventions can aim to either reduce the rate of preterm births or minimize their negative effects. Reducing the preterm birthrate turns out to be a challenge. As doctors become better able to recognize the need to induce early labor, preterm birthrates are rising. Technologies such as in vitro fertilization for couples with fertility problems can also increase the odds of multiple fetuses and preterm births (Goldenberg et al., 2008). Nonetheless, medical advances are enabling doctors to prolong the gestational period without harming the mother or the fetus. Such interventions can range from convincing mothers to stop smoking, to screening for and treating infections promptly, to careful monitoring of the mother's diet and nutritional supplements (Iams et al., 2008).

Even with the most attentive prenatal care, however, preterm births still occur, and so the second form of intervention aims to help children who are born preterm. Studies suggest that among these children, those who experience more parental involvement and stimulating, active play in infancy and educational support in the early school years show cognitive and motor improvements (de Kieviet et al., 2009; Koldewijn et al., 2010). Preterm infants and preschool children have also shown early benefits from additional practice with motor skills and supportive educational programs, but these gains do not seem to be sustained through elementary school (Orton et al., 2009). Health care professionals, teachers, and psychologists still have much to learn about what kinds of interventions can provide long-term benefits for children born preterm. At this point, improving prenatal care to reduce the number of extremely preterm births is likely to be the most effective form of intervention.

Q: What difficulties reduce survival, and what long-term complications are likely when a fetus is born preterm?

Why Does Anatomical Development Progress As It Does?

What determines which body parts develop first? One nineteenth-century hypothesis suggested that the development of an embryo followed the same course as the species' evolutionary history. This idea is summed up in the phrase "ontogeny recapitulates phylogeny," where *ontogeny* refers to the development of an organism and *phylogeny* refers to the evolutionary lineage of a species (Haeckel, 1874; see also Gilbert, 2006; Gould, 1977). Researchers have cited some striking patterns in human embryonic development that seem to support the hypothesis. For example, structures vaguely resembling gills emerge early on, only to transform later into facial muscles, middle ear bones, and other structures. Later, a tail-like structure emerges that is then reabsorbed into the body.

Despite these observations, however, the idea that a species' embryonic development follows its evolutionary history is based on a misconception about evolution. In truth, evolution *does not* proceed in a straightforward path that starts with the simplest one-celled organisms and, over time, yields increasingly complex creatures. Species evolved not through a direct, linear progression but in branching patterns, such that organisms on different branches each acquired their own properties that differed substantially from the features of earlier species (see Figure 2.14).

Keeping that important caution in mind, the hypothesis that "ontogeny recapitulates phylogeny" still has some value when you consider how it relates to the developmental constraint of viability. Some of the earliest evolving structures were those necessary for an organism's basic functioning. These same necessary structures and processes are likely to emerge early in development to ensure that the organism is viable. The systems that support the most basic survival functions must emerge early in development—both in an individual organism's lifespan and in a species' evolution. In later chapters, we will see that this same principle applies to many aspects of cognitive and social development as well.

Diversity out of Uniformity

In considering how such a diversity of anatomical structures eventually develops from the zygote's undifferentiated cells, we have already seen how certain early developing features, such as the primitive streak, guide cells' specialization. In addition, some general patterns of body development are common to a wide range of species. These patterns can shed more light on the mechanisms of cell differentiation that support the formation of specific parts of the body (Larsen et al., 2001; Moore & Persaud, 2003). For example, how does the genetic material in the zygote's cells give rise to a developing hand or an ear? How do these structures emerge in the right place on the body? And what directs more detailed developmental patterns, such as the development of a five-fingered human hand instead of one with four or six fingers?

Much mystery still surrounds these questions. Nonetheless, recent discoveries have dramatically changed our

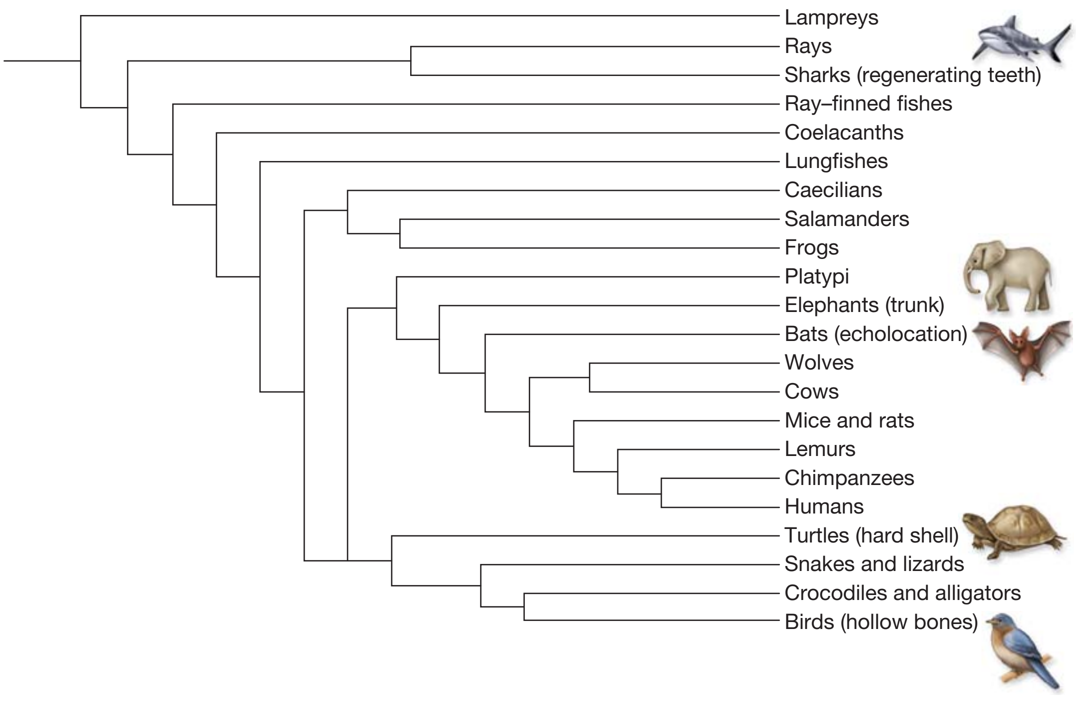

FIGURE 2.14 Evolution as a branching tree. At each branch in an evolutionary tree, a species acquires distinctive new traits, as shown in this small section of the evolutionary tree covering many vertebrates. As the branching structure shows, human development does not involve a progression through the properties of so-called "lower species." Adapted from C. Loeb, Macalester College.

understanding of how the body's overall structure develops, as well as how specific features, like limbs, emerge (Gilbert, 2010; Marcus, 2004; Mark et al., 1997). Special kinds of ordered clusters of master-switch genes known as **homeobox genes** activate or repress gene expression and thereby play an important role in defining the body plan. These homeobox genes contain the **homeobox**, a 180-base-pair sequence in the DNA of many different species of animals—from fruit flies to mice to humans. The homeobox encodes homeodomain proteins, which regulate genetic switches affecting the general structure and organization of certain body sections. First, the homeobox genes regulate the processes that lead to the formation of the anterior (front) and posterior (rear) sections of the organism's body (see Figure 2.15). Then, acting as switches at the top of large gene regulation cascades, they interact with other genes to code for species-specific appendages and other features. More specifically, when a homeobox gene is switched on, it sends chemical signals that reach many sections of the developing body. In response to these signals, genes throughout the body turn on or off as necessary to direct the growth of species-specific body parts, such as legs. The homeobox genes that govern the body plan in vertebrates are often called ***Hox* genes**.

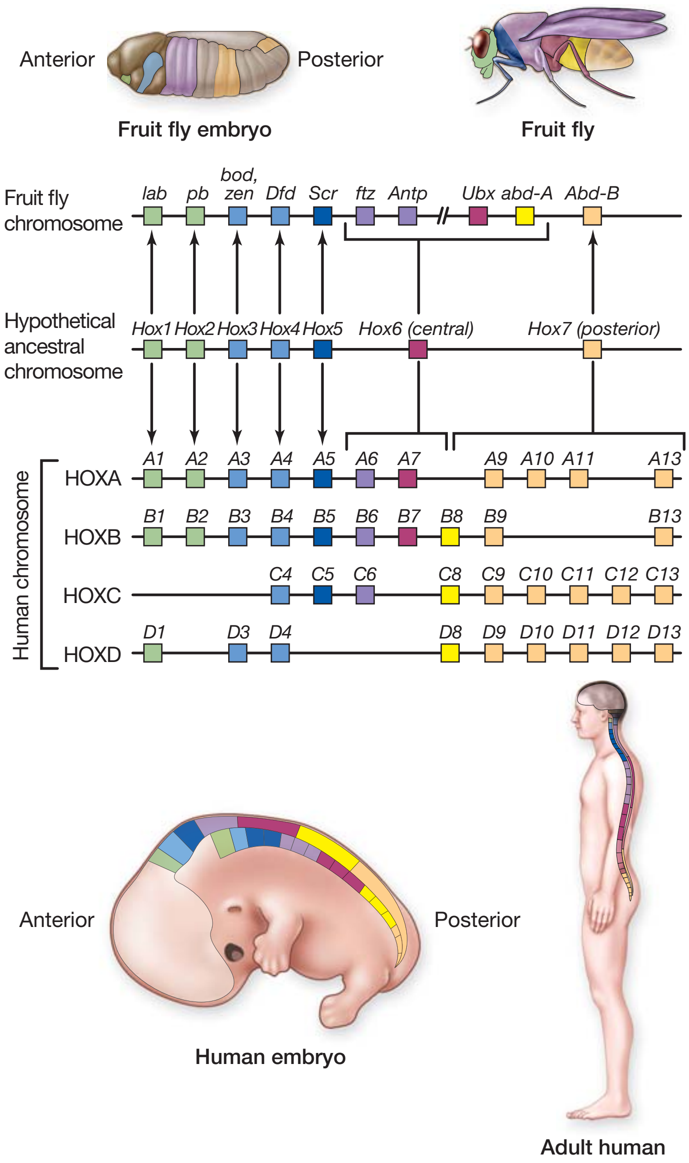

FIGURE 2.15 Homeobox genes. Homeobox genes are ordered clusters of genes that turn on and off genes that affect the general body plan in many species. In this drawing, squares of the same color indicate genes of the same type. Thus, the homeobox genes in the fruit fly also appear in humans, arranged in the same order. For example, genes of the same color code for comparable structures at the front (anterior) of the body across species, even though the particular types of structures differ radically. Adapted from Veraksa et al. (2000).

Q: What are homeobox genes? In what ways are their functions similar across a wide range of organisms?

Once the body's sections and major parts have been specified, how do the genes specify the fine-grained patterns of development, such as the appropriate number of fingers on a human hand? There is no gene sequence that codes for five fingers. Instead, various genetic influences trigger an intricate interaction of several chemicals. At critical points in development, these chemicals diffuse across the tissues from which the limbs later develop. The exposure of these tissues to specific concentrations of chemicals seems to trigger the appropriate number of fingers to develop (see Figure 2.16). The *Hox* genes also play a role in this process. Chemical signals turn these genes on and off in patterns that trigger limb growth in the appropriate region of the body.

The story of genes and body development involves both remarkable specificity and extraordinary generality. Each species' genome, interacting with a normal range of environments, results in that species' unique characteristics—and individuals' genes also cause clear differences within a species. Yet, the same basic genetic framework guides development in a broad range of species as different as insects and mammals. Apparently, very early in evolutionary history, survival depended on body parts developing in the right sequence (for example, heads before front legs, front legs before hind legs) and in the right number (just one head, please!). The solution that emerged in the genes that encode the general body plan was so effective and reliable that these genes remained an active part of the genome in most later-evolving species, with relatively little change in their function.

DEVELOPMENT AND SOCIAL POLICY

Visiting Nurses, Prenatal Care, and Child Development

The city of Elmira, New York, sits near the Pennsylvania border in a region that has been economically depressed for decades, as its manufacturing economy has withered. Elmira's economic peak was in the late 1940s and early 1950s. Today, its population is half of what it was 60 years ago, and almost one-third of Elmira's children under 18 live in poverty. In the 1970s, David Olds, a graduate student at nearby Cornell University, set out to make a difference in the lives of Elmira's children, who at that time had the highest rates of abuse and child neglect in the state (Boo, 2006). Olds started the Nurse-Family Partnership Program, a program in which nurses visited disadvantaged pregnant women to advise them during their pregnancy and then after the birth of their child. Since that time, Olds's program has been extended to sites throughout the United States.

Nurses in the program visit first-time mothers in their homes, beginning during pregnancy and continuing through their child's second birthday. During their visits, they offer guidance about prenatal health and infant care in a nonthreatening, nonjudgmental way. They provide information about prenatal nutrition, explain the threats that smoking and alcohol pose to the fetus, and convey to the mothers the importance of avoiding behaviors that could compromise their own health or harm their infant (Olds, 2006; Olds et al., 2007). They often emphasize the immense promise and potential of the child—if only he or she receives the right kind of care and support (Boo, 2006).

The nurse's job can be extremely challenging. Members of the household, sometimes including the mother, may be hostile about taking an outsider's advice. One account of so-called "swamp nurses" who visited pregnant mothers in rural Louisiana discussed the challenges of an African-American nurse visiting white teenage mothers who often faced a host of problems, ranging from drug addiction to sexual abuse (Boo, 2006). To work well with these mothers, the nurses had to have an extraordinary combination of compassion, sensitivity, and firmness.

The Nurse-Family Partnership Program is evaluated repeatedly to make sure it is effective. Wherever possible, Olds has used ***randomized assignment designs***, meaning that some mothers in a particular area are randomly selected to receive nurse visits and others in similar circumstances in the same area receive no visits. By randomly assigning mothers in comparable situations to either participate in the visiting nurse program or not, it is possible to compare outcomes between the groups to see whether the visits are effective. (Without random assignment, there would be no way to know whether group differences were due to the nurses' visits or to other factors, such as higher levels of motivation among mothers who seek the nurses' help.) In general, these careful studies often show positive effects for newborn infants. The effects are not always large, but the number of successes has encouraged agencies throughout the country to fund such programs.

Several studies have shown that nurse-visited mothers, especially the youngest mothers, have fewer medical complications during pregnancy and are less likely to have premature babies (Baldwin et al., 1998; Olds, 2006). In one study, the babies of nurse-visited mothers were almost a full pound heavier than the babies delivered by mothers in the control group, who were not visited by nurses (Olds et al., 1986). Nurse-visited mothers also tended to have fewer episodes of high blood pressure while pregnant and lower rates of cigarette smoking (Olds, 2006). Given the negative effects of fetal nicotine exposure on later brain development (Ernst et al., 2001; Thomas et al., 2000), these changes in the mothers' behavior represent an important medical treatment for the growing fetus.

The benefits of these programs extend far beyond the direct impact on brain growth. Nurse-visited mothers interact with their babies in a host of more positive ways and are less likely to abuse their children (Olds et al., 2007). After working with a nurse named Luwana, a mother named Alexis observed of her new son Daigan, "He's not as cranky as he was. And one thing I learned already is how he cries different when he's hungry than when he's wet." As Luwana explains to Alexis, "Making that distinction is important. . . . You're listening to him, and in his own way he's explaining what he needs" (Boo, 2006). Children of nurse-visited mothers show continuing benefits on into adolescence (Fisch, 2005; Kitzman et al., 2010; Olds, 2006). In many cases, these effects arise from a continuing pattern of positive interactions between mother and child (Leckman & Mayes, 2007).

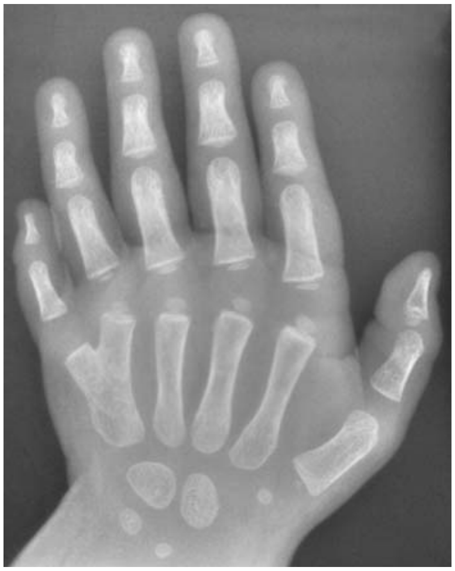

FIGURE 2.16 Finger number. Although infants are occasionally born with extra toes or fingers, as shown here, it is impressive how often the gene sequence results in the standard number. There is no specific part of the genome that codes for five digits per hand and foot. Instead, interactions between many genes result in overlapping chemical gradients that, together, usually result in this number.

Sexual Differentiation

So far, we have examined normal developmental processes common to all humans. But humans and many other animals also show different development patterns, depending on their sex. Differences between males and females are complex and occur not only in major anatomical structures, but also in physiological systems and, to some extent, in the brain (Austin & Edwards, 1981; McCarthy et al., 2009; Parker et al., 1999). Initially, the cells of the embryo do not show sex differences, but **sexual differentiation** starts very early, most likely in the first few weeks after conception. External sexual differentiation—the development of genitalia—occurs earlier in males than in females.

Although sexual differentiation is controlled by the X and Y sex chromosomes, genes do not directly code for sexual differentiation. Instead, these differences are controlled by exposure to particular sex-specific combinations of hormones, which are triggered and regulated through complex interactions between genes (McCarthy et al., 2009; Park & Jameson, 2005). If these genetic interactions trigger the embryo to produce higher levels of the male sex hormone testosterone, the cells exposed to testosterone will specialize to form structures with male characteristics. Likewise, if the embryo produces higher levels of the female sex hormone estrogen, this will trigger differentiation into cells that form structures with female characteristics. If an embryo with two X chromosomes (genetically female) is exposed to higher levels of testosterone before the cells have begun to differentiate along female lines, that embryo can acquire many aspects of male anatomy, including sex-specific brain differences. The same kind of effect happens when undifferentiated embryonic males are exposed to higher levels of estrogen.

One example of early sexual differentiation can be seen in Figure 2.17. Initially, the human embryo has both Wolffian ducts and Müllerian ducts in the lower abdomen, as well as bipotential gonads (gonads that could develop into female or male structures). At this point, either male or female urogenital structures could emerge, but this changes as soon as the tissues are exposed to higher levels of a particular sex hormone. High testosterone and low estrogen cause the Wolffian ducts and testes to grow into a male urogenital system and cause the Müllerian ducts to wither away. High estrogen and low testosterone cause the Müllerian ducts and follicle cells in the ovary to grow into the female urogenital system and cause the Wolffian ducts to degenerate (see Table 2.2).

The adults of some species retain the capacity to change their phenotypic sex as a function of social dominance.

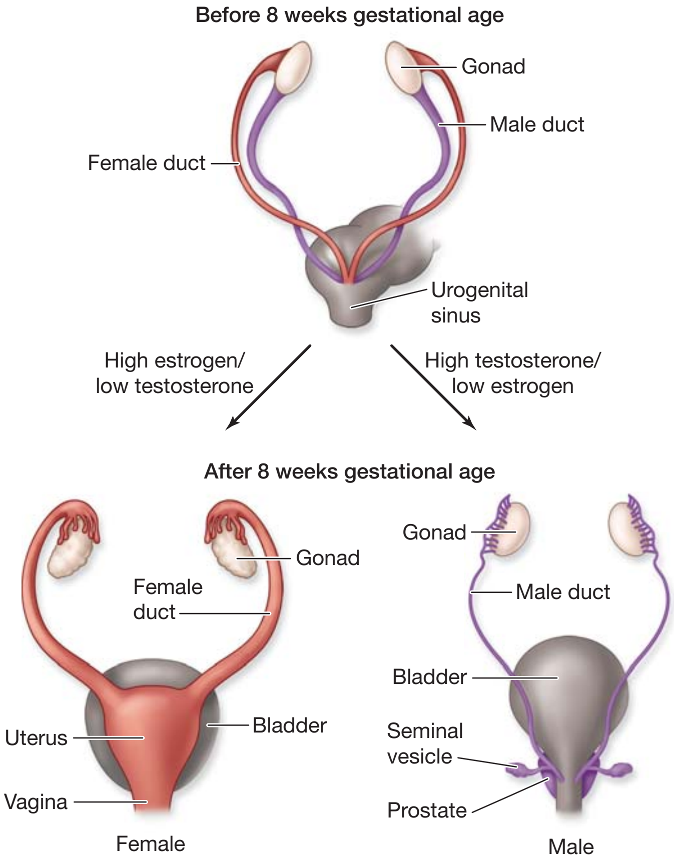

FIGURE 2.17 The emergence of biological sex differences. The early embryo has both the Müllerian ducts and Wolffian ducts. The urogenital system that develops from these ducts depends on which sex hormones contact the relevant tissues. Adapted from Matzuk & Lamb (2008).

Weeks after conception	Males	Females
6 or less	No anatomical differences; embryo is sexually bipotential.	No anatomical differences; embryo is sexually bipotential.
7	Testes start to form.	Ovaries start to form and develop functional subunits.
8	No obvious external differences; testosterone triggers growth of Wolffian ducts and withering of Müllerian ducts.	No obvious external differences; estrogen triggers growth of Müllerian ducts and withering of Wolffian ducts.
10	All internal sexual structures are present.	All internal sexual structures are present.
12	External sexual differences are visible.	External sexual differences are visible.

TABLE 2.2 Changes in sexual characteristics in early prenatal development. The presence of higher levels of testosterone or estrogen affects the development of sexual structures in males and females.

This phenomenon is most prevalent among reptiles, amphibians, and fish. There may be only one phenotypic male in the group whose role is stimulating ovulation in the phenotypic females. When that male dies, the dominant female undergoes a variety of changes that make her a phenotypic male, both behaviorally and anatomically. In these cases of environmental sex determination, all group members usually have the same genotype, and the specific male or female gene pathways are triggered by changes in the social environment (Francis & Barlow, 1993; Fricke & Fricke, 1977; Godwin, 2009; Robertson, 1972; Ross, 1990).

In humans, social context may cause much more subtle changes in hormonal balances, and if these changes occur during pregnancy, they could potentially have long-term effects on the fetus. For example, many studies of prenatal development have demonstrated that during pregnancy, maternal stress levels can affect the timing of the fetus's exposure to different levels of testosterone. One potential effect of these shifts in timing is to cause less sexual differentiation of the male brain; indeed, some researchers have claimed that this effect may be a biological basis of homosexuality (LeVay, 1993), although these claims remain controversial. The extent to which maternal hormones and the prenatal environment influence human sexual orientation remains unclear (Gooren, 2006).

A different aspect of the environment—namely, the number of older male siblings a male has—also seems to influence the frequency of homosexuality among men (Gooren, 2006; Puts et al., 2006). One controversial theory hypothesizes that the more older brothers a male child has, the greater the probability that child will develop homosexual attractions (Dawood et al., 2009). Because this effect only holds for older siblings with the same mother, not stepchildren or adopted children, it may be due to an immune response in the mother against some aspect of the Y chromosome or the hormones that trigger male characteristics. This theory suggests that the mother's immune response builds over the course of multiple pregnancies with male children, so that later sons would more likely be affected than earlier sons. Yet, since many firstborns can be homosexual and many lastborns are not, this pattern is only a small part of any account of how homosexual and heterosexual choices emerge in development. Much more research remains to be done before we can have a clear sense of the many factors contributing to homosexuality.

Sexual differentiation continues well after birth and on into puberty, and changing concentrations of hormones continuously influence the process. During this process, genes also interact with many kinds of environments, ranging from the hormones in the womb to the child's experiences after birth. All along, interactions between genes and the environment contribute to the ways that biological and behavioral traits emerge.

Adverse Influences on the Developing Embryo and Fetus

Given the complexity of development, it is remarkable that all of the body's structures form and grow normally and at appropriate times in the vast majority of cases. But sometimes problems do appear, often because of harmful environmental influences. Between 1957 and 1962, thousands of pregnant women in Europe and North America were given what appeared to be a new wonder drug for morning sickness: thalidomide. The drug has since become infamous for its adverse effects on developing fetuses. Its most obvious effects involved severely stunted limb growth and sometimes an absence of limbs (see Figure 2.18). It also caused serious defects in internal organs, genitalia, and the nervous system. More recent research suggests that thalidomide probably interfered with the activity of genes

FIGURE 2.18 **Thalidomide and pregnancy.** The tragedy of the babies whose mothers were prescribed thalidomide led to increased sensitivity to the dangers of teratogens and how the timing of exposure influences their effects.

that code for normal limb growth or perhaps with the *Hox* genes' timing signals (Marcil et al., 2003; Wolpert, 1999; Zeller, 2010).

Since the thalidomide disaster, doctors and the public have become more aware of possible negative influences on embryos and fetuses and better able to guard against them. Called **teratogens**, these hazardous internal or external environmental factors can potentially cause problems with development during the prenatal period. They can be classified into the categories shown in Table 2.3.

Teratogens illustrate a developmental theme discussed earlier: the importance of timing and sequencing in the developmental process. Specific teratogens tend to have especially strong harmful effects during specific times in prenatal development (see Figure 2.19). Thalidomide, for example, usually had its disastrous effects from 2 to 8 weeks after conception. Because of the sequence of anatomical development, the specific effects of thalidomide depend on the point during pregnancy when it is used. Using it only during a brief, early period in prenatal development, say at 3 to 6 weeks, might have impacts mostly on the arms and other anterior structures, whereas using it at a later period, say at 7 to 8 weeks, would more likely impair growth of the legs and more posterior structures. Generally, teratogens have the worst effects during the embryonic period, from about 2 to 8 weeks after conception, when the most dramatic qualitative changes take place. The central nervous system tends to be most vulnerable in the first few weeks after fertilization, followed by the heart, then the limbs, the eyes, and finally the external genitalia, which do not seem to be influenced until after 6 weeks.

Thalidomide was a new, poorly understood drug when it was widely prescribed to pregnant women, as was diethylstilbestrol (DES), which was used to prevent miscarriage and led to increased risk for cancer in adolescents and adults who had been exposed to DES in the womb. In addition, some common drugs can also act as teratogens. For example, several anti-acne medicines are part of a family of chemical compounds known as retinoids. If a pregnant woman takes even a small amount of these medications, a wide range of birth defects become more likely. Depending on when in her pregnancy she takes the medication and for how long, it can cause hydrocephaly (swelling of the fluid-filled areas of the brain), microcephaly (undersized brain), heart defects, ear and eye defects, and cleft lip and palate (Durston et al., 1989; Maden, 2000). Vitamin A in its various forms is also a retinoid, and high doses of vitamin A during pregnancy can cause comparable defects—even though low doses are essential for normal development (Collins & Mao, 1999). A different drug, valproic acid, which is used to treat convulsive disorders (and sometimes bipolar disorder), can also cause birth defects ranging from neural problems to facial, heart, and skeletal malformation (Duncan, 2007; Finnell & Burn, 2001; Finnell et al., 2002). Even some drugs with minimal or no apparent side effects in adults can endanger a fetus.

Q: How does the timing of exposure to a teratogen affect its consequences for the developing fetus?

Teratogens are not limited to drugs; they can be part of the mother's diet as well. It is well known that drinking alcohol during pregnancy can be hazardous to the fetus, and its effects can be extensive. Depending on the age of the fetus, alcohol can cause smaller brain volume (see Figure 2.20) and impaired development of neurons and supporting cells (Archibald et al., 2001; Riley & McGee, 2005; Sowell et al., 2008; Spadoni et al., 2007).

Hazards posed by foods are often less obvious than the risks of drugs and alcohol. In some cases, foods can be contaminated with a trace amount of a teratogen that, while mildly harmful in adults, might be devastating for prenatal development. Many fish that are high in the food chain, such as swordfish and tuna, retain relatively high concentrations of mercury in their tissues from eating mercury-contaminated fish lower in the food chain. Because mercury can have strong teratogenic effects,

Teratogen type	Examples	Effects
Prescription drugs	Thalidomide	Underdeveloped limbs and organ problems
	DES (synthetic hormone)	Increased risk of various cancers in daughters
	Streptomycin (antibiotic)	Auditory impairment
	Retinoids (often prescribed for acne)	Brain defects, heart defects, eye and ear defects
Illegal drugs	Cocaine/crack	Stunted growth, microcephaly
	Heroin	Reduced neuron populations, memory deficits
Normally ingested substances	Alcohol	Fetal alcohol syndrome (mental retardation, microcephaly, anatomical defects in head and face)
	Nicotine	Anatomical defects, structural and functional impairments of the nervous system
	Aspirin	Amplifies effects of alcohol, bleeding problems
Environmental toxins (can enter via mother's diet)	Lead	Central nervous system damage
	PCB (industrial chemical)	Skin discoloration
	DDT (insecticide)	Impaired learning, neurotoxicity
	Petroleum distillates	Internal and skeletal malformations
Malnutrition	Iron deficiency	Impaired physical and cognitive growth
	Protein deficiency, insufficient calories	Increases negative effects of many teratogens
Infectious diseases	Rubella (German measles)	Deafness, blindness, heart defects, microcephaly, growth retardation, mental retardation
	Toxoplasmosis	Blindness, hydrocephaly, mental retardation
	AIDS	Possible growth retardation, microcephaly
	Herpes	Microcephaly, seizures
	Syphilis	Mental deficiency, hydrocephalus, deafness, blindness, bone malformations
Physiological disorders and immune incompatibilities	Blood incompatibilities	Neurodevelopmental disorders, possibly schizophrenia
	Diabetes	Congenital heart defects, neural tube defects, limb defects
	PKU (an inability to use an amino acid)	Mental retardation, heart defects
	Hypothyroidism (underactive thyroid gland)	Heart defects, reduced brain and body growth

TABLE 2.3 Teratogens and development. Teratogens are internal or external hazardous environmental factors that can affect the developing organism in utero and can result in birth defects. They are diverse both in kind and effects. Some of the effects can be remarkably specific, while others can be more global.

expectant mothers should limit their consumption of fish. Even more subtly, under some conditions, prenatal diets free of known teratogens can still have harmful effects on some fetuses. For example, during pregnancy, diabetic mothers must manage their blood level of insulin even more carefully than usual. Abnormally high or low blood insulin levels may lead to a kind of misprogramming of the fetal systems that regulate weight and metabolism (Plagemann, 2006). In addition, some maternal alleles appear to increase the risk of miscarriage or birth defects unless the expectant mother takes a certain dietary supplement, such as vitamin B_{12}, to offset the problem (Stover & Garza, 2006; Tamashiro & Moran, 2010). Once again, genetic and environmental influences interact to produce developmental outcomes.

Although this book focuses on developmental psychology, a brief survey of biological development of the body as a whole has brought to light many principles that also pertain to neuropsychological development, ranging from canalization to the importance of when an organism encounters particular environments or events. We have also seen how prenatal development can affect postnatal functions and development, a theme we will carry forward in our discussion of brain development as well.

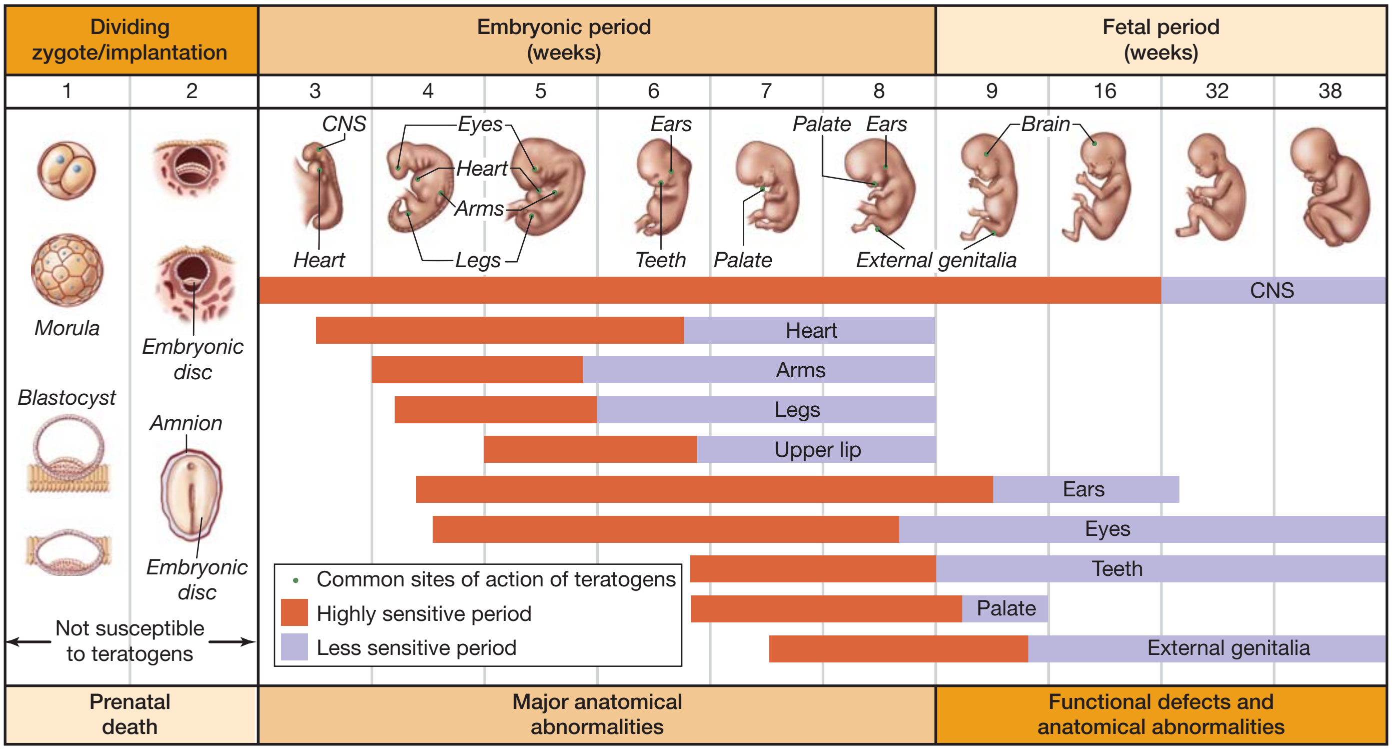

FIGURE 2.19 **Timing and teratogens' influences.** This chart shows the periods in which different body systems and organs are most susceptible to teratogens and other external influences, as well as the periods when they are less sensitive but when exposure to teratogens can still cause damage. Adapted from Moore et al. (2013).

Brain Development

The development of the brain is an intricate process in which many structures develop in a tightly choreographed manner. During the prenatal period, some early-developing brain structures provide necessary frameworks for later ones, and spatial relations between these structures guide further development. Furthermore, the brain continues to grow and change dramatically after birth: the adult brain is roughly four times larger than the newborn brain. As we consider how the brain develops, it helps to keep in mind four themes that describe what is happening and why.

The first of these themes is a familiar developmental principle: vital structures and systems develop first. In the body, the heart is one of the first organs to function; indeed, the circulation of nutrients through the bloodstream is necessary for an organism's survival. In the brain, structures that support such life-critical functions as heartbeat, breathing, digestion, and blood pressure emerge very early. Similarly, structures that enable basic motion and sensing of stimuli tend to develop earlier than those that involve more complex coordination of actions or interpretation of information. The last structures to develop tend to be those involved in reasoning about choices and different patterns of information. Likewise, brain structures mature at very different rates, and brain development tends to follow the "ontogeny recapitulates phylogeny" pattern. That is, brain structures that are evolutionarily older tend to mature earlier than regions that evolved more recently (Turner, 1950). The same pattern

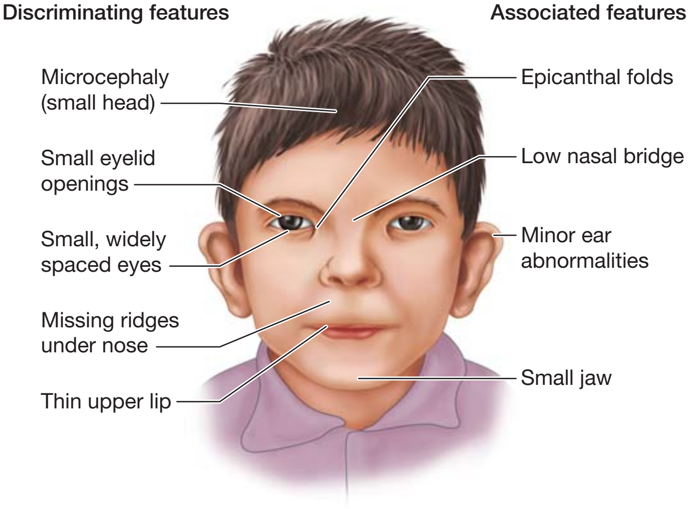

FIGURE 2.20 **The effects of high alcohol consumption during pregnancy.** The child with fetal alcohol syndrome is born with low birth weight, microcephaly (abnormal smallness of the head), a low nasal bridge, a thin upper lip, and small but widely spaced eyes. Adapted from Riley & McGee (2005).

described earlier also holds in the brain: the structures and systems most essential for an organism's survival tend to appear earlier, both in evolution and in an individual's development.

The second important theme of brain development is that the later-developing brain structures tend to inhibit earlier-developing ones. In this case, inhibition is not simply a new system blocking the activity of an earlier one. Rather, as a new system develops, it tends to bring the existing systems under more refined and nuanced control. In later chapters, we will encounter various ways in which this pattern in brain development affects behavior; for example, some reflexes that are strong in newborns disappear as older infants become increasingly able to control and direct their movements (see Chapter 4). Similarly, we will see how development in the frontal areas of the brain during childhood underlies children's ability to inhibit a first impulse in favor of a more considered and effective response (see Chapter 13).

Third, sometimes "less is more" in brain development. That is, in contrast to most other body systems, several brain regions mature and become more sophisticated through processes of trimming away rather than proliferation and growth. Just as a gardener prunes a fruit tree to create a structure that is better suited to bearing fruit, brain regions undergo a *pruning* process to create more streamlined structures for the growing child or adolescent. Pruning brain regions may cause psychological changes in which a previously malleable behavior becomes less varied and more ingrained.

Fourth, the speed and amount of communication between different brain regions increases over the course of development. Many of the main thoroughfares of nerve cell communication can show as much as 100-fold increases in speed between birth and adulthood. These increases in speed and capacity allow different psychological systems to work together more efficiently.

As we look closely at brain development, we will also consider how environmental factors, including the prenatal maternal environment and the variety of environmental influences the child encounters, affect the developing brain. Does an extremely enriched or deprived environment affect an infant's brain? If an organism fails to have an experience before a certain age, what happens to the brain region responsible for processing that kind of experience? While it is obvious that brain development would influence our psychology, we will also see that psychological development influences the brain.

Major Changes to Brain Structures

The mature human brain has several distinct regions with specific functions. Most important for our developmental discussion are the regions shown in Figure 2.21. The brain has three major parts. The **brainstem** is concerned with regulating heart rate, breathing, swallowing, blood pressure, digestion, and other automatic nonvoluntary processes in the body and is evolutionarily very old. The **cerebellum** is involved in coordination of voluntary movement and integration of some sensory information with action. The third and largest part, the **cerebrum**, includes the basal ganglia (involved in both voluntary and involuntary movement), the olfactory bulb (which processes information about smell), and the cerebral cortex.

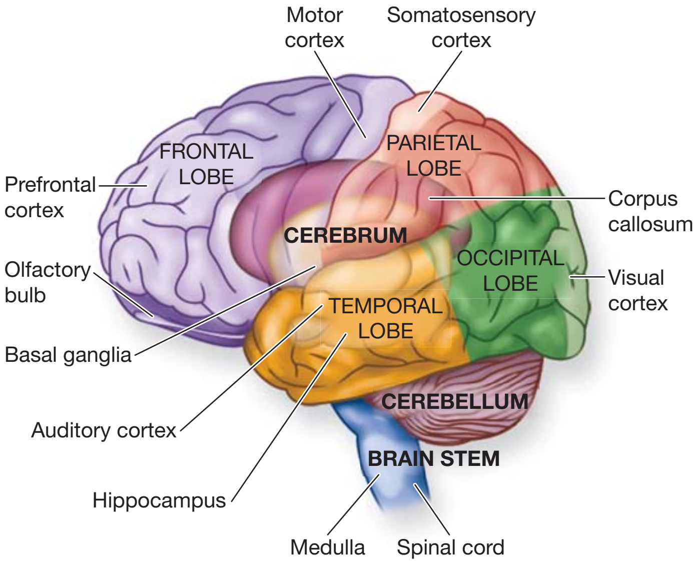

FIGURE 2.21 Basic structure of the human brain. The brain has three major parts and four lobes. Brain structures mature at different times and rates. Evolutionarily old structures required for survival, such as the spinal cord, medulla, and basal ganglia, mature early. Areas of the cortex that process sensory information, such as the visual cortex and the somatosensory cortex, mature earlier than the areas that process abstract information, such as the prefrontal cortex.

The **cerebral cortex** is the most recently evolved region of the brain; it is most developed in humans and other primates and is usually associated with high-level thought. The cerebral cortex is divided into right and left hemispheres, which communicate with each other largely through a central pathway known as the **corpus callosum**.

Each hemisphere is further divided into four lobes that are primarily responsible for different functions. In general terms, the **frontal lobe** is involved in planning, problem solving, and regulating thoughts and emotion. The posterior parts of the frontal lobe are also involved in aspects of motor activity and understanding the grammar of languages. The **parietal lobe** has several functions, including processing and interpreting touch sensations, integrating visual and spatial information, and processing some aspects of the meanings of words. The **temporal lobe** processes auditory information and other aspects of language meaning, and it supports crucial components of memory. Finally, the

occipital lobe processes visual information. These descriptions of the different functions of the lobes are approximate; in fact, the lobes interact extensively with one another and with other brain regions.

Brain structures and the pathways between regions mature at different times and rates. As we have seen, evolutionarily more ancient structures that are required for basic survival, such as the spinal cord, medulla, and basal ganglia, tend to mature earliest because they support such activities as breathing, heart rate, and appetite. Areas of the cortex that process sensory information, such as the visual cortex and the somatosensory cortex, mature somewhat later and continue to mature for some time after birth as higher and higher levels of processing become more refined. Finally, areas that process more abstract information and regulate other areas, such as the prefrontal cortex, tend to mature last. This sequence is only a crude characterization of a much more complex interplay between brain regions over the course of development, an interplay that also helps drive development. Thus, a circuit of mutual interactions between two areas may foster development of both.

Thinking about the brain in terms of regions with specific functions is helpful for understanding some aspects of its structure and capacities. But when it comes to understanding brain development, it is important to keep in mind that the brain is a highly interactive system in which each area depends on inputs from the others. When you recall the flowers at your cousin's wedding, you access and integrate memory traces from many different parts of the cerebral cortex. In this process, you use each of the four lobes in operations such as knowing where the wedding was held, constructing a mental image of the bouquets, remembering their sweet smell, visualizing how they were displayed, and knowing the names of roses, lilies, and orchids.

How does the embryo develop this rich array of brain structures and abilities? As mentioned earlier, in the first few weeks after conception, part of the ectoderm starts to form a groove, which will become the neural tube. By the time the ectoderm starts to close into a tube at 4 weeks, the structure has three distinct bumps: the forebrain, the midbrain, and the hindbrain, also known as cerebral vesicles. At 5 weeks, the forebrain and hindbrain vesicles split and form several distinct brain regions. Three of the most important regions are the *telencephalon*, the *diencephalon* and *midbrain*, and the *brainstem*.

The telencephalon eventually becomes the cerebral hemispheres, the areas that support the highest levels of psychological functioning. The diencephalon and midbrain give rise to the basal ganglia and other structures that reside between the cerebral hemispheres and above the brainstem. These include structures that integrate sensory information, as well as the cerebellum. By 10 weeks after conception, most of the brain's major regions are visible without use of a microscope.

At 20 weeks, the cerebral hemispheres are clearly visible, but they are smooth rather than fissured. This begins to change at around 24 weeks. At that point, the cortical surface develops the folds and fissures that are essential for supporting the complex processing of the human brain. These changes are summarized in Table 2.4 and Figure 2.22.

As noted earlier, the infant's brain grows quite a bit after birth. Weighing roughly 350 to 400 grams at birth, the brain's weight more than doubles in the first year of life, and it weighs about 1,250 grams (a little under 3 pounds) by 5 years. These large increases in brain mass in the first 5 years of life are assumed to increase its processing capacity. After age 5, brain volume stays relatively constant until some shrinkage begins in old age.

Neurons and Neurotransmitters

Along with these large-scale changes, the brain also changes dramatically at the microscopic level, both before and after birth. Since much of the change centers around

Weeks after conception	Event
3	Neural tube starts to form.
4	Three brain regions are now distinct: forebrain, midbrain, hindbrain; neural tube is almost completely closed.
5	Cerebral vesicles are now present.
10	Major central nervous system structures are now visible.
20	Brain weighs about 100 grams; cortical surface appears smooth.
24	Programmed cell death (apoptosis) begins.
28	Cortical surface has clear folds.
38 weeks–birth	Brain weighs 350 to 400 grams.

TABLE 2.4 Timetable of prenatal brain development. Major neural changes occur in a regular sequence of steps representing an extraordinary amount of change in a short period of time.

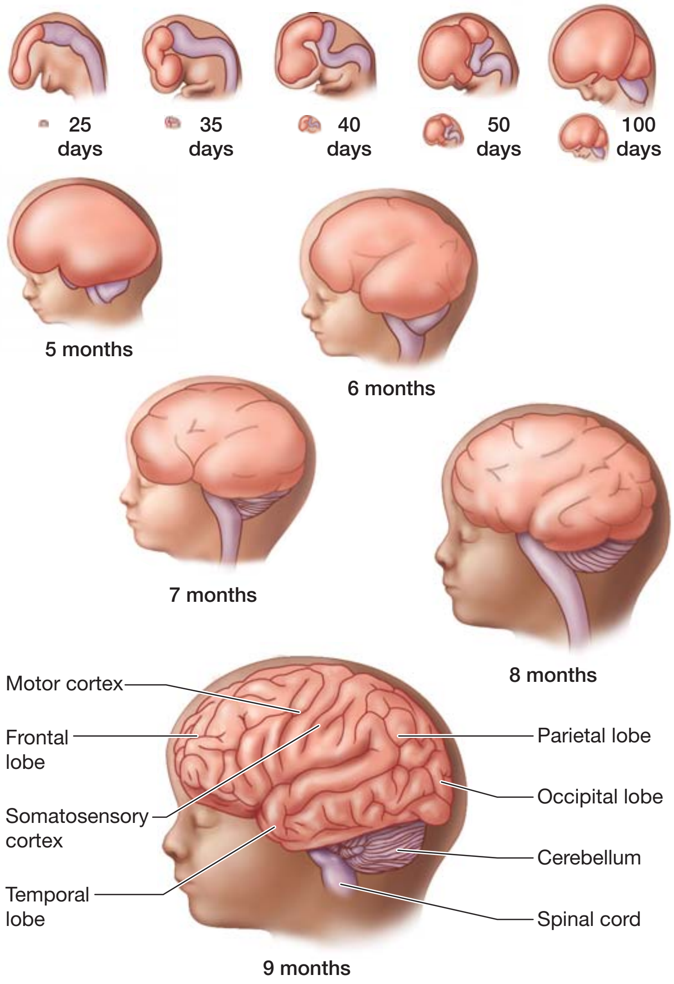

FIGURE 2.22 **Brain growth in the embryonic and fetal stages.** The brain structures are shown from 25 days through 9 months. The size of the developing brain from 25 days to 100 days is enlarged to show the details that would not be apparent at the actual sizes (which are indicated below the enlarged depictions). Note the relatively late appearance of cerebral fissures and the relatively late maturation of the frontal lobe. Adapted from Cowan (1979).

the brain cells known as **neurons**, we will briefly review what neurons are and how they work before considering how they develop and form connections. Like the body's other cells, each neuron is surrounded by a membrane that partitions the cell interior from its surrounding environment. As in other cells, the neuron's cell body contains the structures that support its basic functions as well as the nucleus, which contains its genetic material (see Figure 2.23). Neurons differ from other cells, however, in the specialized structures that enable them to transmit information to one another. Branching out from the neuron's cell body are the **dendrites**, which have receptors that receive chemical signals from other neurons. The number of receptors on a single neuron varies widely and can be as high as several hundred thousand. Many dendrites are also covered with small protrusions known as dendritic spines, which also house receptors. Each neuron also has an **axon**, a tube-like projection that, in adults, can range from over a meter long (more than 3 feet) to less than a centimeter (under half an inch). Neurons typically have many dendrites and only one axon, although the axon may have several branches. Each branch ends in axon terminals, which have small bulbs at the tips that contain chemical **neurotransmitters**, which transmit signals across gaps between neurons.

Communication between neurons occurs at **synapses**, which are the small gaps between the axon terminals of one neuron and the dendrites of another. Neurons can be chained together in elaborate networks, with each neuron's axon terminals ending in synapses that separate them from the dendrites of other neurons—whose axon terminals, in turn, end in synapses that separate them from yet other neurons' dendrites. When the small bulbs at the end of an axon of the presynaptic neuron (the neuron sending the signal) release neurotransmitters into the synapse, these chemical signals cross the synapse and are received by the receptors at the ends of the adjacent dendrites on the postsynaptic neuron (the neuron receiving the signal). There are several types of neurotransmitters, and each neuron's receptors respond to particular types. These chemical signals can cause the receiving neuron to "fire," creating an electrical signal called an **action potential**. When the neuron fires, the action potential travels down the axon to the ends of the axon terminals. There, the resulting electrochemical changes trigger the ends of the terminals to release neurotransmitters into the synapse.

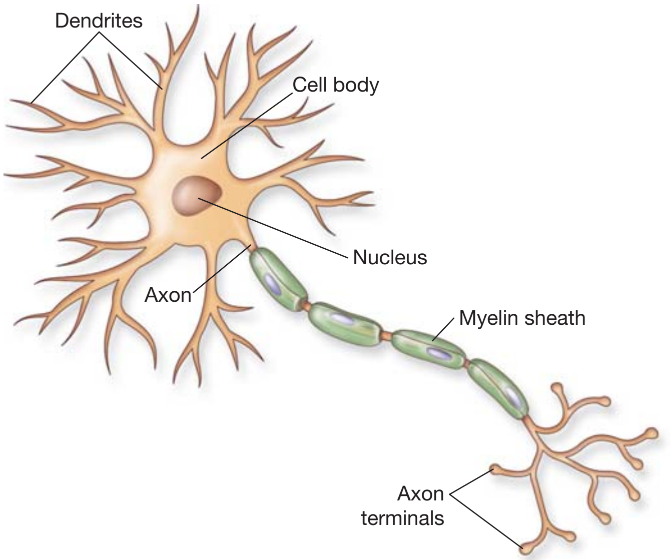

FIGURE 2.23 **The structure of the nerve cell.** Although nerve cell structures vary, most nerve cells have a cell body with a nucleus, dendrites, an axon, and axon terminals. The axon of many nerve cells is covered with a myelin sheath, which speeds transmission of the electrical impulse along the axon.

The speed with which the action potential travels down the axon partly depends on whether the axon is wrapped with **myelin**, a fatty substance that acts somewhat like the rubber insulation that directs electrical conduction along a wire. **Myelination** occurs when the axons are enclosed in a myelin sheath, which speeds the movement of the action potential along the axon. Myelin is produced by **glial cells**, which, generally speaking, serve to support the neurons by providing nutrients, producing myelin, and providing other kinds of structural support. The glial cells' importance and number are often underappreciated. In the human brain, there are roughly 100 times as many glial cells as neurons.

Although electrical signals play a key role in communication between neurons, it is important to remember that the action potential is *not* the same as an electrical current passing through a wire, which can travel at 300 million meters per second. In contrast, the action potential involves a series of electrochemical charges that travel down the axon much more slowly, ranging from 100 meters per second to a relatively sedate 1 meter per second. In development, neurons gradually become myelinated at different times and rates. As we will see shortly, the myelination process is thought to play a significant role in the development of various psychological capacities.

Development of Neurons

The four main processes involved in the development of neurons are proliferation, migration, consolidation, and myelination. *Proliferation* involves the creation of nerve cells and dendritic branches at different times of development. *Migration* refers to the remarkable ways that developing neurons move through brain tissue to their final positions. *Consolidation* refers to reducing the number of connections between neurons as a way of fine-tuning their structure and function. Finally, *myelination* helps speed up the transmission of information along the axonal shaft of a neuron.

Proliferation During the prenatal period, the production of new neurons, or **neurogenesis**, occurs on a massive scale. After the neural tube forms, roughly 250,000 new nerve cells are produced every minute until 100 billion are present. For many years, researchers thought that no new neurons were produced after birth, but postnatal neurogenesis has been documented in several brain areas, including the hippocampus, which is involved in memory and spatial knowledge (Abrous et al., 2005; Gould, 2007; Pujadas et al., 2010; Rakic, 2002; Richardson et al., 2007; Zhao et al., 2008). Although many fewer neurons are produced after birth than during the prenatal period, the neurons generated after birth can become fully integrated into existing circuitry (Zhao et al., 2008). While postnatal neurogenesis has not yet been shown definitively in the human cortex, some positive reports suggest that with better measures it may be demonstrated there as well (Gould, 2007).

Q: Is there growth of new neurons after birth?

Migration and Synaptogenesis New nerve cells develop near the center of the brain and then move through older nerve cells to the outermost layers of the growing neural network, where they will ultimately become parts of various brain structures (see Figure 2.24A). Most of this **migration** is thought to happen either before birth or around the time of birth, but some migration is also thought to occur in adult human brains (Cayre et al., 2009; Ghashghaei et al., 2007). Nerve cells appear to migrate by following the paths laid down by certain **radial glial cells** that serve as guides (Hatten, 1990, 1999; Rakic, 1972, 1981, 1988). Chemical signals in the brain also guide nerve cell migration by providing different "instructions" for different cell groups about where in the brain to go and when to stop (Dodd & Jessell, 1988; Ghashghaei et al., 2007; Tessier-Lavigne & Goodman, 1996; Tessier-Lavigne & Placzek, 1991). Indeed, researchers can predict where axons will grow within tissue clusters based on which tissues are present and which chemicals they emit (Heffner et al., 1990).

After a nerve cell migrates toward the brain's outermost level, its axon starts to grow and interconnect with other neurons. As the axon grows, it finds its way to its appropriate destination, which can be more than a meter away. The end of the growing axon has a **growth cone**, which enables it to push its way through other tissues and track chemical signals that tell it in which directions to move (see Figure 2.24B and C).

When the branching ends of the axon arrive at their destination, they form the bulb-like structures that release neurotransmitters across the synaptic gaps between cells. The neuron also grows thousands of smaller dendritic branches from its cell body. This is where the brain's intricate interconnectedness becomes clear. Each dendritic branch can make synaptic connections with different neurons, so that just a few neurons can make hundreds of thousands of connections in a very small space. Across the entire human brain, the total number of connections is truly massive, somewhere around 10^{15} (that's 1,000 trillion, or a quadrillion!).

Q: What factors influence the direction in which individual neurons grow?

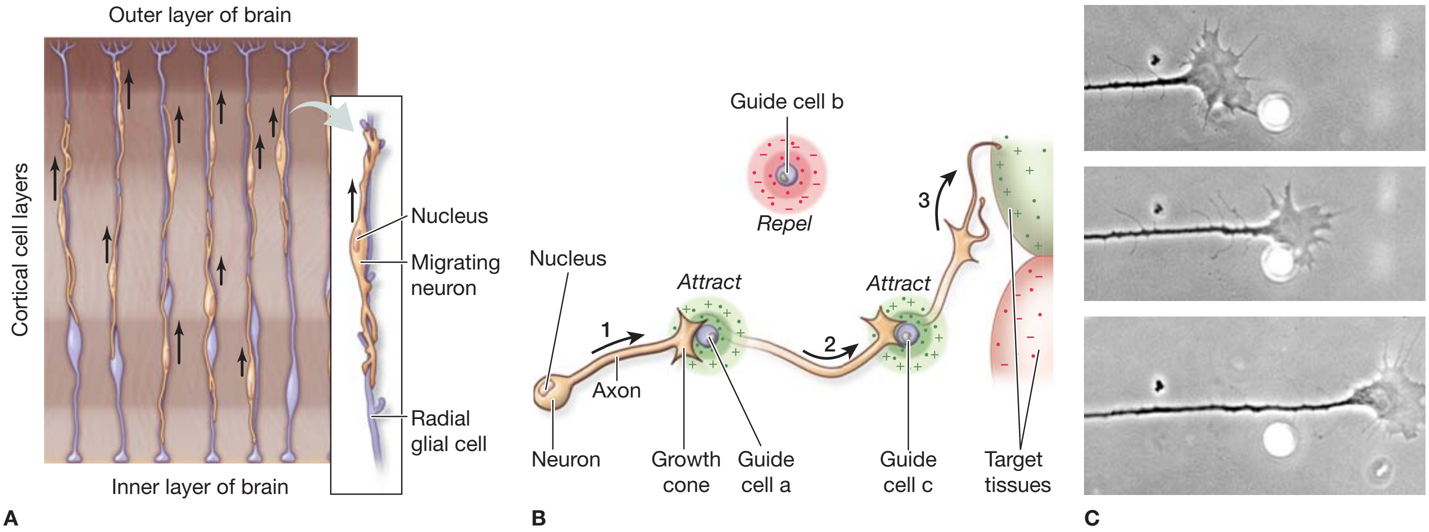

FIGURE 2.24 Nerve cell migration and axonal guidance toward target cells. (A) New nerve cells migrate from the inner layer of the brain through other layers of the cortex toward the outermost layer of the brain, traveling along radial glial cells that act as guides. Adapted from Rakic (1972, 1990). **(B)** Once a nerve cell reaches the outermost layer, it extends its axon by producing growth cones that are guided toward the target cell by chemical signals. These signals, made up of proteins, come from guide cells. Some proteins spur the axon to grow toward them by emitting attractant chemicals (as shown by guide cells a and c); other proteins repel the axon by emitting chemicals that trigger the axon to grow in the other direction (as shown by guide cell b). These signals affect the growing axon, causing the growth cone to twist and turn toward its target. **(C)** This series of three photomicrographs shows the path of a single axon as its growth cone moves toward the circular guide cell, reaches it, and then moves beyond it.

Synaptogenesis, the process of forming new synapses, creates the vast number of connections between neurons; each of our 100 billion neurons is associated with 10,000 synapses. In contrast to neurogenesis, which mostly takes place in the prenatal period, synaptogenesis remains an important process throughout the lifespan. Functionally, synaptogenesis seems to be involved in fine-tuning neural networks during learning. It creates new synapses in the course of certain experiences and eliminates synapses in the course of others (Waites et al., 2005), and it can be quite sensitive to variations in experience and environment (Flavell & Greenberg, 2008). In other mammals, such as rats, just a few days of experience can create new synaptic connections (Ge et al., 2007; He et al., 2010; Waites et al., 2005).

Although newborns do have neurons and synapses, their neurons are simpler in structure and make far fewer interconnections. In addition, around the time of birth, some neurons' growth cones are still seeking their target locations within the brain. Newborns' neurons are also much less myelinated than adult neurons (see Figure 2.25A). In fact, myelination continues well into adulthood in some areas of the brain. Development therefore proceeds both at the cellular level of individual neurons and in terms of their interconnections with other neurons (see Figure 2.25B and C).

Consolidation During development, the number of synaptic connections does not steadily increase. Instead, both prenatally and postnatally, there are periods of considerable pruning, a process that reduces the number of neurons and synaptic connections. Early on in childhood, the human brain has approximately 100 billion (10^{10}) nerve cells and as many as 1,000 trillion (10^{15}) synapses, but through the pruning process, both numbers decrease after childhood. This developmental pattern of an early excess of connections is sometimes called "initial overexuberance."

Neural structures can be pruned through programmed cell death, or **apoptosis**. In apoptosis, cells do not simply die randomly; instead, they die in highly specific patterns that help shape the resulting neural circuits. This type of cell death is first observed at around 24 weeks after conception. Cell death is a natural pattern of development in which neurons are pruned out of a system as a consequence of less use, less environmental stimulation, or less internal stimulation or because a maturational instruction shuts down cell function. When a neuron undergoes apoptosis, it necessarily eliminates all of that cell's synaptic connections. But another, more fine-grained form of **synaptic pruning** is also possible. In this case, the neuron stays alive, but some of its synapses are selectively eliminated. Both forms of pruning seem to be completed by adolescence (Huttenlocher, 1979, 2002). It is not yet clear whether these two forms—apoptosis and synaptic pruning—serve different functions. It seems plausible, though, that apoptosis is associated with larger-scale changes in neural circuits, while synaptic pruning may be more specifically localized and more sensitive to environmental factors.

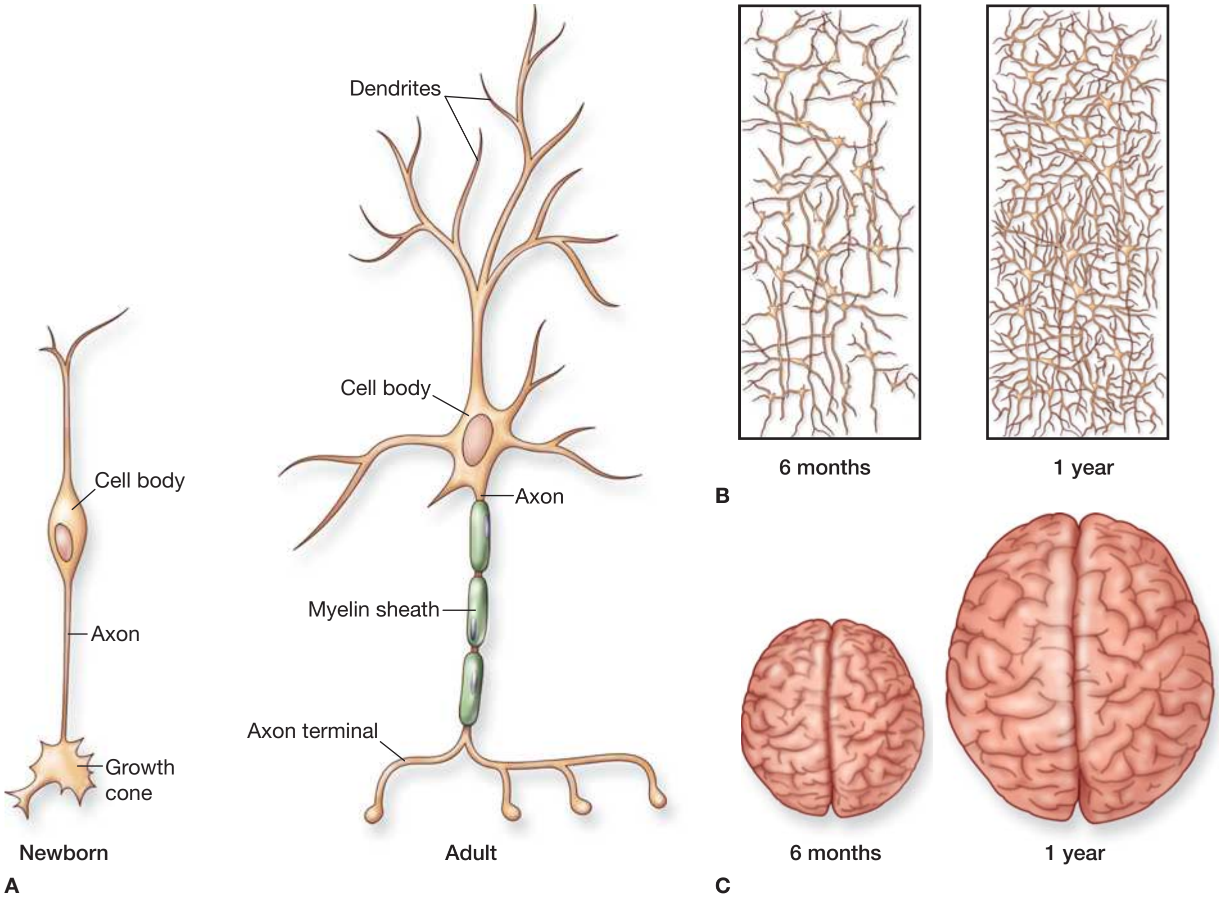

FIGURE 2.25 **Increasing neuronal complexity. (A)** Individual neurons become more complex and increasingly interconnected during the period after birth, as shown in these examples of a newborn and mature neuron in the cerebral cortex. Using growth cones, the newborn neuron is still growing toward target cells, where it will form axon terminals to communicate with other neurons, and it is not yet myelinated. **(B)** Between 6 months of age and 1 year of age, complexity of synaptic connections increases significantly, as does **(C)** the size of the brain. Adapted from Conel & Le (1941, 1967).

Q: How do connections between neurons change after birth?

Both environmental and genetic factors influence the complex processes that govern which cells and synapses get pruned (Blakemore, 2008; Hill et al., 2010; Thomas & Johnson, 2008). One classic study of how vision develops in newborn cats dramatically showed the effects of the environment—and specific experiences—on pruning. When the cats had one of their eyes covered up, and thus deprived of visual input, during the first 2 weeks after birth, the researchers observed striking changes in the cats' brains. The neurons that normally fire only when they receive visual input from both eyes at once actually died off (Wiesel & Hubel, 1963). As a consequence, while the kittens could see well with each eye independently, they lost the ability to mentally fuse the images seen by both eyes, a process that considerably enhances depth perception.

Genetic influences can also cause cells to die or connections to disappear, but the reasons for these kinds of pruning are less clear (Fox et al., 2010; Jacobson et al., 1997; Pettmann & Henderson, 1998). One possible explanation may be that an initial excess of neurons and synapses, which is followed by pruning, simply may be the most efficient growth mechanism early in brain development. As an analogy, consider the way to build a snow sculpture: First you make large balls of snow because it is the easiest and fastest way to get started and perhaps the mass helps link the balls together. Then you carve out the desired form from the large mass. Similarly, it may be especially efficient for the brain to grow large networks of neurons and interconnections as rapidly as possible at first and then to eliminate the excess cells and connections, resulting in a network shaped by both experience and genetic instructions.

Myelination Another remarkable pattern of postnatal neural development is myelination, the process of enclosing axons in the fatty material called myelin, which provides an insulating cover (Yakovlev & Lecours, 1967; see Figure 2.26A). As we have said, the myelin sheath increases the speed at which nerve impulses travel along the axon, making the process up to 100 times faster. Heavily myelinated bundles of axons in the brain are commonly called *white matter*, while the brain tissue that consists of unmyelinated cell bodies and dendrites is called *gray matter*. White matter often forms the connections between clusters of gray matter, where the more intricate circuits exist. The process of myelination begins before birth and continues well into middle age (Bartzokis et al., 2003; Westlye et al., 2009). The earliest structures to be myelinated are the spinal cord and lower brain structures. Myelination then proceeds toward the higher structures of the cortex and from the back of the brain toward the front.

Figure 2.26B shows how different brain regions become myelinated at different ages. Areas that process sensory information tend to be myelinated before birth and shortly thereafter. Areas that direct motor activity start being myelinated shortly before birth, and then myelination of these regions continues through the first year of life. Finally, myelination supporting integration of cortical association areas begins after birth and continues all the way into adulthood. In the cortex, myelination tends to slowly progress forward so that the last steps of myelination occur in the frontal cortex. Some researchers argue that the relatively late myelination of the frontal lobes in the mid-20s helps explain why some adolescents and young adults are especially prone to recklessness and risk taking (Casey et al., 2008; Kelley et al., 2004; Steinberg, 2010).

Experience and Brain Development

As we have seen, the environment influences developmental processes at multiple levels, ranging from its effects on cells and gene regulation to influences on larger bodily systems. Now let's consider environmental influences on the brain in more detail. We have already seen that depriving the brain of visual input from one eye affects the development of vision by causing pruning of nerve cells and synapses designed to receive input from both eyes. Similarly, research suggests that rats that develop in a deprived environment will have fewer and less complex neurons than rats that experience a normal environment (Black & Greenough, 1986).

These examples show that neurons deprived of a specific type of input may die off or show stunted development—but sometimes, they can thrive on a new type of input. **Compensation plasticity** refers to the capacity for an area of the brain that is deprived of its normal inputs and processing routines to become devoted to other functions instead. In some cases, this change results in a heightening of the remaining abilities to help the organism compensate for the loss. Thus, if a child is born deaf, the brain area typically devoted to the processing of auditory information may be repurposed to process visual information. As a result, the child's visual perception may be unusually acute and compensate for the auditory loss (Bavelier & Neville, 2002; Bavelier et al., 2006). In fact, on tasks that require sensitive peripheral vision, adults who were born deaf show distinct advantages over those with normal hearing (Dye et al., 2009). Evidence of compensation plasticity seems especially apparent in the

Sensory areas are myelinated before birth. Myelination of the motor systems also starts before birth and continues past the first year of life. Finally, the integrative systems show little myelination until after birth, and the process continues into adulthood.

brain's association areas (Amedi et al., 2005; Merabet & Pascual-Leone, 2010; Röder et al., 2002).

We have considered the effects of a specific type of deprivation, such as loss of vision, in an otherwise normal environment. What happens at the neural level when a child grows up in a much more problematic environment with massive deprivation of all forms of inputs? Several studies have looked at orphans and abandoned children who grew up in deprived and highly stressful conditions—similar in some respects to conditions that inhibit neurogenesis and synaptogenesis in animals (Chu & Lieberman, 2010; Gunnar, 2001; Gunnar & Quevedo, 2007). A variety of measures suggest that such deprivation can cause changes in brain development. The deprived children showed differences in overall brain size and physiological activity (Nelson, 2007) as well as indications of lesser myelination of the connections between major brain regions (Eluvathingal et al., 2006). Some scholars have suggested that extremely deprived children may experience excessive pruning and have less organized synaptic connections (Nelson, 2007). As noninvasive measures of brain structure improve, it should be possible to document these differences more precisely and to determine whether they are sometimes irreversible.

Since deprivation can cause apoptosis and pruning of synapses, many have wondered whether an enhanced environment could have the opposite effect on brain development. Could engaging stimulation lead to more complex synaptic connections and dendritic branches? Many eager parents have attempted to accelerate their baby's brain development through such environmental "enhancements" as classical music, visually challenging mobiles, and intensive language exposure. In a broad sense, this question remains open, but it cannot be addressed experimentally in humans given the obvious ethical problems of assigning infants to "deprived," "normal," or "enriched" environments.

By posing more focused questions, however, researchers have found some effects of enrichment (Kempermann et al., 1997), many of which result from the learning experiences that take place in an enriched environment. Of course, when an organism learns, the brain changes. If rats are required to learn a new skilled task, that challenging experience will cause them to grow new synapses in the cerebellum (Black et al., 1990). Similarly, when monkeys are taught to use a new tool, their neurons in the brain region involved in grasping and tool use become more interconnected (Hihara et al., 2006).

Aside from growing new synapses, another subtle but important effect of learning is the strengthening or weakening of existing synaptic connections, a process that happens continuously in adult organisms. As we have already begun to see, experience can also affect the number of synapses, the neuronal patterns of connection, and the birth or death of neurons. These kinds of changes demonstrate the brain's **experience-dependent plasticity**, the ability of the brain to be malleable, or "plastic," and physically change as a result of experience (Greenough et al., 1987).

In humans, it is not possible to directly measure experience-dependent changes in the number of dendritic branches or synapses. Indirect measures using neuroimaging suggest that these changes may occur during the process of acquiring and honing a skill. For example, when people learn to juggle, there is an increase in gray matter (where most neural interconnections occur) in the brain region associated with the visual processing of motion (Draganski et al., 2004). Similarly, years of intensive music performance training is associated with increased myelination of the relevant motor neuron pathways (Bengtsson et al., 2005; Hyde et al., 2009). Finally, compared with other adults, veteran taxi drivers have been shown to have enlarged hippocampal regions—areas involved in spatial reasoning and maintaining mental maps (Maguire et al., 2000). Together the findings from human and nonhuman animal studies strongly suggest that the brain restructures itself as a result of focused activity (Dayan & Cohen, 2011; Johansen-Berg, 2007). It remains controversial, however, whether commercial infant enrichment programs are any more beneficial than normal (non-deprived) infant experience.

Puberty and Brain Development

As children enter puberty, their behavior often changes significantly. Even the ancients took note. According to the Greek philosopher Aristotle, "Youth are heated by Nature as drunken men by wine" (Dahl, 2004, p. 8). His observation is borne out by statistics concerning reckless driving, unprotected sex, substance abuse, and a host of other dangerous behaviors carried out by adolescents (Steinberg, 2007). Besides risk taking, adolescents show a variety of behavioral changes, including a surge of interest in sex and romantic relationships, changed sleep patterns, and increased appetite. Several kinds of psychopathology are also much more common among adolescents than among younger children. Many of these changes will be discussed in the book's final chapters. Here we focus on some of the changes in the brain that relate to the upheaval of adolescence.

As mentioned in Chapter 1, puberty is a time of pronounced qualitative biological change. Males develop facial hair and broader shoulders, and females develop breasts and wider hips. Male voices become lower pitched, a phenomenon that led some overzealous medieval choir directors to castrate choirboys shortly before puberty, preserving their ability to hit very high notes (Rosselli, 1988). Given these dramatic bodily changes, it is natural to ask about corresponding changes in the brain—especially since brain signals trigger puberty's hormone surges (Dahl, 2004). Growth hormones increase height and size; adrenal hormones lead to pubic hair, acne, and other changes; still other complexes of hormones cause the sex organs to mature. Brain signals set off these anatomical changes, but what about the brain itself? Do changes in brain structure occur during puberty?

In fact, a number of dramatic changes in the brain occur late in childhood and during the teenage years (see Figure 2.27). Some of the most remarkable, well-documented changes take place in the frontal lobes. This brain region, which is associated with planning, problem solving, and regulating thoughts and emotions, undergoes significant pruning of synaptic connections during adolescence. It shows a 40 percent drop in the total number of synapses from late childhood to adulthood (Andersen, 2003; Huttenlocher, 1979). This decrease is thought to streamline the region's neural circuits to support faster and more efficient performance. At the same time, the amount of white matter in the frontal lobes substantially increases, perhaps supporting better communication and integration between the frontal lobes and other brain regions (Casey et al., 2008; Somerville et al., 2011; Yurgelun-Todd, 2007). In general, the section of the frontal lobes called the prefrontal cortex, which lies below the forehead at the front of the brain, matures the latest. It shows growth into the 20s.

One possible explanation for increased risk taking in adolescence involves interactions between systems in the frontal lobes and another group of brain structures called the limbic system (Somerville & Casey, 2010; Steinberg, 2007). The limbic system is concerned with emotion and memory, among other functions, and it is closely related to a structure called the *striatum*, which is involved in the detection of and response to rewards. For years, adolescents' risk taking was attributed to flaws in their reasoning about risks and consequences. Many experts believed that if adolescents were better informed about the true nature of risks, their behavior would improve. But despite decades of driver's education courses, sexual education courses, and media campaigns about drug abuse, none of these approaches have worked very well in reducing risky behavior. At the same time, other studies have shown that adolescents are just as good as adults at estimating risks when asked to do so in judgment tasks (Steinberg, 2007). Why, then, do they still take more risks?

One clue comes from the finding that among adolescents, risk taking is much more likely in groups. Some researchers suggest that the social nature of this behavior relates to specific changes that take place during puberty in the connections between limbic system structures (the amygdala and nucleus accumbens, which regulate emotions), the striatum (which is concerned with rewards and motivation), and parts of the frontal lobe (the prefrontal cortex, which is concerned with planning and control) (Somerville et al., 2011). One result may be that during adolescence, the emotional arousal system is especially active during social interactions with peers and overrides the control system of the still maturing prefrontal cortex. At the same time, the emotional arousal system seems to undergo neural changes during puberty that make adolescents prone to pursuing greater immediate rewards, even when it means taking bigger risks. One theory suggests that these changes may actually help adolescents to take the risks associated with achieving independence from their parents (Casey et al., 2008). It may also be that the lure of rewards (detected in the striatum) tends to exert much greater influence on teenagers' planning and self-control systems (in the prefrontal cortex) and that only after adolescence do the prefrontal systems develop a stronger influence on regulating the brain's reward systems (see Figure 2.28).

As adolescents mature, the emotional arousal system becomes more regulated and less likely to overwhelm the brain's planning and self-control systems in the frontal and parietal lobes. The increasing myelination of these frontal and parietal regions may allow them to communicate more effectively with the emotional arousal and reward areas. At the same time, the pruning of neuronal

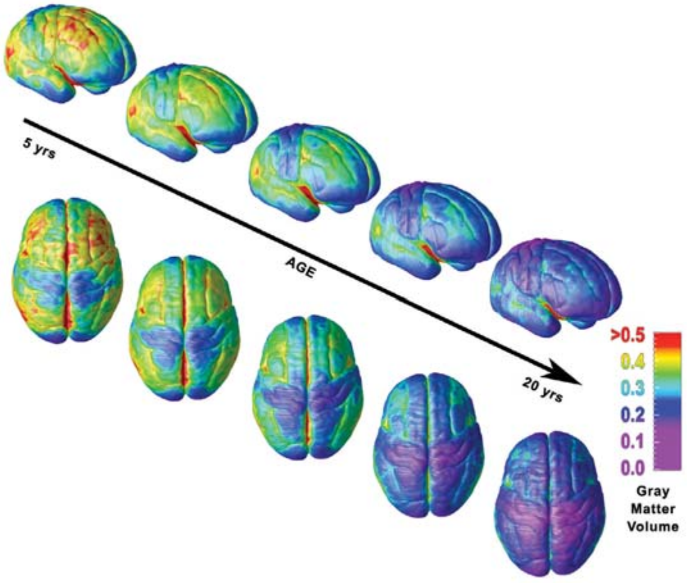

FIGURE 2.27 Changes in gray matter from early childhood through puberty and young adulthood. This set of computer images of right lateral and top views of the brain shows the changes in the distribution of gray matter in the cortex between ages 5 and 20. Red areas indicate high gray matter volume, whereas blue and purple areas indicate striking gray matter loss. Gray matter volume increases in areas associated with sensory and motor functions at earlier ages, but it decreases in these areas as the child grows older. Loss of gray matter volume in areas associated with integrating information and planning begins in late childhood and accelerates during adolescence. The loss of gray matter volume during adolescence may reflect a form of synaptic pruning. From Gogtay et al. (2004).

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Repairing Brain Damage Later in Life?

Many of us know someone who has suffered the effects of brain damage as an adult. The damage can range from a shrapnel wound that impairs speech, a stroke that hampers vision, or the more widespread neuronal death that causes the motor problems involved in Parkinson's disease. For many years, research suggested that humans couldn't develop new nerve cells after birth, so these conditions were considered incurable. In the last decade or so, however, considerable evidence has shown that even adult brains sometimes generate new nerve cells (Arvidsson et al., 2002; Bjorklund & Lindvall, 2000; Muir, 2010). It appears that the different types of myelin cells that ensheathe many axons play a critical role in either inhibiting or promoting regrowth of nerve cells, depending on the type of myelin involved. In rats, the myelin cells that normally ensheathe the optic nerve inhibit nerve cell regrowth. But in one study, researchers cut the optic nerves of adult rats and then ensheathed the severed optic nerve cells with myelin cells transplanted from the olfactory bulb, because they were thought to promote nerve regrowth (Li et al., 2003; Raisman & Li, 2007). Indeed, the transplanted myelin cells promoted the growth of new cells in the severed optic nerves. Researchers have not yet managed to bring about enough nerve regrowth to restore the rats' vision, but that eventual outcome seems likely. In similar experiments aimed at regrowing motor neurons that have been cut, researchers are making progress restoring the cut nerves' functionality.

Myelin appears to affect nerve regrowth in interesting ways. In the central nervous system, the glial cells that produce myelin also produce three distinct proteins that become embedded in myelin and then directly inhibit nerve growth. These growth-inhibiting proteins may help set normal limits on healthy nerves' growth—but they also block regeneration when nerves are damaged (Woolf & Bloechlinger, 2002). Changing the material that ensheathes nerve cells by transplanting glial cells from olfactory nerves that have growth-promoting proteins could become a valuable method of repairing nerve damage in adults. Researchers are actively trying to understand how and why some glial cells promote nerve cell regeneration and others block it (Muir, 2010).

An especially effective way to repair nerve cell damage would be to have a population of cells in the adult brain that could differentiate into particular kinds of neurons. They could then take over functions that were disrupted by the death of other nerve cells. Such cells are known as adult **stem cells**. It was previously thought that the adult brain did not contain stem cells and that the only means of nerve regeneration was to regrow parts of existing neurons. Recently, however, it has become clear that the brain does have adult stem cells capable of becoming new, functional nerve cells, especially when they are surrounded by an appropriate scaffold of cells that doesn't inhibit nerve growth (Ma et al., 2009; Teixeira et al., 2007; Teng et al., 2002).

Moreover, some investigators have suggested that the brain's stem cells are part of an inherent developmental program that allows the brain to adapt to injury (Imitola et al., 2004). This capacity seems to diminish with age, however, which is why children tend to recover from brain damage more easily than adults do (Sun & He, 2010). Nonetheless, adults with brain damage can experience some recovery and neural adaptation, and adult stem cells may be part of this process.

Along similar lines, animal research into many neurodegenerative diseases, including Parkinson's disease, Lou Gehrig's disease (amyotrophic lateral sclerosis, or ALS), and multiple sclerosis (Rice et al., 2003; Silani & Corbo, 2004; Singec et al., 2007), has demonstrated that neural stem cells can repair brain damage and sometimes restore function (Akerud et al., 2001; Arenas, 2010; Isacson et al., 2003; Redmond, 2002). Of course, many questions about these processes remain unanswered, and adapting these treatments for use in humans poses significant risks. Even so, the possibility that neural stem cells could be used to repair brain damage that was long considered irreversible has generated enormous interest. In this case, a deeper understanding of developmental processes is yielding valuable progress on addressing problems in adults.

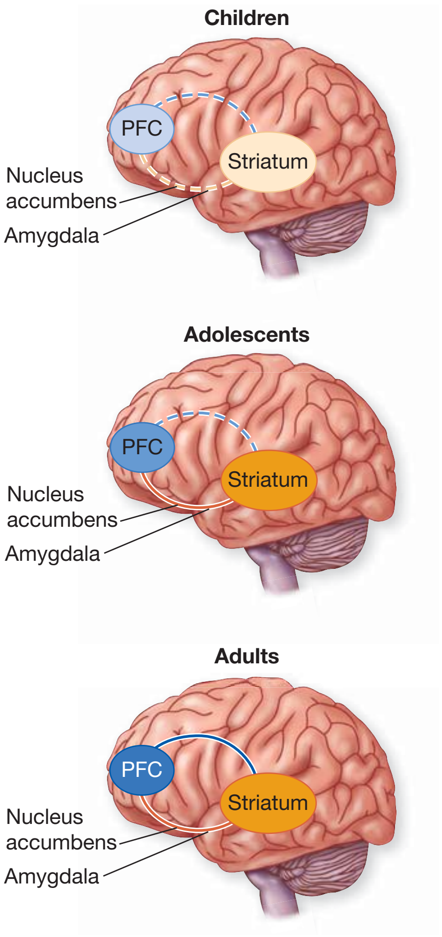

FIGURE 2.28 Changes in reward and control circuits. One key change in adolescence may concern the extent to which the prefrontal cortex (PFC) feeds back on the circuits related to rewards (the striatum). In children, reward circuits from the striatum and control circuits from the PFC are both immature (as shown by the light-colored structures and dashed circuit lines). In adolescents, there is increased sensitivity to reward cues from the striatum (shown by the darker structure and the solid line for the circuit), which overrides control circuits from the PFC, which has not yet fully matured. In adults, both structures and circuits are mature, and the PFC is better able to control the striatum. Adapted from Somerville & Casey (2010).

connections in all of these areas may allow more precise regulation of emotions (Steinberg, 2007). Thus, changes at the neural level may result in better integration of the cognitive control system, reward system, and emotional arousal system.

Q: What are some patterns of brain change that seem to occur in childhood, puberty, and young adulthood?

Behavioral Genetics

The influence of genes on emerging neural structures and subsequent behaviors is a major theme of this chapter. Much of the research beginning to explain these genetic influences has been conducted in the past decade, and research relating gene expression to changes in the brain and behavior promises to remain one of the most active areas of neuroscience. But a line of work with a much longer history, known as **behavioral genetics**, examines how differences in behavior relate to genetic differences between individuals or populations. Because this kind of research predated our fairly detailed biochemical understanding of DNA, behavioral geneticists have historically used statistical techniques to infer the degree to which individuals are related genetically—that is, the proportion of their genes that are the same. Researchers can then compare and correlate this level of genetic similarity with variations in behavior.

One of the most common research techniques in behavioral genetics involves studying monozygotic (MZ) and dizygotic (DZ) twins. Studying twins allows researchers to keep either the participants' genes (in the case of MZ twins) or their environment (twins raised together) relatively constant across experimental conditions. Because monozygotic twins have nearly identical genetic material, many researchers have studied MZ twins who were raised apart in attempts to examine the effects of experiences or environment while holding genes as constant as possible. Dizygotic twins, on the other hand, are only as genetically similar as any two siblings. Researchers have often studied DZ twins raised in the same household as a way to minimize environmental differences in the children's experiences while examining the effects of their genetic differences.

Heritability

Behavioral geneticists often talk about the **heritability** of a trait as a way of describing the extent to which variations in that trait, within a particular population, are due to genetic differences rather than environmental differences. If, in a particular group, all of the individual variations in a given trait were due to differences in individuals' genes, that trait would have a heritability of 1 for that population and environment. Likewise, if all individual differences in a trait were due to environmental variations, the trait would have a heritability of 0. Of course, genetic and environmental influences constantly interact, so no trait has perfect heritability. But the closer a trait's heritability comes to 1, the more that trait's variations—*within the group and environment in question*—are caused by genetic influences.

When heritability measures are applied to behavior, they are used to describe the degree to which behavioral differences among individuals in a population, such as variations in the traits of shyness or excitability, are due to those individuals' genetic differences. As an example of a trait with low heritability, consider the particular language that individuals speak. Our native tongue is solely a consequence of the language (or languages) we are exposed to while growing up, not the genes inherited from our biological parents. On the other hand, a trait with a very high heritability in most environments is height, which runs strongly in biological families. Still, it is critical to remember that heritability measures pertain only to populations, not to individuals. A heritability of .9 for height does not indicate that 90 percent of a specific person's height is caused by his or her genes. Rather, it means that across the whole population being measured, the differences in height are 90 percent attributable to genetic variations between that population's members. A single person's height reflects a complex interaction between his genotype and many environmental factors, including diet, exercise, and even stress. It doesn't make sense to try to describe "how much" of a single person's height is attributable to genes. A heritability measure is meaningful only in describing a population.

Heritabilities depend not only on the range of genotypes in a population but also on the environment in which a population is studied. In certain environments, heritabilities can be greatly reduced. For example, some forms of diabetes have substantial heritabilities, but if a population tends toward a diet that minimizes sugars and carbohydrates, it is likely that fewer people in that population will become diabetic. Thus, in that population, the heritability for the disease would be correspondingly lower, reflecting a stronger environmental influence.

The environment's influence on heritabilities has significant consequences when it comes to interpreting or comparing these measures. Even when the heritability of a trait is high for two separate populations, each in its own environment, it's important not to assume that *differences between the two populations* are also due to genetic influences. Suppose, for example, that height is highly heritable in two groups of children, one in suburban New York and another in a famine-stricken area of the Sudan. Even if height has a heritability of .9 in both groups, this does not mean that differences in height between the two populations are largely genetic. The Sudanese group would likely be shorter than the New Yorkers on average for reasons having nothing to do with genetics. Instead, malnutrition due to famine would likely decrease heights in the entire Sudanese population—even though, as a heritability of .9 tells us—differences in height *within that group* mostly could be explained by its members' genetic differences.

This point is often overlooked and can lead to false and inflammatory claims about the genetic bases for differences among groups. As we will see in several later chapters, the behavioral genetics approach has helped researchers understand the relative contributions of genetic and environmental factors to a wide range of traits, although complex gene-environment interactions can often make interpretations difficult.

Behavioral Genomics

Behavioral genetics still has a role in helping us understand individual differences (Plomin et al., 2000). But the field is rapidly changing in light of new knowledge about various species' genomes and increasingly sophisticated ways of measuring differences in phenotype (Haworth & Plomin, 2010; Kendler & Greenspan, 2006; Plomin & McGuffin, 2003; Toga & Thompson, 2005; Visscher et al., 2008). This new perspective is sometimes called **behavioral genomics** to emphasize the role of understanding a species' genome and its effects at the molecular level.

One way to understand this change in methodology is to see the shift that has occurred historically, starting with the early approach to human differences (Galton, 1883), when researchers could only compare the behaviors they saw with the levels of genetic variation they inferred by comparing twins, siblings, and other individuals. In the 1960s, this approach to research had shifted only modestly. Researchers knew that differences in DNA were responsible for all variances in genotype, but they did not understand how the DNA molecule gave rise to particular physical features, let alone its mechanisms for affecting behaviors. Over the next few decades, researchers began to understand how genes direct the production of proteins and how multiple genes can interact. Finally, in the last 10 years or so, an extraordinary surge of technology has made it possible to construct *gene expression profiles* in which a gene's expression (whether it is turned on or off) can be measured in thousands of tissue samples at various times and under different conditions. In addition, researchers can investigate how one gene's expression influences other genes. It is now also possible to study how changes in gene regulation affect the proteins that cells make.

Taken together, these molecular approaches have begun to suggest mechanisms for linking genetic variation to behaviors (Plomin & McGuffin, 2003). For example, when a certain gene is expressed, or "turned on," it may direct cells to create a protein that causes another gene to be expressed at several locations in the brain. That second gene may then direct the assembly of proteins that form receptors for neurotransmitters. Some of the neural circuits that influence human emotions may work in this way. Thus, regulatory interactions between several genes may make the receptors for certain neurotransmitters more sensitive, resulting in better emotional regulation. On the other hand, if some alleles of the initial gene don't fully "turn on" the cascade of regulatory interactions, individuals with those alleles may find it harder to regulate their emotions under stress (Schloesser et al., 2008). Environmental factors can also affect these complex processes of gene regulation. High levels of stress during development may change the activity levels of the genes that trigger whole sets of genetic interactions. The stress-induced changes could result in different patterns of synaptic connections within emotion-related brain areas (Champagne, 2010; Isles & Wilkinson, 2008; Schloesser et al., 2008).

Figure 2.29 illustrates a simplified model of how such networked effects might work. As this figure clearly shows, the effects of genes on behavior are quite indirect. They involve changes in cell membranes, nerve growth, neural circuits, large-scale physiological systems, and interactions among all of these. Moreover, the behaviors themselves can "feed back" on these systems and affect neural processes and structures. A particular genetic change does not "cause" a behavior as much as it is part of a rich network of causal interactions involving events within the organism and in its external environment.

As researchers develop more sophisticated ways of understanding the effects of gene variation at the cellular level, they are also developing more powerful ways to study how those variations give rise to different features and traits (Visscher et al., 2008). One new method combines the older twin study approach with neuroimaging that allows researchers to measure the size of specific brain regions. Researchers measure corresponding structures in both twins' brains and compare the similarities in the structures' size with the proportion of genes the twins share. The researchers can then calculate heritabilities of different brain regions' sizes by looking at patterns of variation across a large sample of twins (Peper et al., 2007; Toga & Thompson, 2005). Of particular interest is the gray matter in the cerebral cortex, where much of the most sophisticated processing of information is thought to occur. As Figure 2.30 shows, some brain regions, such as frontal areas of the cortex, seem to have much higher heritabilities for gray matter than posterior regions. This, in turn, suggests that cognitive functions associated with the frontal cortex, such as decision making and regulating conflicting thoughts, might also have high heritabilities. Comparable studies have also shown high heritabilities for some regions of white matter, suggesting that the degree of connectivity between certain brain regions may also be heavily influenced by genes.

In behavioral genetics, many genes are highly **pleiotropic**, meaning that one gene affects many traits. One way that genes can have these pleiotropic effects is through the kind of regulatory cascades discussed earlier, in which one gene affects the activities of many others. Another way for a gene to affect multiple traits is in the way it is expressed differently within various tissues because of interactions with other tissue-specific genes. The opposite of pleiotropy (one gene affecting many traits) is evident when a single trait is **polygenic**, or affected by multiple genes. When different genes exert an overlapping influence in shaping a particular trait, that trait is considered polygenic. Both types of genetic influence are common in discussions of behavior, and they are also closely related. If a gene affects many different traits rather than just one, it is more likely that this pleiotropic gene's influences will "overlap" with the influences of other genes. For example, the same "generalist genes" may affect several different cognitive abilities (Kovas & Plomin, 2006).

A pleiotropic gene can affect several traits through quite different mechanisms. Figure 2.31 shows three possible mechanisms for how a gene might influence three separate cognitive functions. In the simplest case, the gene influences one brain region and consequently (in this simplified version) one cognitive function, such as improving an aspect of memory. Changes in that cognitive function would, in

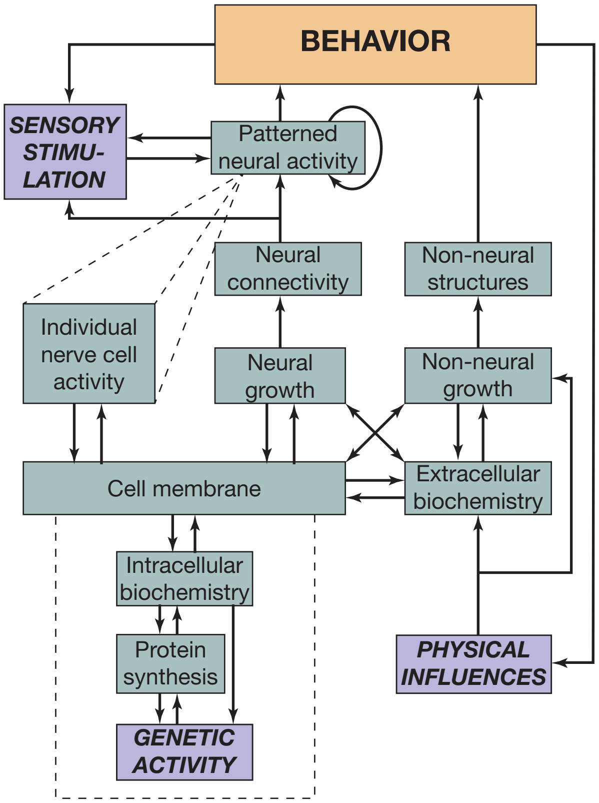

FIGURE 2.29 **A model of gene effects.** The new behavioral genetics, or "behavioral genomics," is not limited to inferring the differences between genotypes based on familial relatedness. Instead, researchers study the effects of gene expression both within cells and across cells. This diagram shows one model of how genes' actions can be linked to brain activity and how experiences can also influence brain and gene activity. From Johnson & Edwards (2002).

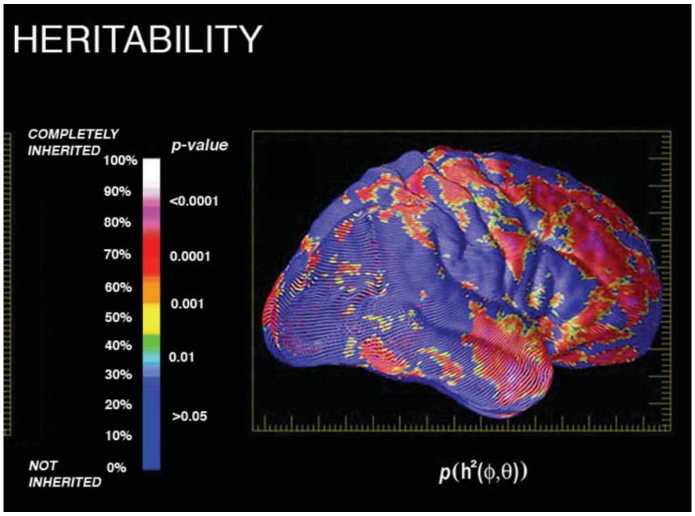

FIGURE 2.30 Heritabilities of gray matter. As neuroscientists develop more precise ways of studying the brain, they can ask how individuals' differences in gray matter relate to their genetic differences. As this computer-generated image shows, the proportion of gray matter in the frontal cortex (shown on the right) has a much higher heritability (indicated by pink and red shading) than the proportion of gray matter in posterior regions (shown on the left and indicated in blue). From Toga & Thompson (2005).

turn, influence related functions, such as attention and reasoning: with better memory, the outputs of attention and reasoning systems could be held in mind longer. In the most complex cases, a pleiotropic gene affects *several* different brain regions, and these regions also interact with each other. Most researchers who examine relations between genes and behavior think that the most complex case is also the most common (Visscher et al., 2008).

In short, researchers are working "bottom-up," starting from the molecular level, and "top-down," starting from the behavioral level, to go beyond correlating genotypic variations directly with behavioral variations. Their goal is to eventually explain all the specific interactions between genes and behaviors and the results of those interactions. Rather than simply asking which genes are "responsible for" particular behaviors, researchers are exploring the richly interconnected system of relationships between genes, proteins, various neural structures, and many facets of cognition, perception, and emotion—as well as their interactions with a wide range of environmental factors, from diet to visual stimulation.

Conclusions

Developmental biology is one of the most exciting and rapidly changing areas of research in the life sciences. Genetic mechanisms and anatomical structures are being more closely linked than ever before. While a great deal of work remains to be done, researchers have already uncovered patterns in the way structure and function develop. These patterns of change are informative at one level as the necessary underpinnings for behavioral and psychological changes. At another level, they illustrate how developmental systems emerge while simultaneously, and continuously, solving problems of growth and form.

Perhaps the fundamental principle of the biology of development is that the most basic functions for survival tend to mature first. Initially, this means that the growing embryo must be able to receive nourishment and eliminate waste. Before long, though, the emerging organism needs more structure and function to survive, including a basic circulatory system and early segmentation of the body into compartments, which promotes further cellular differentiation. More broadly, the different tissues must be able to communicate so that cell migration, specialization, and other patterns of change can proceed. As we have seen, these lines of communication are set up by chemical changes triggered by the cells themselves.

The clearest pattern in biological development is the hierarchical nature of cell differentiation by which cells that are initially similar can become different kinds of specialized cells at later stages. The pattern is clearly sequential; cells pass through stages that are mostly, but perhaps not strictly, irreversible. Very early in the blastula stage, cells show considerable flexibility in terms of their function; when certain cell groups are moved at an early stage, the organism can adjust to continue normal development. Thus, a cell's final fate is not prespecified in its first few steps of differentiation. Instead, specializations emerge later, as a function of the cell's surrounding anatomical and physiological context.

These patterns in biological development suggest some similar principles for how psychological processes develop and differentiate. As you will see in later chapters, simpler emotions, such as joy, fear, anxiety, and anger, are thought to provide a necessary context for the development of more complex emotions, such as guilt and pride. Similarly, some argue that a child's early emerging understanding of her physical and social worlds influences the way she later comes to understand the biological world.

As researchers seek to understand the origins of psychological systems, they must confront questions about the different kinds of influences that shape those systems. The powerful influences of "nature" and "nurture" have been discussed for millennia, and in the past few decades, the "either/or" arguments about them have given way to an account of their interactions. Genes are one component of interrelated biological processes that are also subject to environmental influences at many levels. The local environment of a particular cell in the body, for example, might activate a

gene in that cell, causing it to produce a new protein. When the new protein becomes part of the cellular environment, it can cause chemical changes that subsequently turn other genes on or off. In this manner, one gene can interact with many others. A more global environmental factor, such as a toxin in drinking water, might also affect gene activities, often causing harm. Likewise, a deprived environment or one that is especially stimulating may affect brain growth through gene regulation pathways.

In all of these interactions, timing—as they say in vaudeville—is everything. We have seen how timing influences many patterns of development. During the blastula stage, even the timing of an individual cell's migration through the primitive streak influences its differentiation and development. During embryonic development, the length of a critical period can determine whether a neck like a giraffe's or a neck like an antelope's will result. Likewise, the effects of a teratogen depend on when it is introduced into the prenatal environment.

Sequencing, which is intimately related to timing, also exerts its own powerful influences. If, for example, the sequence of development of the basic body plan specified by homeobox genes is disrupted, we can see a proliferation of incoherent structures in the first most anterior compartment. The sequence of development is also crucial when particular structures, such as the neural plate, must serve as the foundation or the scaffold for later-developing structures. The earlier structures guide growth of what comes later and even influence patterns of cell specialization.

STUDY AND REVIEW

SUMMARY

The Basis of Development

- All living organisms go through systematic changes in anatomical and physiological systems across the course of development from conception to maturity. In recent years, major advances have been made in understanding the mechanisms that underlie these changes and how there are biological underpinnings of psychological development.
- Biological and psychological development both are characterized by common patterns, including critical periods and the tendency for vital systems to develop earlier than systems that are less important for survival.
- The inputs to the biological system are the genes, which contain the inherited instructions in the form of DNA for producing proteins and regulating expression of other genes, and the environment, which influences gene expression. The genotype is the full set of genes of an organism, while the phenotype is the expression of anatomical structures, biochemical processes, traits, and behaviors. Genes and environment constantly interact in complex ways to produce the phenotype.
- DNA is stored in the organism's chromosomes, which are found in the cell nucleus. In humans, chromosomes normally occur in pairs, with each parent contributing one chromosome containing gene variants known as alleles. If the offspring inherits the same allele from both parents, the child is homozygous for the gene; if the offspring inherits different alleles from the two parents, the child is heterozygous for the gene. A dominant allele is expressed when both alleles are dominant or when the other allele is recessive; the recessive allele is only expressed when both alleles are recessive.
- There are three constraints on development: the continuous need for viability of the developing organism, the differentiation of cell types and anatomical structures as development progresses, and the timing of when genes are switched on or off to produce developing cells and structures in particular sequences.

The Beginnings of Development

- The first stages of development are quite similar across most sexually reproducing organisms and involve formation of specialized cells called gametes for reproduction by meiosis, followed by fertilization of the female egg by the male sperm to produce the zygote.
- Once fertilized, the zygote makes a series of splits by mitosis. The first cell divisions initially produce what looks like an ever more fine-grained bumpy sphere. At a critical point, however—about 4 days in humans—the apparent spherical symmetry disappears as parts of the sphere fold in on itself, becoming the morula, and then, at day 5, becoming the blastocyst, which has an outer and inner ring of cells.
- Through a process called gastrulation, cells and cell clusters form three distinct layers—the ectoderm, the mesoderm, and the endoderm—that ultimately lead to formation of inner organs and structures, including the brain and skeleton.
- Cells that are initially undifferentiated become ever more specialized as sets of genes are turned on and off as a function of the local environment of surrounding cells.

Anatomical Development

- The embryonic period is from 2½ weeks to the end of 8 weeks after conception; the fetal period is from 9 weeks after conception until birth. From about 4 weeks after conception, the human embryo has features, such as a head and limb buds, which begin to visually resemble their adult counterparts.
- Initial brain formation is called neurulation and is completed in the fourth week after conception. There is a very early bias toward development in the head; embryonic development follows a head-to-toe progression known as cephalocaudal development.
- When babies are born 3 or more weeks early, they are known as preterm (or premature) infants, and they may be at increased risk for medical or psychological problems. The likelihood of preterm birth can be increased by infection in either the mother or the fetus or by smoking, drinking, or drug abuse by the mother.
- During the prenatal period, it is tempting to see development as obeying the principle of ontogeny recapitulating phylogeny. A closer examination, however, reveals the fallacies in this argument and shows that it is better understood as the idea that functionally important systems tend to emerge earlier both in development and in the evolutionary history of organisms.
- At a very broad level concerned with the order in which large body segments develop, there is a strikingly universal genetic code made up of clusters of genes known as homeobox genes (*Hox* genes in vertebrates) and shared by a wide variety of species. Within this framework, however, cascades of regulatory genes determine when genes are switched on or off, which provides for the enormous variations seen within and, most importantly, across species.
- Sexual differentiation is controlled by the X and Y chromosomes and by exposure to sex-specific combinations of hor-

mones. Higher concentrations of testosterone in male fetuses and higher concentrations of estrogen in female fetuses result in different genital structures in males and females and sex-specific traits and brain differences.

- The order in which body segments develop helps explain why hazardous compounds cause highly specific effects at certain times in development. When a particular segment is in its most active period of formation, internal or external hazardous environmental factors known as teratogens are most influential. Another body segment, usually farther away from the head, might not be as vulnerable until several weeks or months later.

Brain Development

- Brain development is dramatic during the prenatal period, when brain structures most essential for an organism's survival appear earlier than other brain structures and when later-developing brain structures inhibit earlier-developing brain structures. Extensive change occurs both in anatomical terms and in terms of patterns of cell growth.
- Brain cell growth includes not only the production of new nerve cells (neurogenesis), but also the tremendous elaboration of connections, wherein new synapses are formed between neurons (synaptogenesis). In addition, later pruning of connections, or synaptic pruning, and forms of programmed cell death, or apoptosis, seem to be used to sculpt efficient neural pathways in response to patterns of experience and neural firing. Myelination, the enclosing of axons with myelin, speeds the conduction of the nerve impulse.
- New nerve cells develop near the center of the brain and migrate to outer layers of the brain. Individual neurons "find their way" to remote locations in the brain using chemical gradients that guide them to their targets. When the growing neuron reaches its destination, chemical gradients trigger the growth cone at the end of the axon to interconnect with other neurons.
- Brain structure changes considerably after birth, primarily from the formation of new neuronal connections rather than from the production of new neurons. Moreover, neurons deprived of specific input may die off, but compensation plasticity may lead a brain deprived of normal inputs and processing routines to form new connections and become devoted to other functions instead.
- Puberty is a period distinguished by changes not just in the anatomy and physiology of the body as a whole, but also in the brain in particular. Neural circuits involving emotions, reward systems, and cognitive control become interconnected in ways that shift the degree to which adolescents and young adults engage in a range of behaviors, such as taking risks.

Behavioral Genetics

- A classic technique for studying links between genes and behavior, behavioral genetics typically uses twins with different degrees of genetic relatedness (MZ and DZ twins) and asks about the extent to which variations in phenotype are related to variations in genotype.
- The more recent field of behavioral genomics examines variations in individuals' genomes and the ways that those variations relate to gene interaction and protein synthesis, physiology, neuroanatomy, and ultimately behavior.

THOUGHT QUESTIONS

1. What constitutes an enriched environment? We have seen that severely impoverished environments, such as those caused by sensory deprivation or extreme stress, can psychologically affect a developing infant or child and even influence brain development. Some have argued that the reverse might also be true: that extremely enriched environments might accelerate and enhance brain development. If you wanted to test this possibility, what would the maximally enriched environment look like, and why?
2. Although the nineteenth-century notion that "ontogeny recapitulates phylogeny" is no longer accepted, what kernel of truth to this idea still has value today?
3. Should parents be allowed to "design" their babies? As researchers are increasingly able to link specific human genes to developmental outcomes, it may soon become possible for parents to specify, in cases of in vitro fertilization, which sperm should be allowed to fertilize which egg. How much control should parents have over specifying the kind of baby they want?

Conclusions

Summary

On the northwest coast of India, outside the city of Ahmadabad, there is a small village. Many of its inhabitants live in extreme poverty with minimal access to health care. In one family that lived together in a 10-by-12-foot room, a baby girl was born with dense cataracts in the lenses of both eyes, which prevented her from seeing patterns of light; instead, she could see only the kind of diffuse light and shadowy forms that might be visible through a dirty, frosted windowpane. From her birth in 1972 until the age of 12, she lived as a blind person who could tell only general differences in dark and light. She needed a guide to help her walk about or to identify objects. When she was 12, her parents received a government subsidy that allowed doctors to remove the cataracts and provide her with glasses, which allowed her eyes to receive patterned light for the first time.

The critical question was whether, at age 12, she would still be able to learn to see. Would she come to recognize faces, places, and objects that she had never experienced visually? Could she use vision to find her way around in the world? For vision, is there a critical period in which certain kinds of experiences are necessary for normal visual development? Some 20 years after her surgery, researchers visited the woman and addressed these questions in great detail (Ostrovsky et al., 2006; see Figure 3.1).

The researchers discovered that it is possible to be able to learn to see surprisingly normally, even after spending the first 12 years of life essentially blind. The woman now used her vision to recognize faces and facial expressions, and she perceived depth well enough to judge objects' locations. Although her ability to see fine details seemed permanently degraded and she made more face recognition errors than normal viewers would, the consensus was that she had made a striking recovery. Moreover, she seemed to have acquired these perceptual skills gradually, learning ways of seeing shapes and patterns.

FIGURE 3.1 Restored vision and ability to see. The 32-year-old woman seated at the computer is being tested for her visual skills by researchers who are studying whether there is a critical period to learn to see. The woman was born with severe cataracts that prevented her from seeing more than light and dark as a child. After she had an operation to remove her cataracts at age 12, she was able to acquire the perceptual visual skills that enabled her to recognize shapes and faces and to judge depth, although she did have some subtle deficits in facial processing.

Her experience raises some central questions about perceptual development. How does the newborn perceive the world, and how do perceptual capacities change in the first years of life? How much of perceptual development is based on learning from experience, and how much depends on the biological maturation of perceptual systems? Does vision or any other sense have a critical period, such that certain kinds of perceptual experiences must happen during a particular time frame for the perceptual ability to mature normally? How does information from different modalities, such as vision and hearing, interact in the course of development? These questions, along with others raised later in this chapter, frame the study of perceptual development.

Recall the newborn that we discussed at the beginning of Chapter 1. Remember the perceptual challenges that he was faced with during his first week of life—blinking lights, loud noises, people looming over him. Remember his apparent helplessness when he was assailed by sounds and sights as he was moved from the hospital nursery, put into a car, and driven home by his parents. Yet, despite their seeming helplessness, newborns actually come prepared to recognize some visual patterns and voices and tastes. In this chapter, we will see that infants are not like formless clay, waiting to let experience leave its mark on them. Nor are they fully mature perceptual creatures. A great deal of perceptual development and learning occur in the first year of life. The mechanisms of developmental change often involve **feedback loops** between the infant and the environment, in which an experience causes a change in the infant's state, which in turn influences how the infant's next experiences are processed. For example, early experience with visual patterns helps foster growth of areas of the visual cortex that support pattern perception. Growth in the cortex supports higher-resolution pattern perception, which in turn causes further development in the visual cortex. This constant interplay between organism and environment is an essential theme throughout this book.

In addition, we will see that a fundamental developmental challenge is to be able to categorize different stimuli into groups, whether it is a color category, such as *red*, or an object category, such as *dogs*. That essential ability to categorize makes perception and cognition more efficient by allowing us to apply some of what we learn to whole categories of things, rather than having to learn about each instance separately. In this chapter, we will see that several kinds of categorization play fundamental roles in perceptual development.

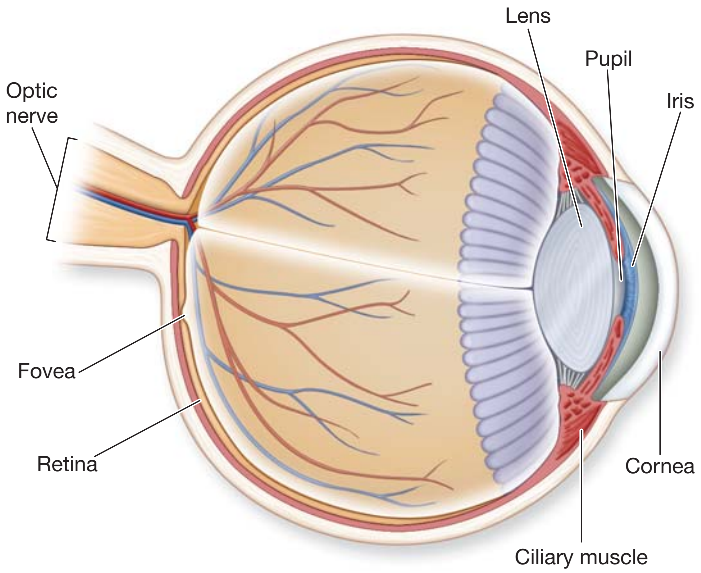

FIGURE 3.2 Innate specializations in the eye. More than 300 years ago, it was obvious that the eye contained specializations at birth for the kind of information (light) that it processed. Long before the invention of the camera, people were aware that the eye was "designed" to project images of light on the retina in such a manner that it could be "read" by the mind within. Such specializations included a lens and cornea to focus the light, an iris to control the amount of light, a ciliary muscle to adjust the focal length of the lens, a retina for receiving the focused light, a fovea for processing the most important information, and an optic nerve for transmitting information to the brain. All these specializations were clearly present at birth and were tailored for information in light, as opposed to sounds or smells.

We begin our discussion of perceptual development with vision, often thought to be the most complex perceptual system in development. Vision also nicely illustrates the contrast between sensation and perception. Sensation involves registering sensory information as it is initially taken in—for example, by the retina of the eye, the hair cells of the auditory system, or the taste buds of the tongue. Perception involves interpreting sensory input, such as understanding that certain shapes and contours make up a face, knowing that one object appears farther away than another, or recognizing particular sound patterns as a voice. We will examine such topics as the sharpness of vision, color vision, depth perception, and face perception.

From vision we move on to hearing, asking how infants notice and locate sounds and how they pick up on more complex patterns, such as those of speech. We then consider the chemical senses of taste and smell, asking whether newborns seem to distinguish different tastes using the same categories that adults do and whether smells help them respond more effectively to the world. Finally, we consider how infants integrate information across these different avenues of perception—for example, how a baby links his sister's voice with her face. In all these explorations, we will return to the questions raised earlier about the blind girl whose sight was restored and the newborn arriving home.

Vision

Thinkers in several fields have long been interested in our understanding of the visual world and how it develops from infancy. In fact, seventeenth-century scholars already had a fairly detailed understanding of the anatomy of the visual system. They knew that from birth, the human visual system consists of two eyes, each with a cornea, a lens, an iris, a retina with a two-dimensional, light-sensitive surface, and an optic nerve that seems to carry visual information from the retina to the brain (see Figure 3.2). In short, they realized that the visual system has extensive anatomical specializations tailored to receiving information in the form of light.

Given the easily observable structures and specializations of the eye, an empiricist would argue that these are simply *sensory* constraints that affect the initial processing of visual information. In this view, these sensory specializations are largely separate from the more impressive *perceptual* abilities—such as seeing objects in depth, differentiating colors, and recognizing patterns and objects—which are thought to arise from an all-purpose associative learning system. By contrast, the nativist would argue that specializations similar to the eye's facility for processing light might well occur at every level of perceptual processing—from the most peripheral sensory receptors in the eye all the way "upward" to the highest-level conscious impressions of visual perception. Over the centuries, both points of view flourished and attracted many adherents, largely because there was no experimental evidence that seemed to strongly favor one view over the other.

Starting in the 1960s, however, a rapidly growing body of research on young infants' capabilities started to reveal the extent to which visual perception requires specialized processing capacities. One way to approach the current state of this research is to consider the sensory and perceptual capacities of the young infant as we move "upstream" from the most peripheral, basic, and sensory visual input to more central, complex, and perceptual visual experiences. For example, at a peripheral, sensory level, much of the ability to register light at different levels of brightness involves processing that takes place in the retina, at the back of the eye. The more "midstream" level of visual processing, which involves much of the processing of color, happens in midbrain structures.

Finally, the highest levels of visual perception, which include processing patterns, such as faces and distinctive shapes, heavily involve the brain's visual cortex. Nativists and empiricists agree that specialized processing is crucial at the peripheral, sensory level; but as we move "upstream" from sensation to perception, specific research findings are needed to help us determine whether higher-level visual processing is based on a general learning system or specialized processing capabilities. We will therefore start by considering some of the earliest, "downstream" visual capacities that involve perceptual understanding: the ability to see differences in brightness and the ability to see the contrasts between light and dark that represent lines and edges. Working our way "upstream," we will then explore more complex aspects of visual perception, such as the ability to perceive colors, depth, and finally patterns.

Perceiving Differences in Brightness and Acuity

Virtually all theorists would grant that the newborn's ability to detect different levels of brightness provides an important foundation for more sophisticated perceptual activities, such as understanding patterns. If newborn infants couldn't even distinguish between different levels of brightness—to perceive, for example, a dark line on a light background—it is difficult to imagine how they could learn anything else about the visual world. For this reason, asking about the different levels of brightness that an infant can perceive serves as a common point of departure for researchers with different views, rather than a source of controversy.

Over an enormous range of brightness levels, a typical adult can perceive changes in brightness of as little as 1 percent. Young infants do not consistently perceive this full range of differences, but even newborns have brightness discrimination abilities that are sufficient to form a basis for higher-level perceptual skills (Aslin, 1987). For example, infants as young as 2 days old perceive differences between lamps of different brightness (Hershenson, 1964). Even more impressively, by at least 4 months of age, infants can judge relative levels of brightness in an image by comparing two adjacent areas (Chien et al., 2003; see Figure 3.3). Perceiving such relationships is a critical part of figuring out the actual brightness of an object seen under different lighting conditions. Thus, if you see a pure white square in low light, it may appear darker than a gray square lit with bright light. But if you see the white square next to the gray one and compare them, the white one clearly looks brighter, even under different levels of illumination.

Q: Do young infants see differences in brightness?

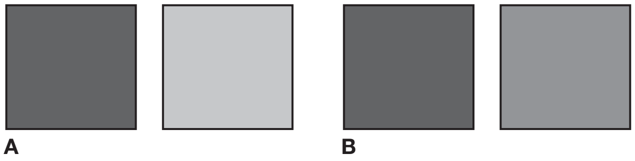

FIGURE 3.3 Brightness perception in infants. **(A)** Although young infants can see differences in brightness levels, **(B)** they may not be able to see the subtle differences that adults can see.

Visual Acuity The ability to distinguish levels of brightness within a field of view is typically not enough to know what that visual field looks like. Even when you can discern subtle differences in brightness through a frosted windowpane, you still may be completely unable to discriminate any patterns or to tell what kind of thing you are seeing. Thus, a crucial precursor to higher-level pattern perception must be **visual acuity**, the sharpness of vision based on the ability to see the contrasts in the world that represent lines, shapes, and shadows. Does the newborn view the world as if through a frosted window, seeing nothing more than blurs of varying levels of brightness? Such a world of undifferentiated dark and light blotches would severely limit the infant's visual experiences and, at least in the realm of vision, would strongly resemble William James's "blooming, buzzing confusion."

Since infants aren't able to report what they see, researchers have devised indirect methods for investigating their visual and perceptual abilities. One of the oldest of these techniques is called the **preferential looking method**. The idea behind this method is that infants might prefer looking at some displays (for example, striped patterns) more than others. When infants are presented with two types of displays at once and they reliably prefer to look at one rather than the other, this suggests that they can detect a difference between the two. Researchers have used this technique to explore whether infants see only undifferentiated areas of light and dark or more detailed patterns and whether they have expectations about certain events.

To measure an infant's visual acuity using the preferential looking method, a researcher could place two circles—one with wide black and white stripes and the other entirely gray—side by side where the infant can see them and then monitor the infant's eye- or head-turning patterns (see Figure 3.4). If the infant sees the difference and prefers to look at, say, the circle with stripes, the experimenter might then replace that circle with another that has thinner stripes and therefore requires greater visual acuity to distinguish it from the gray circle. As long as the infant continues to show a preference for the circle with stripes, the experimenter continues to substitute new patterns of finer and finer stripes to show along with the gray circle, until the infant shows no preferential looking. At that point, the researcher assumes that the infant can no longer detect a difference between the

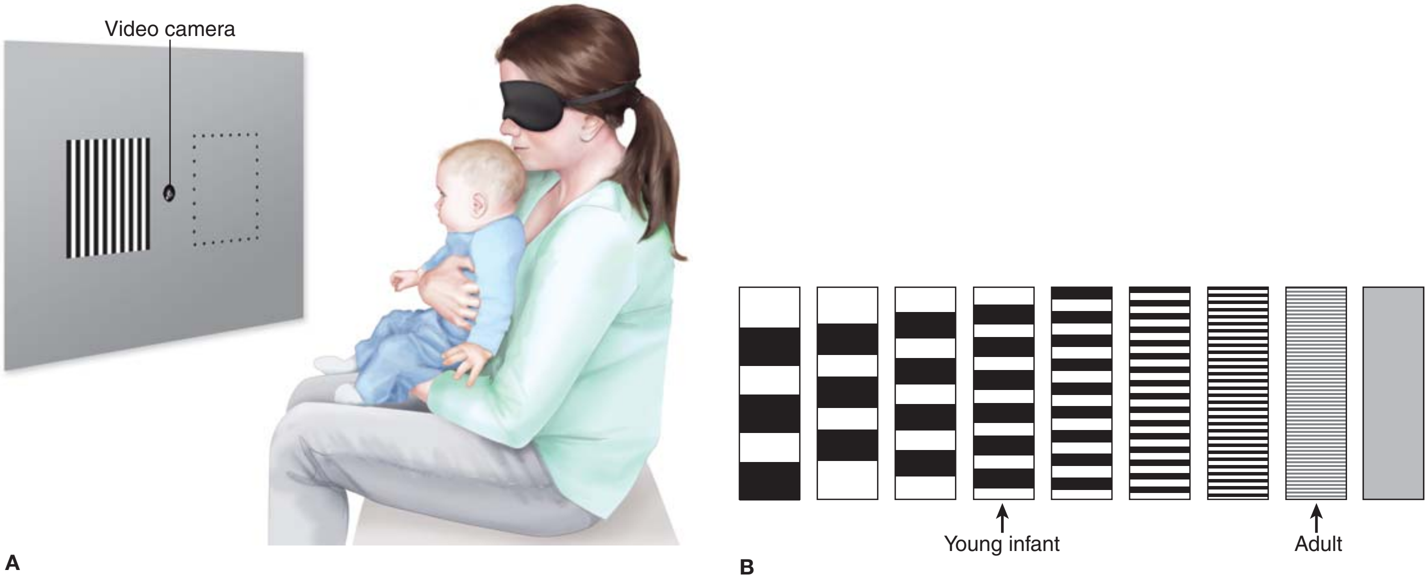

FIGURE 3.4 **Testing visual acuity in infants.** **(A)** This setup for assessing visual acuity has a rectangular panel containing a square with gratings (thick or thin stripes) and a gray square (indicated by the dots) that cannot be distinguished from the background. To assess whether the infant can detect the square with the stripes, researchers monitor where the infant prefers to look, as indicated by fixation of his gaze. Adapted from Courage & Adams (1990). **(B)** Ever finer gratings are used until the infant is not able to discriminate between the horizontal lines and a gray square that is matched for the same overall level of brightness. At some point, all of us can no longer tell the difference between a very fine set of lines and gray; for newborns that point seems to come quite a bit sooner. Although newborns certainly do not see a formless blur, their visual world is considerably less sharp, and a 1-month-old's acuity is far below the adult level of performance. From Teller & Bornstein (1986).

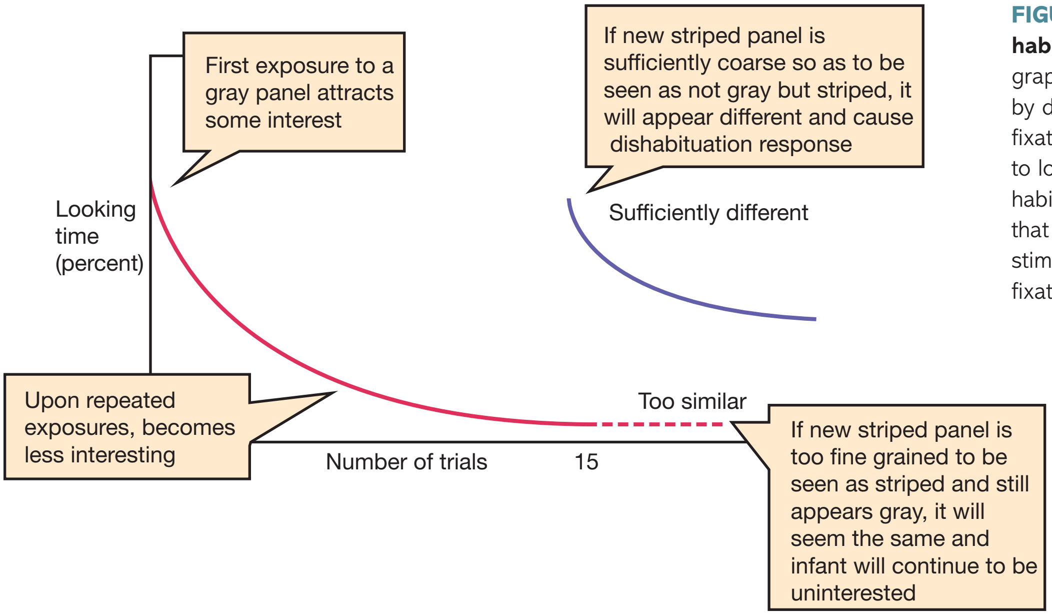
circles. If this procedure were repeated with many infants of a particular age, the aggregated results would suggest a threshold for visual acuity at that age, which could be compared with the threshold values for adults.

As simple as it sounds, there are several challenges in making this technique work reliably. Researchers must be vigilant that some other factor besides acuity isn't causing infants to look at one pattern more than another. For example, researchers must ensure that the panels differ only in the acuity level required to see a difference between them, and not in other ways, such as overall brightness. In addition, if the infant sits in a parent's lap (which is common) and the parent can see the stimuli, the parent might unknowingly hold the infant a bit differently when the infant looks at the gray panel. (This can be overcome by blindfolding the adult.) Moreover, the researchers collecting the data must be "blind" to the experimental condition—that is, they should be unaware of which panel the infant is viewing. Otherwise, their own biases might influence the process. Finally, a challenge involved in interpreting data from preferential looking paradigms is the possibility that an infant who can easily tell two displays apart visually might not always show a preference for one over the other.

A second approach to measuring infants' visual acuity involves the **habituation method**. Rather than hoping that infants' preferences will be strong enough to provide evidence that they can discriminate between stimuli, as the preferential looking method does, the habituation method, in essence, creates preferences. Most of us become bored if we see the same thing again and again. The habituation method purposely creates this kind of boredom as a way to create a preference for a new stimulus. At first, a gray panel might be interesting enough to an infant that she would look at it for some time. But if it is shown and removed repeatedly, even an infant reaches a point when she would rather look at almost anything else. When the infant seems completely bored with the panel, so that she hardly looks at it when it is presented, she is said to experience **habituation** to that stimulus. Habituation is used to study not just vision, but also audition, olfaction, and taste.

The experimenter then starts the critical second phase of the habituation method by introducing a second panel and watching to see whether the infant shows **dishabituation**—that is, renewed interest in response to the new panel. In a study of infants' visual acuity, this new panel might have very fine-grained black and white stripes. If the infant doesn't perceive the new panel as different from the original gray one, then she should not dishabituate—that is, her looking time should not increase in response to the new panel. But if the infant does see a difference, she should initially look much longer when the new panel is presented, followed by a gradual decline in looking at the panel as she becomes bored with it. To find a threshold measure of acuity, an experimenter might start with the second panel with the finest-grained pattern and then gradually substitute panels with more coarse-grained patterns until dishabituation occurs. Changes in



First exposure to a gray panel attracts some interest
If new striped panel is sufficiently coarse so as to be seen as not gray but striped, it will appear different and cause dishabituation response
Sufficiently different
Looking time (percent)
Upon repeated exposures, becomes less interesting
Too similar
Number of trials
15
If new striped panel is too fine grained to be seen as striped and still appears gray, it will seem the same and infant will continue to be uninterested

FIGURE 3.5 Idealized example of habituation and dishabituation. The graph shows habituation as measured by decreases in looking time. The infant fixates on a new stimulus and continues to look at it until she grows bored and habituates. When a new stimulus appears that is clearly different from the original stimulus, the infant will dishabituate and fixate on that stimulus.

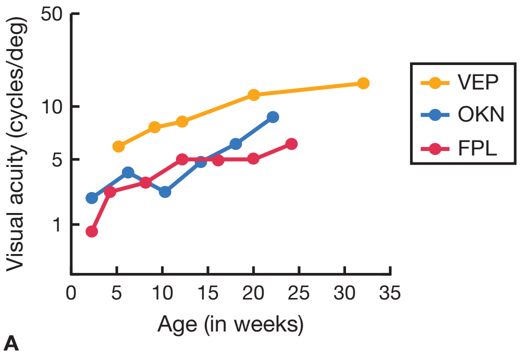
looking times at a stimulus in a standard habituation/dishabituation sequence are shown in Figure 3.5.

A third way of testing acuity is by the **optokinetic nystagmus method**. Optokinetic nystagmus is the jumping of the eyes as they track a continuous succession of objects that stream by, such as watching telephone poles stream by while looking out of a moving train. In this method, researchers drag a panel of vertical stripes from right to left in front of an infant to determine how fine-grained the stripe pattern must be before the infants' eyes stop jumping from stripe to stripe and behave as if it were one homogeneous gray pattern moving from right to left.

Finally, acuity can be tested by measuring the electrical activity in the infant's brain that is evoked by visual displays. This method, known as the **visually evoked potential (VEP) method**, involves attaching electrodes to the baby's scalp to measure brain activity and to determine at what point the changing striped patterns that the infant is watching on a screen no longer cause corresponding changes in the brain's electrical activity. Thus, as an infant watches the screen, the researcher might present a sequence of patterns, alternating between the same all-gray screen and different black and white striped patterns, while monitoring the electrical activity in the infant's brain. At the beginning of the sequence, the striped pattern would be coarse-grained with a few wide stripes. As the sequence progressed, the infant would be shown finer and finer-grained stripes. Initially, every time the image on the screen switched from gray to striped, the researcher would measure a related change in brain activity. But when the striped pattern became too fine-grained for the infant to tell it apart from the solid gray pattern, the brain activity corresponding to the switch to the striped pattern would not occur.

In young infants, VEP measurements reveal sharper levels of acuity than preferential looking or habituation methods do. This discrepancy raises a fascinating question: Do some parts of the infant's visual system start to detect fine-grained patterns before the infant is able to act on such information? That is, the infant's brain may be registering a certain level of acuity during initial perceptual processing, but it may not be able to translate that information into actually "seeing" at that level of acuity and using it as a basis for action. It may take time for those initial stages of perceptual processing to become fully integrated with higher levels of perception. The difference between VEP measures of acuity and those from habituation or preferential looking highlights an important point about studying preverbal infants. Older children and adults can describe how they are experiencing a visual display, but even with careful, well-designed measurement techniques, it is still much more difficult to know exactly what preverbal infants are experiencing.

Even if we assume that measures based on habituation and preferential looking are the best indicators of what very young infants actually see, they still show that infants have enough acuity to perceive some lines, edges, and outlines. Over the first year of life, acuity improves considerably (Norcia et al., 2005). Figure 3.6 summarizes the changes in acuity in the first 3 years, based on average measurements from visually evoked potentials, optokinetic nystagmus, and preferential looking techniques (Courage & Adams, 1990; Kellman & Banks, 1998; Teller & Movshon, 1986). Averaging across these measures, by age 6 months, the infant has nearly 20:100 vision, meaning she can see patterns at a distance of 20 feet about as well as an adult with normal vision could see the same patterns at 100 feet. Many nearsighted



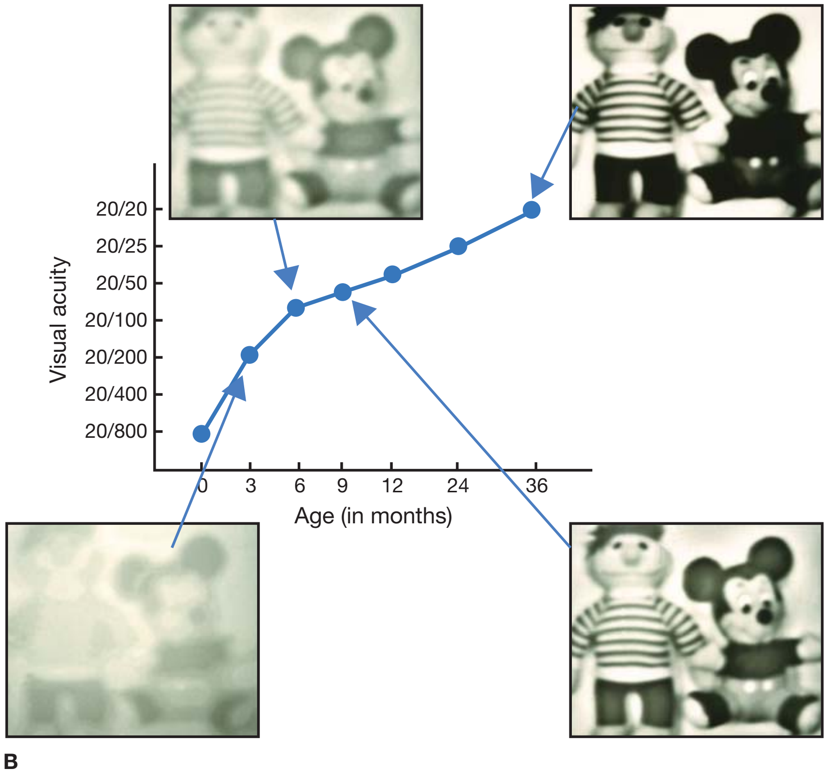


FIGURE 3.6 Changing visual acuity in infants. Acuity clearly improves in the first 3 years of life regardless of the particular measure used. **(A)** Here increased visual acuity is shown using visually evoked potentials (VEP), optokinetic nystagmus (OKN), and (forced choice) preferential looking (FPL) methods. By 6 months or so, the infant's acuity is sharp enough that it would rarely limit other perceptual tasks. Adapted from Kellman & Arterberry (2006). **(B)** The same photo is superimposed on a preferential looking methods curve to show how it would look to the infant at different ages as acuity increases.

adults without glasses cope with this kind of modest difference in acuity throughout their lives.

Q: What are three different ways of measuring visual acuity in the human infant?

Many other acuity-related factors also change during the first year of life, especially **astigmatism**. In astigmatism, stimuli at different orientations are perceived with different levels of acuity. Thus, a vertical line might be in sharp focus while an otherwise similar horizontal line would be blurry. The perceptual differences caused by astigmatism are dramatic in very young infants, but only minor in most 1-year-olds and adults (Mutti et al., 2004). When adults experience astigmatism, it is typically due to distortions in the lens of the eye or the cornea, but in young infants astigmatism is normal. It happens because the eyeball is irregularly shaped in early infancy, and consequently, the retinal surface is irregular as well. As a result, only a small portion of the light that reaches the retina can be in focus at one time. As the infant matures, the eyeball grows and develops a more spherical form, which reduces the astigmatism. Soon after the infant is 1 year old, his eyeball has become roughly spherical, such that the light passing through the lens now lands, in focus, on the whole retina.

These changes in the eye's shape do not happen automatically according to a timetable of biological maturation. Instead, the eye's growth depends on whether it receives focused input—that is, whether the light patterns falling on the retina are sharply focused by the lens of the eye. If the light patterns on the retina are out of focus, the eye continues to grow until the patterns become more focused (see Figure 3.7). Apparently, the eye "assumes" that if the pattern is out of focus, it is because the eye is too small and the image is falling behind the retina, so the eye grows to adjust. This is generally true; a newborn's eyes are almost always too small to project images optimally on the retina.

Humans are not the only species in which the growth of the eyes depends in part on how sharply the retinal images are focused. Researchers have found that manipulating the degree of focused input to the retinas of newly hatched chicks affects the growth of the chicks' eyes. If, from birth, a baby chick wears contact lenses that keep its retinal images blurry, its eyeball and retina will continue to grow far larger than normal as the visual system keeps trying to expand to the size that will properly focus the image. Conversely, if the chicks experience sharply focused light on large regions of the retina unusually early in their development, the eyeball and retina will stop growing at a smaller size than normal. These environmental effects on the growth of the chicks' eyes start to happen almost immediately after the image on the retina goes either out of or into focus (Judge, 1990; Wallman et al., 1987; Zhu et al., 2005). Of course, there are

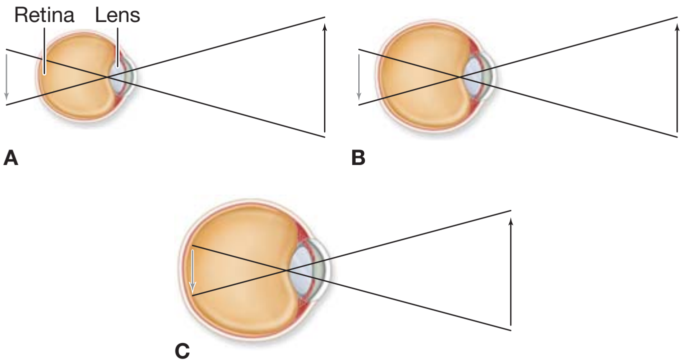

FIGURE 3.7 **Growing the eye into focus.** **(A)** In the more immature eye, the focused image would fall behind the retina. **(B)** The defocused image that falls on the retina causes the eye to grow until the image gets closer to the retina. **(C)** When the image is finally focused on the retina, feedback from that focused input tells the eye to stop growing. This pattern of eye growth is yet another illustration of the feedback loops that exist between structures in the organism and the ways in which the organism interacts with its environment, in this case with the surprising result of sensation influencing anatomy. Adapted from Zhu et al. (2005).

many important differences between the visual systems of chickens and humans, but the similar findings in monkeys (Hung et al., 1995; Smith et al., 2009; Troilo et al., 2000; Wiesel & Raviola, 1977) make it seem likely that such an effect would also be found in humans.

These findings in the visual system, in which biological maturation and environmental experience complement each other, also illustrate how development can advance by way of a feedback loop. If incoming visual information from the environment is being processed at a low level of acuity, the brain directs the eyeball and retina to keep growing. When the eyeball and retina get large enough to properly focus the incoming light, the brain senses an adequate level of acuity in its visual perception and directs the eye to slow its growth. Thus, environmental experience modifies the internal system, which then modifies the organism's experience.

Q: How can different environmental experiences change the structure of the eye?

Visual Experience and Brain Development Both the eye itself and the visual processing areas of the brain grow in ways that depend not only on biological maturation but also on input in the form of visual experience. These two levels of growth can be best understood by considering the distinction between *optical acuity*, the sharpness of the image on the retina, and *processing acuity*, how well the brain's visual cortex (near the back of the brain) processes the information received from the retina. If you think of the visual system as a video camera, its optical acuity would be a function of how well the lenses focus the incoming light; its processing acuity would depend on the sophistication of the software—namely, how well it is able to process and integrate the information from incoming light to assemble a complete image. The development of processing acuity in infants is not a simple maturational matter in which the relevant neural networks develop on a set schedule regardless of visual inputs. Instead, similar to the development of the eyeball and retina, the infant's visual cortex also requires increasingly focused input to develop the elaborate neural connections that enable higher and higher levels of acuity.

When the optical acuity of the eye itself is impaired, it sends degraded inputs to the visual cortex, which can directly lead to impairments in processing acuity as well. This is why, in many species, including humans, depriving the visual cortex of focused input inhibits the development of processing acuity in the brain, even when the eye's optical acuity is restored later. As described earlier in the case of the girl in India, people born with cataracts who receive corrective surgery after childhood never seem to regain full acuity (Ostrovsky et al., 2006). Regions of the brain require "practice" with certain kinds of visual experience and input to develop their normal processing capacity.

The effects of experience on acuity vividly illustrate the concept of critical periods, those developmental "windows of opportunity" during which specific sorts of inputs can profoundly affect the organism in ways that are largely irreversible after the period is over. Thus, if the visual cortex doesn't receive appropriately focused input in the first few years of life, no compensating experiences later—even 20 years of wearing perfect corrective lenses—can fully restore some forms of processing acuity in the visual cortex (Lewis & Mauer, 2005, 2009). At the same time, processes of biological maturation are also crucial to processing acuity and the ability to benefit from the necessary kinds of visual stimuli and experience. For example, preterm babies show some early developmental delays in visual acuity compared with full-term babies, even when they have the same amount of visual experience (Dobkins et al., 2009). The preterm babies' visual systems simply need some time to mature before the babies can fully benefit from their visual experience.

Q: What sorts of critical-period effects are found in cases of deprivation of early visual experience?

Color

Color is a vivid part of most people's lives and may have important uses in all cultures, such as picking out a brightly colored object from a cluttered background, determining the ripeness or poisonousness of various fruits, and perceiving changes in the weather. Newborn infants have quite impressive color vision. They not only are able to tell apart different wavelengths of light (called **hue**), but also can cluster wavelengths into categories very much like the ones that adults use. Although it might seem that hue is simply a formal word for color, it actually refers only to the aspect of color that depends on wavelengths of light. Our impressions of color are also influenced by the ratio of color to white light (saturation) and the display's overall brightness. For the most part, when researchers discuss color vision in infants, they are talking about hue.

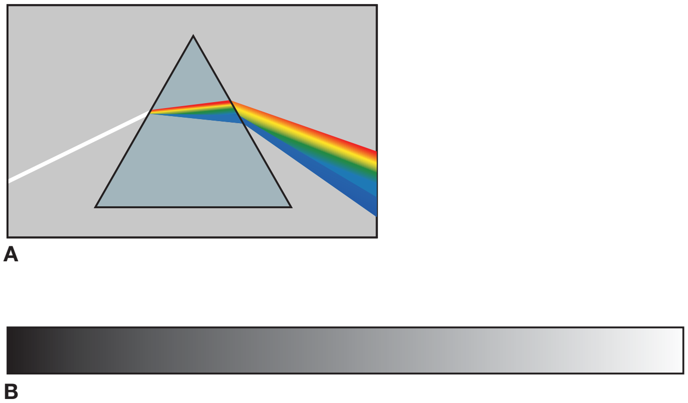

FIGURE 3.8 Light categories and continua. (A) The light coming out of a prism (or rainbow), which is a smoothly varying continuum of light frequency, appears to have "bands" corresponding to such easily labeled colors as "red," "blue," and "green"; these bands are the consequence of the categorical perception of color. **(B)** By contrast, light intensity for continuously varying shades of gray varies in a smooth, gradual manner from dark to light with no obvious "bands."

Perceiving Hue and the Clustering of Hues

Early on, researchers used the techniques of preferential looking and habituation to test infants' color vision. In many of these experiments, the investigators showed the infants pairs of different-colored panels of equal brightness and then observed whether infants could distinguish between them. The studies suggested that infants have color vision very early and that it improves significantly in the first 4 weeks of life as infants develop the ability to distinguish ever-smaller differences in hue (Peeples & Teller, 1975; Teller, 1998). These improvements are thought to result from increases in the processing abilities of the whole visual system, not just from parts specialized for color (Kellman & Banks, 1998).

Perceiving differences between hues is one thing; clustering sets of hues into color categories is quite another. When you look at Figure 3.8A, it seems to have red bands, yellow bands, and green bands, among others—but these bands of color are actually psychological constructs. The light pattern depicted in the figure, like the patterns created by prisms and rainbows, is actually a smooth continuum of hues that runs from reds (with wavelengths of approximately 700 nanometers, or 0.0000007 meter) to blue-purples (with wavelengths of about 400 nanometers). All the colors of the rainbow are situated at different points along this continuum of wavelengths. As observers, however, we do not experience a world of gradually shifting colors; instead, we tend to see classes of colors that seem to have distinct boundaries. This is in marked contrast to how we see a continuum of different levels of brightness, as in the panel shown in Figure 3.8B. If shades of gray were perceived in the same manner as hue, we would see bands reflecting different classes of grayness from white to black.

This process of clustering wavelengths of light into familiar colors is one aspect of **categorical perception**. In its broadest sense, categorical perception refers to a tendency to cluster stimuli that vary along a continuum into discrete categories. Even though the stimuli differ only in small, consistent increments, those that are grouped together in a category seem highly similar to each other, while those in different categories seem markedly different (Goldstone & Hendrickson, 2010; Harnad, 1987).

Figure 3.9 illustrates the process of categorical perception of color. The difference between the wavelengths of blue 1 and blue 2 is the same magnitude as the difference between the wavelengths of blue 2 and green 1. Yet, blue 2 and green 1 appear much more distinct from each other than do blue 1 and blue 2. The same pattern holds for other color boundaries, such as green/yellow and yellow/red. Even when we're looking at identical differences in physical wavelengths of light, we don't always perceive the same degree of difference between hues. Across most of the continuum of wavelengths, a difference of 35 nanometers between hues is hardly noticeable. But at certain critical boundaries—compare 470 and 505 nanometers—the 35-nanometer interval appears to separate quite different shades of blue and green (Boynton, 1979; Wandell, 1985).

These differences in our discrimination abilities simply mean that we cluster groups of light wavelengths into classes, which we know as familiar colors such as red, green, blue, and yellow. One benefit of this perceptual tendency to categorize is that it simplifies our interactions with the world and with others. Communicating the color of an object is much easier if a relatively large range of wavelengths can be treated as roughly equivalent—as members of the same class. Consider how much simpler it is to convey a color than a specific shade of gray on the smooth continuum between black and white.

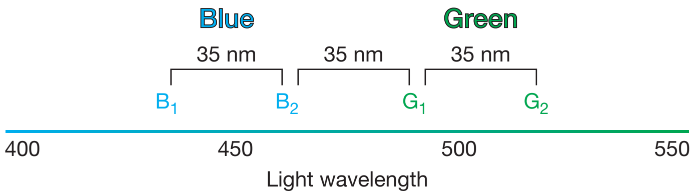

FIGURE 3.9 Categorical perception of color. This section of the light spectrum shows the transition between blue and green light. There is a constant continuum of increasing wavelength from 400 nanometers to 550 nanometers. B_1, B_2, G_1, and G_2 represent particular wavelengths of light along the continuum. Categorical perception occurs because B_1 and B_2 are put in the same category and are seen as quite similar to each other, as are G_1 and G_2, while B_2 and G_1 are seen as more different, even though the difference in wavelength between each of the pairs is the same (35 nanometers). These subjective differences in similarity create the bands that we see in a rainbow. The critical developmental question is whether these categories emerge as a consequence of visual experience and possibly exposure to language or whether they are part of how infants see the world right from the start. Adapted from Boynton (1979).

Categorical Perception of Color Where do our color categories come from? Do we come into the world with perceptual capacities that lead us to group hues into certain color categories, or do we learn color boundaries from our elders through language and experience? Could repeatedly hearing "red" in reference to a certain range of wavelengths instill in the child a sense of how to perceptually group different reds together? In fact, no such experience seems to be necessary.

Using the habituation method introduced earlier, researchers have shown that even 4-month-olds perceive color in categories. The infants are first habituated to a certain wavelength of light projected on a screen. Once habituated, the infants are tested to see how they respond to two other hues of light, which are equidistant from the first in terms of wavelength. The crucial difference between the two new hues is that one falls within the same color category as the first (habituated) hue, and one falls outside this color boundary. For example, the infants might be habituated to an intermediate blue (blue 2 in Figure 3.9) and then tested to see whether they dishabituate more to green (green 1) or to a different blue (blue 1), both of which are 35 nanometers away from blue 2 on the spectrum.

These studies have found that the infants dishabituate more strongly to wavelengths that fall outside the color boundary of the hue to which they were habituated (Bornstein, 1975; Bornstein et al., 1976; Franklin & Davies, 2004). Evidence for categorical perception of color in infants younger than 4 months of age is somewhat controversial, but some studies suggest that even newborns show categorical perception (Jones-Molfese, 1977). Demonstrations of categorical color perception in young infants provide strong evidence that the color categories we perceive are not just the result of experience and cultural exposure.

Studies of color perception across cultures further support the idea that we do not learn color categories solely from older members of our society but are instead endowed with perceptual color categories long before culture has had much influence. It is true, however, that different languages can help create the categories we perceive. Older children and adults sometimes show patterns of categorical perception that are closely linked to the color categories of their primary language (Reiger & Kay, 2009). Nonetheless, multiple studies have also found some cross-cultural commonalities. For example, people from a diverse range of cultures and linguistic backgrounds tend to select the same hues as the "best" examples of color categories (for example, "the reddest red"; Berlin & Kay, 1969; Goldstone & Hendrickson, 2010; Heider & Olivier, 1972; Reiger & Kay, 2009).

How is it possible that preverbal infants tend to categorically perceive colors in the same way, but older children and adults tend to intermix such cross-cultural consistencies with differences linked to language and culture? It now appears that there may be two systems that influence the categorical perception of color. The first one, in the brain's right hemisphere, seems to be largely language free, is present in early infancy, and probably develops largely through a process of biological maturation. The other is housed in the left hemisphere, where language is typically most active, and it tends to emerge during the preschool years (Franklin et al., 2008a). In fact, toddlers will categorically perceive colors that they don't yet have words for with their right hemisphere, but they will categorically perceive colors that they can name with their left hemisphere (Franklin et al., 2008b). In most contexts, if language-based color categories conflict with preverbal ones from infancy, the language-based categorical perceptions will tend to dominate. These findings suggest that infants initially experience universal, common color categories that are shaped and constrained by the early development of the first, preverbal system. Within a few years, the second system's language-derived categories gain a predominant influence. Even adults can learn new, artificial color names for categories not represented in their own language—and when they do, categorical perception of these colors is lateralized in the left hemisphere (Kwok et al., 2011; Zhou et al., 2010). Some scholars think that the left hemisphere may have a broader ability to acquire new color categories and categorically perceive them such that it can do so even when the process is not mediated by language (Holmes & Wolff, 2012). There are still clearly two systems, with the right hemisphere being more maturation driven and the left hemisphere more experience driven, but language may be only one way of gaining such experiences.

Q: What evidence supports the claims that very young infants can see color and that they perceive colors categorically?

An important principle emerges here that will extend to our later discussions of cognitive development as well: the ability to perceive and understand the world requires categorization. There is simply too much raw information for any organism to master unless it simplifies and treats the members of some large classes of stimuli, such as colors or shapes, as equivalent for certain purposes. The ability to categorize is one of the most important ways in which infants and young children gain early footholds in perceptual and cognitive development.

Depth Perception

When a mountain goat is born in an especially steep area of the Sierra Nevada Mountains, it needs to be able to tell the difference between a small step down and a deep abyss as soon as it can walk. Likewise, it is highly uncommon for a baby squirrel to leap too far and miss the next branch in its sights or for a puppy to fail to catch the ball you've tossed. Animals that move about on their own would not survive long if they could not sense the distance to objects and surfaces. As adults, we use depth information whenever we reach out and grasp something and whenever we move through the world; we use it to drive, walk through crowds, and avoid dangerous drop-offs. But despite the obvious evidence that mature members of most visual species can perceive depth, the question of whether human infants can do so proved difficult to answer.

Cues to Depth Adults perceive depth with the help of three types of cues: *dynamic cues*, *binocular cues*, and *pictorial cues*. Researchers have explored the question of whether infants have depth perception by designing experiments that test whether infants perceive each of these kinds of depth cues.

Dynamic cues to depth are most active when either the observer or the observed objects are moving, and they work equally well when seen with just one eye or with both eyes. They do not require much acuity to be effective, which is one reason they can work so well even in low light or in a visually cluttered scene, such as when glimpsing objects through the branches of a tree. Dynamic cues seem to be the first depth cues that infants can use; even newborns use them to some extent. They are also clearly used by other species.

One of the simplest dynamic cues seems to be *looming*—namely, the perception that a rapidly expanding object is moving closer. When infants as young as 1 month observe such expanding patterns, their reactions indicate that they perceive depth. For example, if the looming object appears to be on a trajectory to collide with them, they will pull their heads back. Alternatively, if the looming object is a doorway-like opening, they will not try to move out of its path but instead will seem to anticipate moving through the opening (Carroll & Gibson, 1981; Schmuckler & Li, 1998; Yonas, 1981). Thus, not only are very young infants able to use looming as a depth clue, they are also able to interpret looming objects differently from similarly sized looming openings.

Another type of dynamic cue, called **motion parallax**, tracks the different ways that near objects and far objects appear to move relative to the motion of the eye. As Figure 3.10 shows, when an observer sees an object, an image of the object falls on the observer's retina. When the observer's eyes move, the images of those objects on the retina move

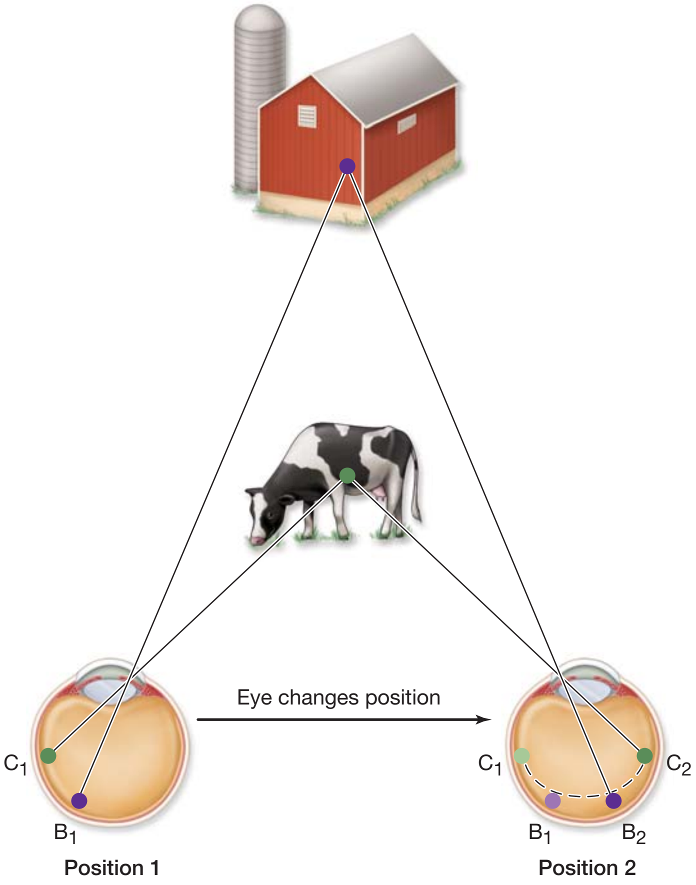

FIGURE 3.10 **Motion parallax.** Dynamic cues to depth work when either the observer, aspects of the scene, or both are in motion. Motion parallax cues to depth are based on the relative movement (or apparent movement) of objects based on their distance from the observer. When an observer moves, near objects and far objects move at different rates. Here, the near object (the cow) seems to move the longer distance (from C_1 to C_2), while the far object (the barn) appears to move the shorter distance (from B_1 to B_2). These differences can be used to infer the relative distances of the objects.

at different rates, depending on how close up or far away the objects are. In this particular example, the near object is initially seen to the right of the far object. As the observer moves from left to right, the near object appears to shift to the left of the far object. These differences in relative rate of movement allow us to perceive the relative distances of the two objects.

Motion parallax can be difficult to measure in young infants because it requires that they continuously track the motions of multiple objects while also keeping track of their own movements. Nonetheless, at least by age 3½ months, infants do seem to use motion parallax to perceive depth. By this age, they dishabituate when they view a screen in which depth relations between two objects appear to change in ways that would be highly unexpected or impossible looking to someone using motion parallax cues (Nawrot et al., 2009). At about the same age, they show a tendency to preferentially reach for objects that motion parallax cues indicate are closer (von Hofsten et al., 1992). Other researchers have inferred the use of motion parallax even in newborns. For example, when newborn infants have one eye covered and are presented with side-by-side stimuli consisting of a three-dimensional display and a two-dimensional photograph of that display, they will prefer to look at the three-dimensional version (Slater et al., 1984). The researchers argued that with one eye covered, the only major depth cue the infants can use is motion parallax.

In short, infants begin using dynamic cues to perceive depth as early as the first moments after birth and begin using them to guide their actions as early as 1 month of age. Experimental evidence suggests that they may not use some dynamic cues, such as motion parallax, across the full range of settings until somewhat later, possibly not until the third month of life. However, given that a wide range of species use motion parallax cues in their earliest moments, including many insects that move their heads from side to side to gauge how far to jump toward an object (Kral, 2003), it seems plausible that some early versions of motion parallax cues may be present at birth in humans as well.

Binocular cues rely on subtle differences between the two eyes to gauge how far away an object is. Two kinds of binocular cues are most important to consider: binocular parallax and convergence. **Binocular parallax** (also known as **binocular disparity**) refers to the slight disparity between the two eyes' views of any object. As Figure 3.11 shows, the right and left eyes always view any object from slightly different vantage points, and the difference between their views can be used to predict how close the object is to the eyes. The greater the disparity between the two retinal images, the closer the object is. The effect of binocular parallax is easy to observe by simply moving your fist closer and closer to your face while alternately viewing it through just one eye, then the other. As your fist gets closer, the difference between the images that each eye sees becomes larger, and the perceptual system interprets that disparity as information about distance. The process of using these binocular parallax cues to perceive depth is called **stereopsis**, which involves fusing two images into one image with depth.

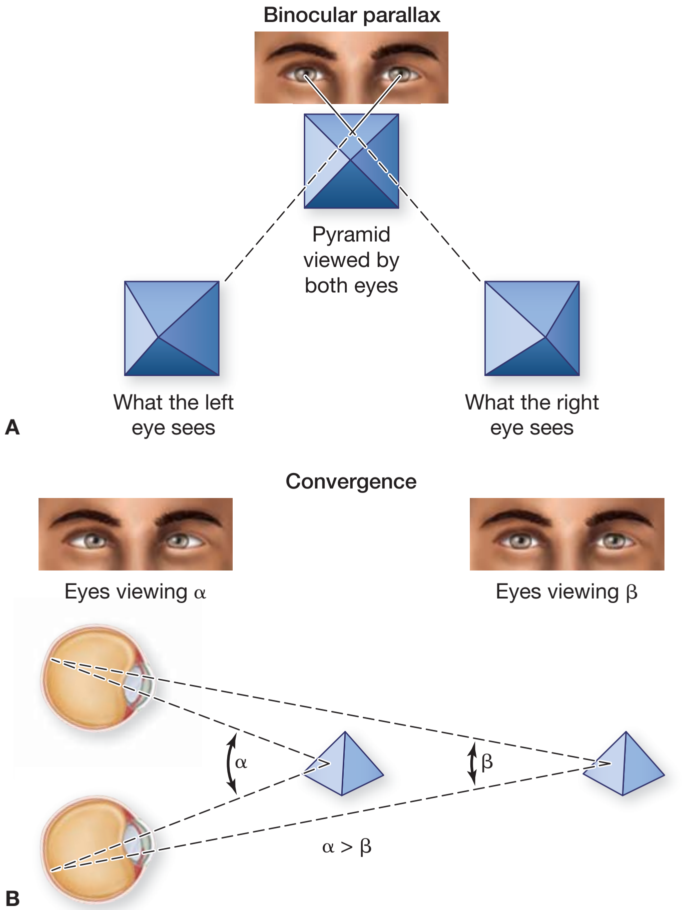

FIGURE 3.11 Binocular cues to depth. Binocular cues to depth require both a three-dimensional world and a viewer with two eyes. Distance is based on **(A)** binocular parallax, which is the disparity between two images (shown here as two different top views of the same pyramid), or on **(B)** the sensation of convergence of the eyes as they become less and less parallel for closer and closer objects (angle α is greater than angle β). These cues tend to lose their effectiveness for objects that are not nearby, as the relative difference between the eyes becomes negligible for faraway objects.

The second binocular cue, **convergence**, is similar to binocular parallax, but rather than using the disparity between the two eyes' retinal images, convergence relies on the way the two eyes move—becoming increasingly cross-eyed in order to focus on closer and closer objects. If you focus both eyes on your finger while holding it very close to your nose, you can feel a sensation of muscle strain; this is also illustrated in Figure 3.11. Convergence cues allow us to estimate the distance of an object by using the sensations of muscle tension in our eyes that correspond to pulling them into various angles of convergence.

The seventeenth-century empiricist George Berkeley proposed that convergence cues are a key component of the way infants learn to perceive objects in depth (Berkeley, 1709/1901; Pastore, 1965). More specifically, Berkeley suggested that the infant is born with only two simple depth-related sensations—the convergence feedback from the eye muscles when focusing on the object and the sensation of the degree of reaching or movement required to touch the object—and an ability to associate these two sensations. Simply put, infants would begin to associate a strong sense of binocular convergence with a near reach and weaker feelings of convergence with longer reaches.

Berkeley's empiricist model of learning to perceive depth makes some general predictions. First, if this model is correct, the very young infant should simply be unable to perceive depth, since she has not had time to learn the sensory associations that Berkeley describes. Second, depth perception should emerge gradually, based on the amounts and kinds of visual experiences the infant has had. The biggest problem with Berkeley's view is the evidence that many species, including humans, have excellent depth perception abilities in the absence of any learning experiences. Infants' eyes will converge automatically to fixate on a close object as early as 1 month (Hainline & Riddell, 1996), and infants between 5 and 8 months old can use convergence information as a cue to depth.

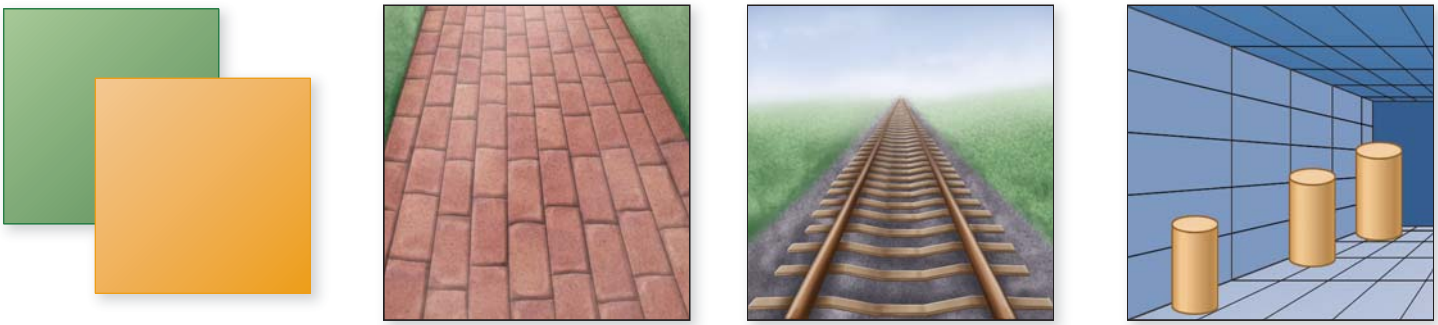
It is more difficult to tell whether infants use binocular parallax to perceive depth with normal objects because this ability involves a precise mental comparison of the tiny differences in the images that the two eyes see. But it is possible to artificially generate images that can only be seen when they are fused by the two eyes using parallax cues. (With each eye individually, the viewer sees only a seemingly random pattern of dots.) To see whether infants use binocular parallax cues, researchers present such images to infants on a computer screen. When the images are set in motion on the screen, the researchers monitor whether the infant's eyes track the images' movements. This technique has suggested that stereopsis emerges in about the fourth month of life and becomes increasingly sophisticated over the next few months (Fox et al., 1980; Granrud, 1986; Wattam-Bell, 2003). One possible reason that younger infants do not use stereopsis is that it may require greater visual acuity than they have yet developed (Brown & Lindsey, 2009). If young infants can't see patterns below a certain level of resolution, as shown in the blurriest images in Figure 3.6B, they may not be able to detect disparities in highly similar images.

The development of stereopsis presents another example of a critical-period effect. Some children are born with eye muscles that make their eyes excessively converge or diverge, resulting in either a "cross-eyed" or "wall-eyed" condition. As a result, the separate images that their right and left eyes see are too different for the brain to fuse them into a single image or to use the disparity between the images to provide depth information. If this situation persists for several years, the inability to fuse the right and left eyes' images becomes irreversible, even if the problem with the eye muscles is later surgically corrected (Fawcett et al., 2005). Thus, a child as young as 6 years old who has surgery to correct a cross-eyed condition is unlikely to fully recover stereopsis, even after several years of normal visual experience. In such cases, the child often comes to rely on one eye much more than the other to avoid seeing double. This critical-period effect is thought to apply to stereopsis in particular, and not to convergence, because children with misaligned eyes might still register the muscle sensations associated with eye movements toward greater or lesser degrees of convergence.

Q: What is some evidence for a critical period for binocular vision in humans?

The critical period for developing binocular depth perception has been documented more precisely in monkeys and cats. Like humans, monkeys and cats have certain neurons in the visual cortex that fire only when both eyes receive input simultaneously. These cells seem to be involved in computing the disparity between the two images and fusing them into one image. In a newborn kitten or monkey, however, these binocularly driven cells tend to be less responsive than they are in older animals. They become more fine-tuned only with considerable experience. If the animal wears eye patches on alternating sides to prevent that experience, the number of binocularly driven cells starts to diminish and eventually die off (Freeman & Ohzawa, 1992). When this happens, no amount of binocular visual experience later on can resurrect them (Crawford et al., 1996). This level of neural analysis concretely illustrates how critical-period effects are manifested in the nervous system. It shows how some neural circuits are attuned to certain stimuli during a critical period and then become much less changeable, allowing them to operate more efficiently (Hensch, 2004; Wang et al., 2010).

Pictorial cues can convey depth even in two-dimensional scenes like paintings and photographs and can do so even when seen with only one eye. Figure 3.12 illustrates three different types of pictorial cues: interposition, texture gradients, and convergence in the distance. *Interposition* occurs when one shape overlaps another, suggesting that it must be in front of the other. *Texture gradients* serve as cues to depth when a repeating pattern on a surface, such as the rough grid of a brick path, gets smaller and smaller the farther away the surface is. *Convergence in the distance* describes the way parallel lines, such as straight railroad tracks, seem to meet as they extend toward the horizon and thus show linear perspective, or the appearance of distance as the lines converge. Adults in all cultures



A Interposition **B** Texture gradients **C** Convergence in the distance **D** Perspective illusion

FIGURE 3.12 Pictorial cues to depth. Pictorial cues to depth are those that indicate distance from the viewer by means of patterns on a two-dimensional surface or picture. They work equally well with one or two eyes. **(A)** Some, such as interposition, in which one object covers part of another object, appear in some of the earliest drawings in history. **(B)** Others, such as texture gradients, in which objects are depicted as smaller as they become more distant, appeared later in art history. **(C)** Still others, such as convergence in the distance, which provides linear perspective, appeared relatively late in the history of art and represented a major revolution in how to depict depth in paintings and drawings. Pictorial cues require fairly high levels of acuity to be effective and also have the potential to be misleading, as shown in **(D)**, where the cylinder farthest to the right appears much bigger than the one farthest to the left, even though they are the same size. The apparent difference in size is caused by pictorial cues to depth that suggest that the rightmost cylinder is farther away than the leftmost one.

can use these pictorial depth cues, but infants younger than about 6 months do not seem to use them (Kellman & Banks, 1998). Thus, only humans older than 6 months are likely to be fooled by the illusion in Figure 3.12D, in which identical-size cylinders in fact look very different in size because of surrounding pictorial cues.

One technique that researchers have used extensively to investigate when infants use pictorial depth cues relies on the simple fact that when young infants are presented with two objects, they consistently reach for the nearer one. A clever experimenter can use this reaching preference to find the conditions under which the infant sees a difference in depth. In one study, researchers showed 5- and 7-month-old infants a "window" like the one in Figure 3.13, which contained several pictorial cues to depth (Yonas et al., 1978). They then observed whether the infants more often reached toward the side of the window that would appear closer if the infants were relying on pictorial depth cues. The 5-month-olds showed no preferential reaching for the edge that would seem nearer based on pictorial cues. Instead, they responded to the surface as if it had no patterns on it at all, reaching for various parts seemingly at random. In contrast, the 7-month-olds consistently reached for the edge that would have looked closer to someone using pictorial cues. Recall from the visual acuity studies discussed earlier that 5-month-olds could easily see the lines and shadows that serve as the pictorial cues. Nonetheless, they did not use them to see depth.

Studies of many other pictorial depth cues have found this same time frame to be significant: 5-month-olds typically do not use pictorial cues effectively, but 7-month-olds do (Hemker et al., 2010; Kellman & Banks, 1998; Yonas et al., 2002). These findings suggest that at around 6 months of age, a capacity emerges for using and integrating different kinds of pictorial cues. It is interesting that in some tasks, 5-month-old infants can readily see depth with two eyes by using binocular cues, but they cannot see it with one eye when only pictorial cues are available (Hemker et al., 2010). This pattern of results does not necessarily mean that the ability develops solely as a consequence of maturation;

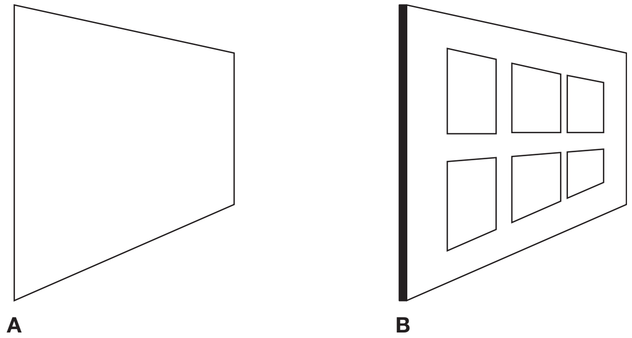


FIGURE 3.13 Sensitivity to pictorial depth. **(A)** A simple trapezoid conveys an illusion of depth, but it is not as compelling as **(B)** the illusion conveyed by an Ames window, where the right side seems farther away because of pictorial cues to depth. These cues are convergence in the distance (the top and bottom lines of the window become closer to each other) and texture gradients (the window panes become smaller in the distance). Young infants who cannot use pictorial cues to depth will reach equally for the right and left sides of the Ames window or in the middle, while older infants will reach more for the left side, thinking it is closer. This is one case where younger infants are more accurate; they are not misled by an illusion of pictorial depth. Adapted from Ames (1951) and Yonas et al. (1978).

learning experiences could be important as well. It is not yet clear why the ability to use pictorial cues develops later in infancy than the ability to use dynamic cues or binocular cues. One possible reason is that getting depth information from pictorial cues may require more learning or cognitive interpretation than the other types of cues. Another possibility is that pictorial cues may require more advanced levels of visual acuity.

Which Depth Cues Predominate? Gibson's Visual Cliff Studies Several research projects have also shown which kinds of depth cues dominate when different types are pitted against each other. Generally, the earlier-emerging cues tend to trump those that develop later. The best-known research techniques to explore these questions were developed by Eleanor J. Gibson, the twentieth century's most influential researcher in perceptual development. Gibson had an extraordinary talent for devising ways of studying infant behavior that could yield remarkable insights into their perceptual development. She developed numerous experiments that explored infants' perceptual abilities in circumstances that resembled their natural interactions with the world.

In the 1950s, while studying perception in newborn goats, Gibson was inspired to create a new experimental technique for studying infants' depth perception. She noticed that the busy handlers in the lab often had trouble keeping track of the baby goats, since even the newborns were able to wander around. The handlers solved this problem by placing restless baby goats on a raised surface, such as a stool or countertop. At the edges of these surfaces, the young goats would freeze, apparently because they immediately perceived the difference in depth and feared falling. Gibson realized that the newborn goats perceived depth without any prior experience. She devised the visual cliff technique to explore this phenomenon systematically in several species, including humans.

Figure 3.14 shows the **visual cliff** that Gibson developed. It consists of a large, transparent, and nonreflective pane of glass with two similar checker-patterned displays below it. One-half of the glass pane had a checkered pattern directly beneath it, so that the surface appeared solid. The other half of the glass pane had the same checkered pattern roughly 3 feet below, giving the impression of a sudden drop-off, or "visual cliff." A wooden plank across the pane's surface divided the two halves. The studies performed with this apparatus usually began with placing a 6-month-old on the wooden "bridge" between the two sides of the glass surface and observing where the infant crawled. Gibson and her team were especially interested in how the infants would respond to the "cliff" side of the pane. Their findings were clear and dramatic. The infants were quite reluctant to move onto the glass above the apparent drop-off, even when the infant's mother was on the other side smiling and enticing the baby with a favorite toy (Gibson & Walk, 1960).

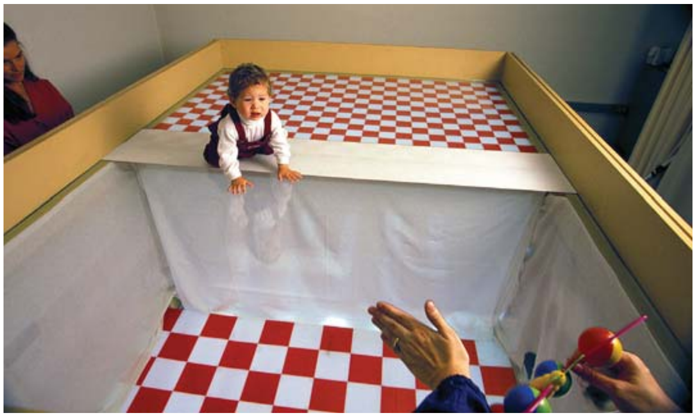

FIGURE 3.14 **The visual cliff.** Despite attempts by his mother to induce him to cross the visual cliff, this infant is clearly hesitant. The glass that covers the deep side of the cliff is nonreflective and illuminated such that the infant sees only the sudden drop-off.

How do we know which kind of depth cues the infants primarily used to avoid the "deep" side of the cliff? To check for use of pictorial cues, Gibson and her associates compared infants' performance on the two cliff setups shown in Figure 3.15. Cliff A was carefully designed so that the drop-off could not be seen by using pictorial cues to depth. On the deeper side of the cliff, the size of the checkered pattern was larger than the pattern on the shallow side. The pattern sizes differed by precisely the right amount to project identically sized squares on the retinas of infants crawling across the glass surface; based on pictorial cues alone, the whole

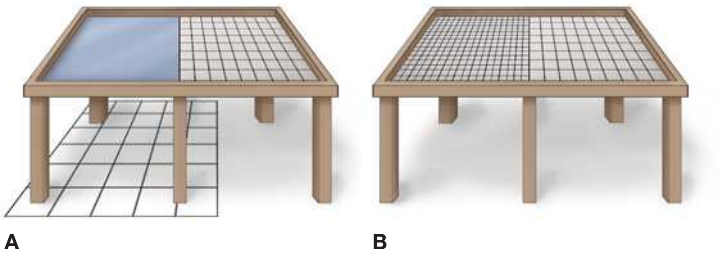

FIGURE 3.15 **Dynamic clues to depth and performance on the visual cliff.** Infants were tested on visual cliffs in which there were **(A)** motion parallax cues (dynamic cues produced by the different rates at which the two surfaces were seen to move when the infant moved his head) without pictorial cues to depth (larger squares below appeared on the infant's retina as the same size as the smaller squares above) or **(B)** pictorial cues (smaller squares on the left grid making it appear as if these squares were farther away than the larger squares on the right grid) without motion parallax cues to depth (no differences in perceived rates of movement, since both grids were on the same surface). The infants resisted crossing the visual cliff when dynamic cues indicated that there was a drop-off but not when pictorial cues indicated a drop-off. Adapted from Gibson & Walk (1960).

surface would appear level. Based on dynamic depth cues induced by motion, especially motion parallax produced by the different rates at which the upper and lower surfaces were seen to move when the infants moved their heads, the visual cliff would be obvious. The results were clear. The infants fearfully stopped at the "edge" even when the pictorial cues indicated a level surface, suggesting that they were relying on dynamic cues. This finding gained further support when the experimenters altered the visual cliff setup so that pictorial cues indicated a drop-off while dynamic cues indicated a level surface. In this case, the infants happily crawled across (Gibson, 1969; Gibson & Walk, 1960). To rule out use of binocular cues, researchers have conducted similar studies in which the infants wore an eye patch over one eye. In these cases, infants using only monocular cues were just as likely to avoid the cliff's edge, indicating again that they were very likely relying on motion parallax cues (Walk, 1968).

Q: In what ways does depth perception in young infants differ from depth perception in older children and adults?

Functional Significance of the Depth Perception System As we have seen, the development of depth perception reveals a consistent pattern (see Figure 3.16): The use of dynamic cues emerges possibly as early as the first month of life. Then the effective use of binocular cues develops around 4 months, followed by the effective use of pictorial cues around 6 months. From an evolutionary perspective, what might account for this sequence?

One important advantage for the early emergence of dynamic cues such as motion parallax is that they are almost always reliable in the natural world. By contrast, later-developing pictorial cues can be misleading in many optical illusions that show contradictory representations of depth (see Figure 3.17). In addition, dynamic cues do not require good visual acuity, but both pictorial cues and binocular cues do. Under blurred conditions and with only one eye, it is still possible to use dynamic cues such as motion parallax or looming to infer depth relationships, even while it is not possible to use the other sorts of cues. Thus, dynamic cues are most useful to infants who initially have poor acuity and who have to judge depth in conditions of reduced acuity, such as in low light or with tears in the eyes. The key point is that natural selection favors the most robust and reliable early system for depth perception, the dynamic cues, and these are the dominant cues in young infants of most species. We will see that these sorts of evolutionary considerations, especially in comparative research across several species, can often provide meaningful interpretations of developmental patterns. Ideally, they also help predict new patterns and motivate new research.

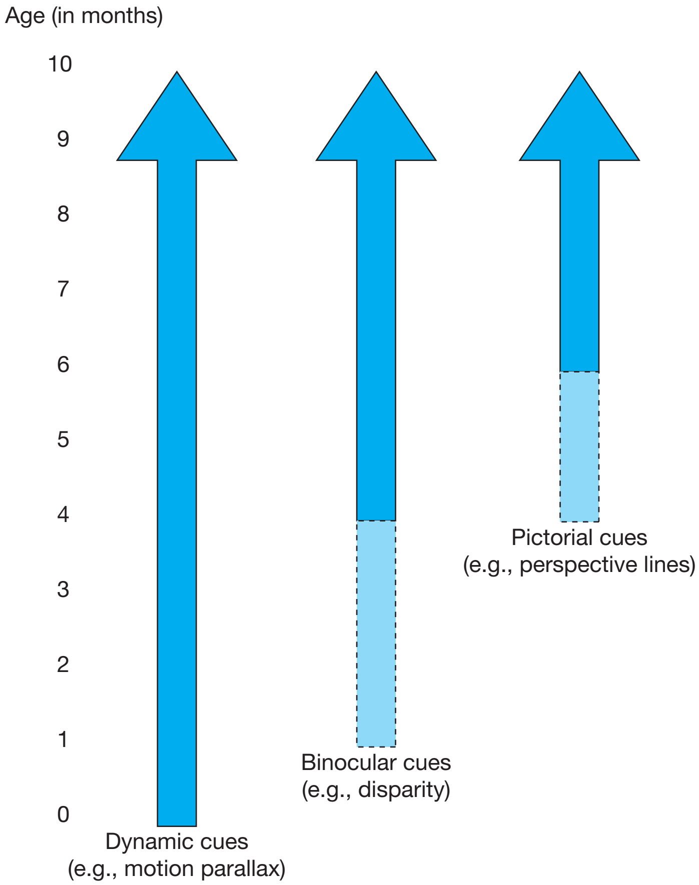

FIGURE 3.16 Three different sets of cues specify depth for the infant. Dynamic cues such as motion parallax appear to be used first, probably right at birth. Binocular cues start to emerge as partially effective at around 1 month (as depicted by the dashed lines), becoming much more effective at 4 months. Pictorial cues are not effectively used until around 6 months of age, although some sensitivity to pictorial relations may appear as early as 4 months (as depicted by the dashed lines).

Q: Why might infants be able to use dynamic cues to depth before binocular and pictorial cues?

Perceiving Patterns and Recognizing Objects

Do infants perceive meaningful patterns in the same ways that adults do? Do they, for example, devote more attention to human faces than to other recurring patterns in their

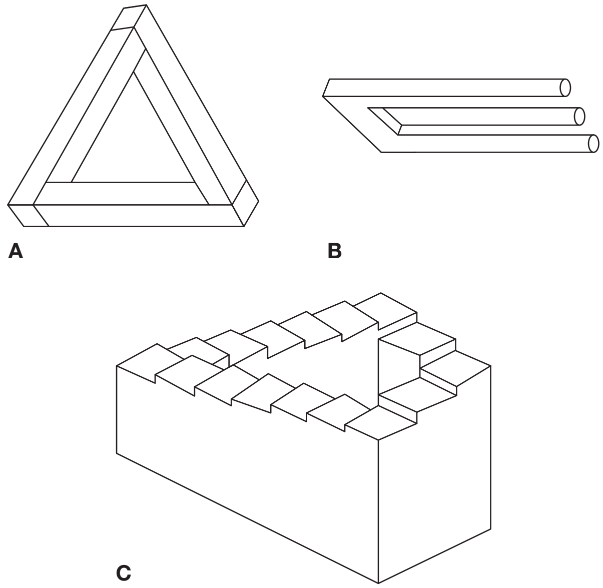

FIGURE 3.17 **Misleading pictorial cues.** These "impossible" figures only look impossible to perceivers who use pictorial cues to depth. Pictured here are **(A)** the Penrose triangle, **(B)** the devil's tuning fork, and **(C)** the Penrose stairs. The ability to identify impossible figures may not be present in infants until at least 4 months of age. Adapted from Shuwairi et al. (2007).

environment? Are their perceptions of other more novel things, such as a new kind of toy, completely unorganized, or do they seem able to interpret and understand unfamiliar things to some extent?

A strict empiricist account would hold that the newborn does not have any perceptual capacities along these lines. But we have seen that Berkeley's early empiricist view that infants have to learn depth perception from experience is incorrect. Not only do newborns of other species see objects in depth, but even human newborns rapidly develop depth perception on a reliable, regular time frame. These observations don't fit well with the empiricist account of having to learn the various ways of perceiving depth. Furthermore, it makes sense that components of depth perception would not require learning through experience, since the ability to perceive depth allows organisms the basic, necessary capacity to move through the world. But is it possible that infants' innate propensities might stop at the level of depth perception and that they need experience to learn more complex, "higher-level" types of perception, such as recognizing patterns and objects?

The idea that humans may come into the world with propensities to see only the simplest visual elements, such as angles, dots, and lines, which the brain then unites into more elaborate patterns through general laws of association, is a very old one (Helmholtz, 1866/1962). This idea resembles a method often used in the physical sciences, which involves reducing complex phenomena to a small set of "primitives," or basic components that can be combined to yield all the more complex outcomes. A purely empiricist account of using visual primitives to perceive patterns would claim that no prior biases influence the ways we form associations between primitives. Instead, the only factor determining which primitives become most closely linked in the mind would be the frequency with which we see them together in the environment. Thus, if an infant more often encountered two dots stacked vertically and enclosed by an oval shape rather than two dots side by side within an oval, that infant should become more attentive to vertical-dot ovals than to pattern configurations that resemble human faces. Alternatively, if infants do have a built-in bias to prefer face-like stimuli, they would prefer to look at patterns that resemble faces, even if they encountered those patterns less frequently than other patterns.

Pattern Perception in Other Species To understand how pattern perception develops in human infants, it is useful to consider some other species that can be more easily tested to determine whether pattern perception is possible *without* learning from experience. If pattern perception must develop from learned associations between basic visual elements, organisms would never enter the world with predispositions to perceive certain patterns. To challenge this view, we would have to study either newborn animals or those deprived of visual experience from birth to determine if there are some species that can perceive patterns even without any experience. In fact, we don't have to look very hard; many species are born with such abilities.

Consider, for example, the barnyard chicken, which must keep watch for predatory birds such as hawks. Since hawks have a highly characteristic silhouette, as shown in Figure 3.18, it might seem that the chicken's simplest pattern perception ability would simply trigger a reaction to a hawk's silhouette. Unfortunately, many chicks' environments are also populated by harmless geese with quite similar silhouettes—except for one critical difference. The hawk's head and the goose's head are on opposite sides of the same overall shape. Because the chicks need to recognize the dangerous hawk silhouette from too great a distance to make out the details of the head, they are endowed with an elegant solution: the chicks' "hawk detector" only signals danger when the silhouette moves in a direction compatible with the hawk's head placement (see Figure 3.18).

This very early pattern perception ability has been demonstrated experimentally by towing silhouettes overhead across large yards of chicks or ducks. They scatter and seek cover only when the smaller bump on the silhouette is on the leading edge of its movement (Canty & Gould, 1995; Tinbergen, 1951). Chicks will show this behavior without any prior exposure to hawks, geese, or any other predatory birds (which share a similar silhouette). Thus, the chicks have an innate ability to perceive not just a pattern but a

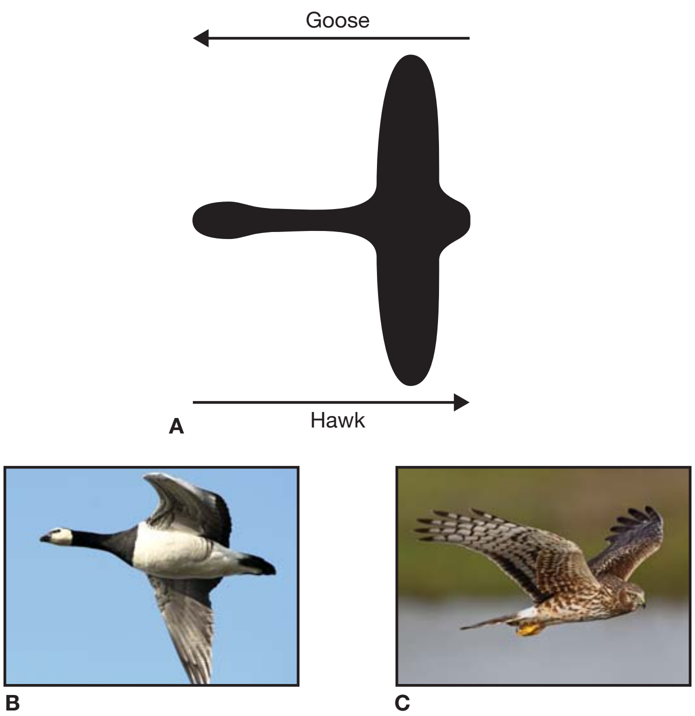

FIGURE 3.18 Innate pattern perception and avoidance of predators. **(A)** The silhouette appears as a hawk when towed to the right and as a goose when towed to the left. Barnyard chickens recognize this dynamic combination of a pattern and path of movement when they see **(B)** a goose in flight and **(C)** a hawk in flight. Silhouette adapted from Tinbergen (1951).

pattern moving in a certain direction relative to its shape. This remarkably sophisticated ability shows that not all pattern perception requires learning from experience.

A simpler example in the same species has to do with the way chicks peck at their food. Newborn chicks will not peck the same amount at all seed-size objects; their pecking rate strongly depends on the object's shape. In general, they peck more at rounded objects than at those with straight edges and sharp angles (Fantz, 1957; see Figure 3.19). This preference makes sense, given how rarely natural foods—or other things in the natural world—have straight, angular contours. This might seem strange, since chicks didn't evolve in an environment that would have required them to distinguish natural from human-made objects. But their perceptual bias is better understood not as a tendency to avoid non-natural things, but as a tendency to better perceive and act on natural ones. These built-in preferences are not for specific foods. Rather, these broad predispositions provide a "head start" in perceptual learning about natural foods that makes the learning process easier. Later work has suggested that, beyond foods, newborn chicks have quite general perceptual preferences toward displays that are physically possible as opposed to impossible (Regolin et al., 2011). As we will see in later chapters as well, rather than placing limits on what the developing organism can perceive or do, an evolutionary perspective on development can help us understand the organism's tendencies to more easily perceive or behave in certain ways.

Finally, consider the complex perceptual problem that some species of frogs need to solve to survive. They must identify nearby bugs fast enough to snatch them out of the air with the sticky end of their projectile-like tongue. We know that these frogs are able to identify edible bugs without prior experience, and we have a good grasp of the neural anatomy that enables them to do so. More than 50 years ago, neurobiologists showed that clusters of cells in the frog's retina fire when a small, bug-shaped object makes jerky, bug-like movements in the frog's field of view (Lettvin et al., 1959). Thus, even before the visual information reaches the frog's modest brain, the retina itself detects a "bug" in the environment and initiates the sequence that leads the tongue to dart out. In this case, "pattern perception" is achieved without full processing by the central nervous system, thus illustrating how pattern recognition can occur without the support of any of the systems that normally support learning in vertebrates.

Q: Give examples of visual pattern recognition abilities in nonhuman species that are present from birth.

It might seem as if this wide array of built-in mechanisms for picking out specific environmental patterns would provide powerful evidence against empiricist accounts of the development of pattern perception. But the empiricists have a strong reply when it comes to using these kinds of findings about nonhuman animals to theorize about pattern perception in humans. Consider again the frog's bug detector. Although it is marvelously efficient, it has one potentially devastating drawback for organisms that live in varied and changing environments. It is so "hard-wired" in the frog's visual system that it is inflexible and unable to deal with environmental changes. When a new type of bug that is much easier to catch and more nutritious enters the environment, the frog can only benefit if this new food source has the right properties to trigger the bug detector. Some species

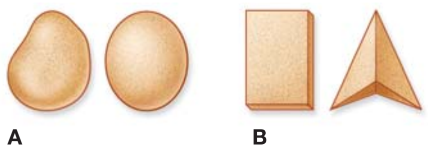

FIGURE 3.19 Perceptual bias for natural shapes. Newborn chicks prefer to peck at objects like those shown in **(A)** as opposed to those in **(B)**. In this way, they show built-in constraints on pattern perception. Adapted from Fantz (1957).

of frogs will starve in a cage full of nutritious, anesthetized bugs just like those they normally catch in the wild because the bugs are not moving and the frogs don't recognize them as food. Thus, as remarkable as these early emerging examples of pattern recognition are in other species, we need to look beyond these fixed and inflexible pattern recognition abilities to fully understand the development of pattern perception in humans. Like many animals, humans have the capacity to learn to recognize many novel patterns after having some exposure to them.

Plasticity in Perceptual Development When considering capabilities and behavioral tendencies from an evolutionary perspective, it can be helpful to think of the process of evolution by natural selection interacting with two developmental challenges that compete with each other: (1) The organism needs to be viable from birth onward, which requires that a number of systems must be immediately and continuously available, such as those that recognize food. (2) The organism needs to be able to flexibly respond to new challenges and opportunities. Thus, there is a critical tradeoff between highly efficient but inflexible abilities (like the frog's bug detector) and more adaptive, flexible abilities that may be less efficient at first but that enable the organism to adjust to environmental changes later in development. Abilities that enable an organism to adjust to environmental changes are often described as "plastic," and the potential advantages of such **plasticity** are enormous. Plastic perceptual skills also enable the organism to adjust to its own changing states over the course of development. For example, in many growing organisms, the distance between the eyes can change dramatically. In other cases, an organism may suffer damage to an eye that degrades the quality of visual input. A plastic perceptual ability could adjust to these kinds of changes as well.

The benefits of plasticity make clear a powerful tension between two different paths for perceptual development, each of which confers different advantages for the organism. One developmental course favors a newborn who is immediately able to negotiate his world, and the other course favors a developing organism who is less capable early on but becomes able to adjust flexibly to a changing world and his own changing needs. The process of natural selection has yielded different kinds of resolutions to this tension in different organisms. Some are born with powerful but inflexible systems of behavior, while others come into the world with fewer initial competencies but with considerable plasticity. More complex organisms usually develop more plasticity. For example, mammals seem able to respond to their environments with much more plasticity than insects can. We will see that human infants show great plasticity in the ways they learn to perceive not only visual patterns, but auditory patterns as well. At the same time, we will also see that this plasticity initially develops within a set of perceptual constraints that are critical for the earliest pattern perception.

Q: What are the tradeoffs between a pattern recognition ability that is fully functional at birth and one that requires considerable environmental input?

Perceptually Grouping the World Right from the start, our highly plastic perceptual abilities are guided by constraints that do not require prior learning. These perceptual frameworks help guide the growth of our more flexible, adaptive abilities to perceive patterns. These interactions between broad, foundational constraints and more plastic perceptual abilities are evident in the way that an infant comes to perceive an object's different parts as components of a single, unified whole based on **Gestalt principles**, which provide ways of distinguishing one whole object from another. Consider the objects shown in Figure 3.20, part of a series of studies that explored the infant's ability to infer the shape of an object partly hidden behind a barrier (Kellman & Spelke, 1983; Kellman et al., 1986). It turns out that infants show no preferences for the solid rod over the broken rod when the entire display is standing still. When the rod moves behind the barrier, however, the infant clearly expects it to be one object. This pattern is related to the classic Gestalt principle of *common fate*, whereby elements that move together are likely to be perceived as part of the same object (Koffka, 1935; Palmer, 1999; Wertheimer, 1958). For infants, common fate seems to provide a weaker cue than it does for adults about whether distinct parts make up a single object. If the two parts' edges are misaligned (so that the lines appear to be offset), then 4-month-olds have much

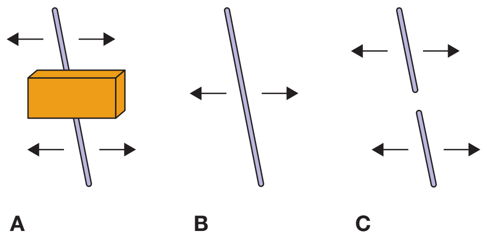

FIGURE 3.20 Perceiving object unity and common fate. When 4-month-old infants see two rod segments moving behind an occluding box **(A)**, they infer that one unbroken rod is present **(B)** and not two fragments **(C)**, even though the fragments are in some respects more similar to the original display. When the initial display is static, the same infants tend to prefer the broken rod display. Younger infants prefer the broken rod even in the dynamic condition. Newborn chicks, however, prefer the unbroken rod in the moving condition. Adapted from Kellman & Spelke (1983).

weaker expectations than adults do about the two parts being connected (Smith et al., 2003). Edge alignment is one form of another Gestalt principle known as *continuation*—that is, perceiving smoothly continuous or aligned edges as bound objects (Palmer, 1999). Young infants use both common fate and edge alignment, which reinforce each other, to yield a perception of a unified object, whereas older children and adults can easily make the same inference based on just one of those cues.

Thus, infants' depth perception and pattern perception have an important feature in common: both are greatly enhanced when the infant is looking at a dynamic, moving scene. It might seem that still images would be simpler to perceive, and in fact, some researchers suggest that newborns initially are sensitive to the static properties and need a few weeks to learn the dynamic relationships between those properties, which then override the static ones (Johnson, 2004; Slater et al., 1990, 1994, 1996). Some early theorists suggested that infants are innately endowed with the ability to use the full set of Gestalt principles, such as common fate and continuation, to group their perceptions in meaningful ways (Bower, 1971, 1974, 1979). More recent investigations of those principles have revealed two things: First, in some circumstances, young infants can use perceptual principles similar to the classic Gestalt principles to make sense of visual patterns and configurations. Second, early on they are much more prone to benefit from such visual information when it is presented in moving and/or three-dimensional contexts (Bertin & Bhatt, 2001; Johnson, 2001; Kellman & Banks, 1998; Valenza & Bulf, 2011). Young infants use a diverse set of perceptual strategies to perceive objects in the world around them.

Q: What are some perceptual features or principles that infants can use to perceive objects as bounded wholes?

Face Perception

As infants use various perceptual principles and strategies to begin to perceive and understand distinct objects, one of the objects they encounter earliest and most frequently is the human face. The ability to recognize a caregiver's face enables an infant to know where to direct his efforts for comfort or protection. The ability to tell a happy face from an angry face enables an infant to know when to approach or avoid another person. The salience of human faces in infants' lives has led researchers to ask whether young infants, and perhaps even newborns, are predisposed to process the features of a human face. Are humans born with a neural circuit that is specialized to be sensitive to face-like configurations?

Before testing whether infants can recognize particular faces or emotional expressions, researchers first sought to determine whether infants recognized the distinct configuration of human facial features. In particular, they tested whether infants responded differently to the normal arrangement of facial features than they did to a "face" in which all the standard features were present but their placement was scrambled (see Figure 3.21). Only if infants are able to distinguish between normal faces and scrambled ones does it make sense to take the next step and investigate whether they can detect differences between facial expressions or tell individuals apart.

Do newborns prefer to look at normal faces over scrambled ones? It is surprisingly difficult to find such a preference consistently, but research increasingly suggests that when their responses are measured with sufficiently sensitive experimental methods, infants do prefer normal faces (Pascalis & Kelly, 2009; Quinn & Slater, 2003). Even when the scrambled features are arranged symmetrically around a vertical centerline, like normal faces are (see Figure 3.22), newborns prefer to look at the normal face (Easterbrook et al., 1999).

When newborns show a preference for normal faces over scrambled ones, does this preference suggest that they have a perceptual system specialized for faces? Such claims are tempting, given that monkey cortex cells are tuned to monkey faces and sheep cortex cells to sheep faces (Kendrick & Baldwin, 1987; Perrett et al., 1992). Furthermore, monkeys without any prior experience with faces can recognize other individual monkeys' faces (Sugita, 2008), and they prefer faces over non-face stimuli (Sugita, 2009). The young infants in the scrambled face studies are clearly picking up on some information that distinguishes the normal faces, but some researchers argue that the infants' face preference is actually rooted in a much broader perceptual bias: newborns prefer

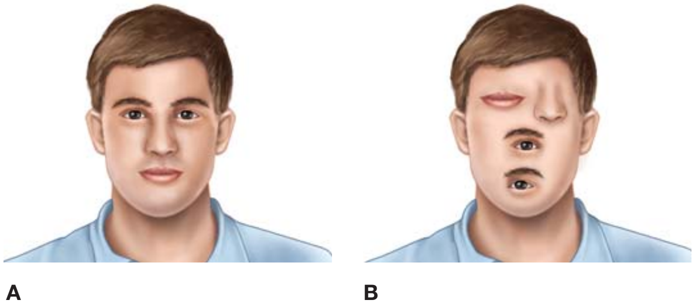

FIGURE 3.21 Normal versus scrambled faces. From 3 months on, humans immediately see a dramatic difference between faces in which features are normally configured **(A)** as opposed to scrambled **(B)**. Although it is much more difficult to show such preferences in newborn infants, most researchers today would agree that such preferences are present at birth. Adapted from Bhatt et al. (2005).

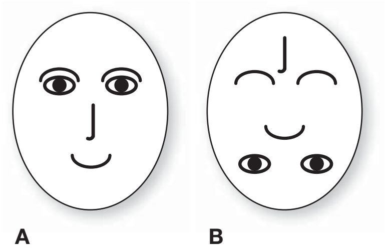

FIGURE 3.22 **Scrambled but symmetrical faces.** Even when scrambled faces are symmetrical around a vertical centerline (the way normal faces are), infants prefer **(A)** normal faces to **(B)** scrambled but symmetrical faces. Adapted from Easterbrook et al. (1999).

to look at ovals with "top-heavy" patterns—that is, arrangements with more dark features in the upper half of the oval—rather than "bottom-heavy" ovals (Macchi Cassia et al., 2004; Turati, 2004). Thus, even when the stimuli look nothing like a face, infants prefer patterns with more features packed into the top half of the figure than the bottom half. The top-heavy bias cannot account for all the ways in which newborns and young infants prefer faces (Farroni et al., 2007), but it does raise an important caution. The studies of other species are not definitive for humans. It remains a possibility that human infants are unique among primates in the extent to which they must learn about faces during the first few months of life. In addition, the preference for faces by human newborns does not seem to just be for human faces. Thus, newborn infants show no preference for human faces over monkey faces while nonetheless being able to tell them apart (Di Giorgio et al., 2012). In addition, they prefer to look at upright monkey faces over inverted faces, just as they prefer upright human faces. Taken together, these findings suggest a quite general face preference system that is somewhat abstract in nature; initially it doesn't even involve a preference for human faces but instead emphasizes a more schematic face-like pattern.

Although they show a preference for faces over many other stimuli, newborns probably perceive faces quite differently from the way older children and adults do. Moreover, they likely do a great deal of learning about faces in the first few months of life (Balas et al., 2010). Some of this learning is especially early and rapid. For example, within hours of birth, newborns start to show a visual preference for their mother's face compared with the faces of other women (Bushnell et al., 1989; Pascalis et al., 1995). Remarkably, they can recognize their mother's face from its outer features (hairstyle and head shape) without the inner features (facial expression) and also from the inner features without the outer ones (Turati et al., 2006, 2008). These abilities must be based on learning because newborns couldn't possibly know before birth how their mothers would look.

Beyond their ability to distinguish scrambled faces from normal ones, newborns can also discriminate happy expressions from fearful ones, showing a preference for happy faces (Farroni et al., 2007). They also prefer face-like stimuli over other kinds of stimuli when the face's eyes and mouth are dark relative to the background (as is true of humans from all backgrounds), but they do not show this preference when the eyes and mouth are lighter than the background (Farroni et al., 2005). As we will see shortly, they also show preferences for attractive faces over unattractive ones (Slater et al., 1998, 2000a).

Despite newborns' impressive face perception abilities, more subtle analyses of faces seem to take a few months to develop (Lee et al., 2013). For example, although newborns prefer normal faces to scrambled ones, they do not show a preference for normal faces over highly distorted faces in which the eyes are much too far apart, looking almost rabbit-like. In contrast, 3-month-olds clearly prefer normal faces over the faces that have extreme distortions (Bhatt et al., 2005). These findings suggest that newborns may have some sense of how facial features are laid out, but they have not yet developed a sensitivity to the normal spatial relations between those features, a factor that may also explain why they initially show no preference for human faces over monkey faces. Visual experience in infancy and early childhood also seems to be important to developing some of the more subtle sensitivities involved in normal face perception. The beginning of the chapter described the remarkable recovery of a girl who had minimal visual experience before having congenital cataracts removed. Studies of face perception in adults who had similar minimal visual experiences in infancy and childhood suggest that these individuals do not show some of the heightened responsiveness to facial configurations that is typical of people with normal vision in infancy and childhood. These adults can learn to recognize faces (Ostrovsky et al., 2006), but they may show permanent, subtle deficits in face-specific aspects of processing, suggesting that there may be an early critical period for developing these nuanced perceptual abilities (Le Grande et al., 2004; Putzar et al., 2010).

Another way in which newborns differ from 3-month-olds relates to biases toward faces of their culture. Newborns show no preferences for faces of their own race. But by 3 months of age, Caucasian infants prefer to look at Caucasian faces, African-American infants prefer to look at African-American faces, and 3-month-olds of other racial groups also show an own-race preference (Kelly et al., 2005, 2007a, 2009). Apparently, in their first few months, infants are learning to recognize the patterns of facial features that they see most often. These familiar patterns seem to provide them with a kind of race-specific template for interpreting faces and facial expressions, one that works especially well for novel faces of a familiar racial group.

This process of becoming attuned to same-race faces is part of a more general pattern of developmental change.

Through **perceptual narrowing**, infants increase their processing ability and precision in a narrow category, but often at the expense of processing outside that category. Thus, older infants can have more difficulty than younger infants at telling other-race faces apart (Kelly et al., 2007b, 2009). Similarly, while young infants can tell apart both individual human faces and individual monkey faces, perceptual narrowing causes older infants to show a decline in the ability to tell monkey faces apart but an improvement at distinguishing between human faces (Pascalis et al., 2002).

The same-race processing bias also interacts in an interesting way with another face bias that infants show. By 3 months of age, infants prefer to look at photos of female rather than male faces, presumably because most infants see female faces more frequently, so female faces become a more familiar category (Quinn et al., 2002). Intriguingly, this face-based bias toward the primary caregiver's gender seems to apply only to same-race faces. When Caucasian 3-month-olds were shown male and female Asian faces, they did not show the preference for female faces that they showed for female faces of their own race (Quinn et al., 2008a). The effects of perceptual narrowing can interact across categories such as race and gender. But narrowing is also continuously malleable. For example, brief daily exposure to Asian female faces can reverse the normal perceptual narrowing for Asian faces that occurs in older Caucasian infants, such that 8- to 10-month-old Caucasian infants can discriminate between different Asian faces (Anzures et al., 2012).

Development of Face Perception: A Two-System Model We have seen that newborns have a perceptual bias to process faces, but this bias is supplemented in important ways by learning in the first several months of life. One model of the early development of face perception suggests that there are initially two face perception systems developing simultaneously. This notion is partly based on the ways in which newborns seem especially sensitive to faces that are moving (see Figure 3.23). Even at less than 1 hour old, newborns use head and eye movements to track a moving picture of a face more than they will track a comparable picture of a scrambled face (Goren et al., 1975; Johnson et al., 1991). But surprisingly, after 1 month of age, infants seem to have more difficulty tracking the normal face than they had earlier, and this pattern of decline continues until around 4 months of age, at which point performance sharply rises. This pattern—an initial ability that declines and then suddenly improves—raises the possibility that two distinct face perception systems are developing (Johnson & Morton, 1991; Morton & Johnson, 1991).

This two-system theory suggests that the first system helps the newborn orient toward moving, face-like stimuli but is too crude to support more sophisticated recognition of individual faces. For example, it may only be sensitive to feature configurations that resemble an upside-down triangle, with two dots for eyes and one dot for the mouth (Johnson & Morton, 1991; Morton & Johnson, 1991). According to this view, the first rudimentary face perception system sends information to a second system that gradually emerges in the first few months of life and becomes fully functional at around 6 months. The second, more sophisticated face perception system is able to learn much more about particular facial patterns and telling individual faces apart. If the first system is especially activated by moving, normal faces, this could also explain why newborns show a strong preference for normal faces over scrambled ones

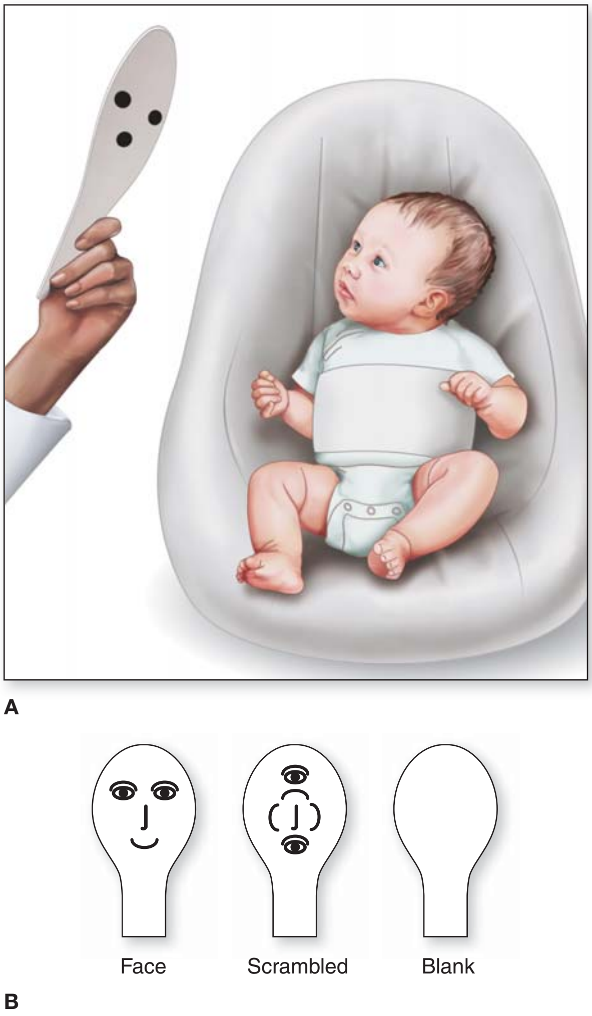

FIGURE 3.23 Tracking moving faces. (A) Newborn infants followed a moving normal face more than either a scrambled face or a blank surface as they will an inverted triangle of three dots (shown here). This ability declines after a month or so and then reemerges a few months later. Johnson and his colleagues interpreted this pattern as evidence for two face perception systems in development in which the earlier system is largely sensitive to a simple triangle configuration consisting of two eye dots with a lower mouth dot. **(B)** Stimuli showing a normal face, a scrambled face, and a blank surface. Adapted from Johnson et al. (1991).

when the faces are moving, but show a weaker preference when they are still.

The distinctive pattern of infants' face-tracking abilities is one of the earliest examples in development of a **U-shaped developmental curve**. In this developmental pattern, which we will revisit in several other domains, an early ability is supported by a rudimentary and relatively crude system. The initial ability then declines as this rudimentary system is replaced by a new system, which will eventually become more sophisticated than the first. As the new system matures and takes over the task, performance improves, so that the graph showing the changes in performance over this period of time forms a U shape (see Figure 3.24).

The two-system developmental model of face perception offers one explanation for a particular brain region becoming exclusively devoted to processing a particular kind of information, such as faces, even if that region has no innate face-processing biases. It is possible that the only innate component of an infant's ability to perceive faces is a rudimentary, crude face detection system that sends all face-related information to a particular region of the brain. This region could house a second perceptual system, which becomes specialized for processing faces because of the face-related input it receives, even though it did not initially have any neural circuits specialized for processing faces (see Figure 3.25). In this way, it is possible for an empiricist-leaning researcher to grant a very basic face detection system as "built in," but still consider the brain's more complex and sophisticated capacities, including the specialized functions of particular brain regions, to be a result of experience (Elman et al., 1996). The nativist alternative to this view argues that a much richer degree of specialization for processing faces is present in the newborn's brain from the start, perhaps in both face-processing systems.

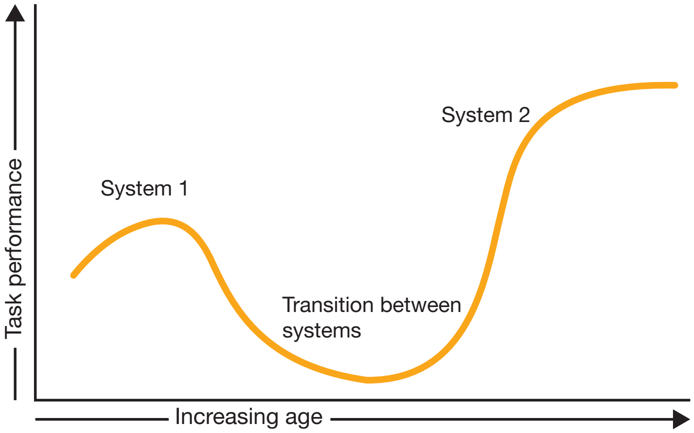

FIGURE 3.24 U-shaped curves. U-shaped developmental curves often suggest to researchers the operation of two systems. The first may be cruder but easier to initially employ. Then during the transition to the second more complex system, there is a temporary drop in performance before an even higher level is achieved. Although suggestive of two systems, it is important to note that some models can create U-shaped patterns without having to invoke two different systems.

Region of brain that receives input only from ovals with inverted triangles
A
X
Inverted triangle bias causes brain region to receive only face-like input, and the region gradually becomes specialized for faces
B

FIGURE 3.25 The emergence of a face area in the brain. **(A)** In the Morton and Johnson theory, there is no piece of neural tissue early on that has a specialized face-processing system. Instead, there is an undifferentiated area of neural tissue that receives inputs only from objects on which the dominant pattern is an inverted triangle in the shape normally created by the eyes and the mouth. **(B)** As those objects are almost always faces, over time that region of neural tissue receives only face-related information, and it gradually becomes specialized for processing faces. Damage to that region in adults might then cause a specific deficit in recognizing faces.

It is not yet clear exactly what is present in the initial "rough and ready" face-processing system. As we will see again in Chapter 4, there seems to be more at work than simply a detector for upside-down triangles or top-heavy patterns, but the two-system model still provides a useful developmental account of the way a brain region could become specialized for one kind of information without having such a bias from the start. Regardless of the details of the final account, however, researchers from the different camps agree that even newborns have some perceptual biases that lead to a preference for faces and that by 3 months, they are able to recognize specific people's faces and to engage in sophisticated processing of facial expressions.

Q: What is a U-shaped developmental curve, and why does this pattern suggest a two-system model for the development of face perception?

Facial Attractiveness Before leaving our discussion of faces, it is important to consider one bias that is present in newborns and that increases in the first few months of life—a preference for attractive faces. This preference suggests a high level of perceptual sophistication early in infancy. Adults in a community usually agree on what makes a face attractive. For many years, this consensus was thought to reflect specific cultural norms rather than innate, universal biases. Consequently, researchers believed that infants—who had not yet absorbed the beauty standards of their culture—would show no preferences between the faces that Western adults judged most and least attractive.

Quite surprisingly, however, when infants were shown pairs of college yearbook photos, with each pair including one face that adults had judged as unattractive and one face that adults had considered attractive, the infants looked longer at the attractive faces (Langlois et al., 1987, 1990, 1991). Even newborns show this preference (Slater et al., 1998, 2000a). Figure 3.26 shows some computer-synthesized examples of the sorts of faces that the infants found more and less attractive. The faces they preferred do not seem to share any common feature, which makes sense given that adults' judgments of attractiveness are based on a complex interplay of features. The infants' preferences also remain constant across faces from different racial groups and for faces of both adults and other infants (Langlois et al., 1991). In many cases, even infants who have never seen either an adult member or a baby from another ethnic group prefer faces from these unfamiliar groups that correspond to those that adults consider attractive. This pattern of broad agreement in judgments of facial attractiveness between adults and infants, including newborns and those without prior exposure to particular groups, also fits with another surprising finding: judgments of facial attractiveness do not vary much across cultures (Maret, 1983; Maret & Harling, 1985). How could this be?

Almost paradoxically, studies have shown that adults find a face with features that are uniformly average in size and arrangement—generated by mathematically averaging many digital images of individual faces—much more attractive than a real "average-looking" face (Langlois & Roggman, 1990; Langlois et al., 1990, 1991; Rubenstein et al., 1999). This is because few faces have all features and relations at the average level. There may also be a related preference for faces that are more symmetrical around the vertical axis (Rhodes et al., 1998; Thornhill & Moller, 1997). The infant's special endowment for perceiving faces may include an approximation of the arrangement of facial features and their likely proportions, and this rough facial "sketch" may give rise to infants' apparent aesthetic preference. If this is the case, infants must somehow adapt or normalize the sketch for different groups, since an average, or attractive, infant face is, of course, very different from an average adult one. In fact, 3-month-olds can even normalize nonhuman faces, preferring the cat and tiger faces that adults judge more "attractive" as well (Quinn et al., 2008b).

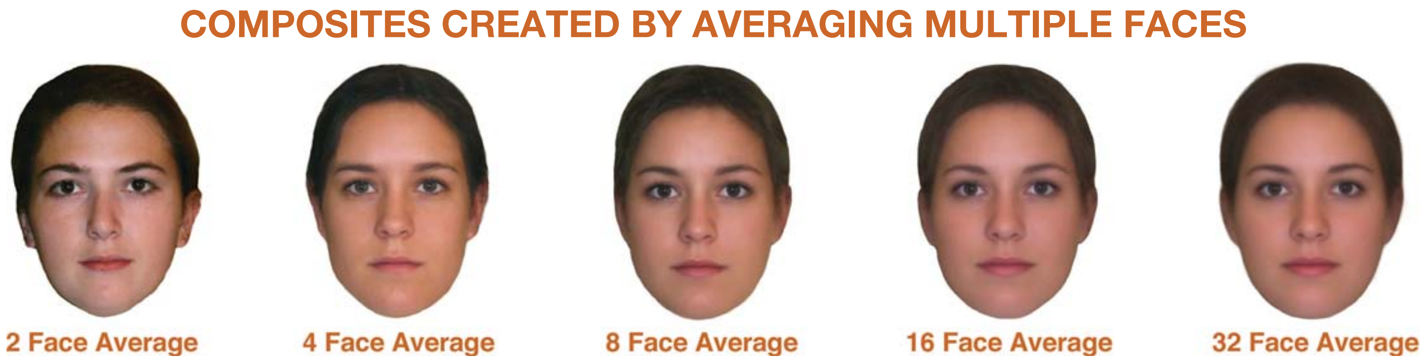

FIGURE 3.26 Facial attractiveness. Most adults agree that some of these faces are more attractive than others. These particular faces are computer-synthesized images that blend together attributes of the faces of many individuals. The computer generation of images allows for systematic manipulation of facial properties. When these sorts of faces are shown to infants as young as 6 months of age, the infants show preference patterns comparable to those of adults. One property of the images that predicts preference is the degree to which all facial features and distances between them approach an average for all faces. A face that is average in all respects turns out not to be "average-looking" at all but very attractive, even for infants. In this illustration, the most average faces are those constructed from the largest number of faces (32-face composites).

This provocative work on attractiveness may tie into deeper issues about the origins of face perception in general. If infants have an innate preference for particular feature relations and proportions, it must be abstract enough to apply to faces of all ages and backgrounds. The preference for symmetry and average features fits the evolutionary argument that members of a species should be more attracted to potential mates who appear especially healthy and therefore more likely to produce healthy offspring. According to this argument, individuals with average, symmetrical bodies and faces are more attractive because they appear to be less likely to have biological problems (Thornhill & Moller, 1997). Related processes may also motivate parents to be more attracted to healthy-looking newborns. Several studies show that adults tend to interact more positively with attractive infants (Hildebrandt & Fitzgerald, 1983; Langlois et al., 1995; Sternglanz et al., 1977). At the same time, there is now some evidence that relevant experiences with unusual faces may fine-tune attractiveness preferences, even in adults (Principe & Langlois, 2012). Thus, even when there is an innate set of biases to favor certain patterns, those biases still may be modified by experience or result in multiple sets of preferences.

Q: Why might "average" faces be more attractive, in evolutionary terms?

Hearing

A young infant is exposed to an enormous array of sounds as well as sights. From the first moments of life, babies hear the excited voices of parents and the calmer voices of medical professionals. Recall the newborn baby's first trip home from the hospital that was described at the beginning of Chapter 1. In the next few weeks, this infant will hear the voices of adults, the cries of other babies, water splashing, music playing, and dogs barking, among thousands of other sounds, often several at once. Although the study of vision has dominated research on infant perception, we also have a good understanding of the early development of the other senses, especially hearing. In fact, infants start perceiving with the other senses, including hearing, while still in the womb, giving these modalities a sensory head start over vision.

Even more important, the senses show some strikingly similar developmental patterns. Hearing offers some of the most interesting parallels with vision because using these two senses requires confronting similar kinds of perceptual problems. Just as we saw with visual information, infants must learn to categorize sounds into groups in order to make sense of an extraordinary flux of auditory information. Not every splash or bark should be a totally novel auditory event. At some point, infants need to recognize a sound as an instance of a broader category of similar sounds that share a common meaning. Before considering sound categorization, however, we must establish how and when infants notice and remember sounds.

Noticing and Remembering Sounds

Just as with vision, newborns appear ready and eager to notice the sounds they hear and to try to make sense of them. As already mentioned, their sound perception abilities are already at work before birth. The sounds a fetus hears while in the mother's uterus can instill auditory preferences that are manifested after birth (DeCasper & Fifer, 1980; DeCasper & Spence, 1986; Kisilevsky et al., 2009). For this reason, newborns already prefer their own mother's voice over the voice of a stranger, and they prefer a story that their mother read aloud during the last weeks of pregnancy over an unfamiliar story. Newborns probably recognize the distinctive patterns of low-pitched sounds in the story that they heard before birth, since low-pitched sounds penetrate most effectively into the uterus. In fact, while still in the womb, fetuses show different heart rate patterns in response to nursery rhymes that they have heard their mother read aloud repeatedly as opposed to unfamiliar nursery rhymes (DeCasper et al., 1994).

In the womb, the fetus may also start to become attuned to some of the distinctive properties of the mother's language. For example, if French newborns hear two recordings of a woman speaking, one in French and the other in Russian, they can tell the two recordings apart. A newborn whose mother speaks neither French nor Russian cannot make the same discrimination and apparently has not yet learned to hear a difference (Mehler et al., 1988; see also Kisilevsky et al., 2009).

This ability to detect contrasts between languages may arise from an evolutionarily ancient ability to detect different rhythmic patterns in sounds. Thus, Dutch and English have very similar rhythmic patterns, while Japanese, Polish, and English are all quite different from each other. Young infants have difficulty distinguishing languages with similar rhythmic patterns and find it easier to tell apart those with different rhythms (Ramus, 2002). This skill might seem to be uniquely human, since it relates to the human capacity for language, but cotton-top tamarins, a relatively primitive primate, show the same ability to distinguish between languages with different rhythmic patterns and the same tendency to confuse languages with similar rhythms (Ramus et al., 2000; Tincoff et al., 2005). Apparently, as the language capacity evolved, it incorporated this more general auditory skill to help organize linguistic patterns. In addition, infants also show early abilities to learn rhythmic patterns unrelated to language, such as preferring the musical meter that is typical of their own culture (Soley & Hannon, 2010).

Of course, infants, like the rest of us, do not pay equal attention to all the sounds they hear. Certain classes of sounds seem to stand out, even if they are not any more dramatic in terms of their physical properties. In particular, very young infants and even newborns seem to be especially attentive to human speech (Minagawa-Kawai et al., 2011; Vouloumanos & Werker, 2004, 2007). But here, too, a form of perceptual narrowing takes place early in infancy. Newborns are more attentive to monkey sounds than to synthetic sounds created to resemble speech. In contrast, 3-month-olds do not show this preference; they only prefer human speech sounds over the synthetic sounds (Vouloumanos et al., 2010).

In addition, infants are maximally attentive not just to any speech, but especially to the sort most likely to be directed at them. Researchers previously used the term "motherese" for the style of communication that people typically use with babies and young children (Newport et al., 1977), although it is also used by fathers and just about anyone else talking to an infant or young child. Such child-directed speech (more widely known as "baby talk") usually involves a higher-pitched voice, rising intonations at the ends of phrases, and longer pauses between sentences, among other properties. This kind of speech seems somehow more appropriate for interacting with infants—and research confirms this. Four-month-olds prefer to hear an unfamiliar adult's child-directed speech rather than the same person's normal adult speech pattern (Fernald, 1985), and this preference may be present as early as the first month of life (Cooper & Aslin, 1990; Cooper et al., 1997). Additional research suggests that child-directed speech helps infants detect boundaries between words by making them more salient (Thiessen et al., 2005).

Infants as young as 6 months are also able to pick up on some universal properties of communication; they can discriminate intonation patterns that indicate approval from those that indicate disapproval, regardless of the language of the speaker. Furthermore, they seem to be somewhat aware of the emotional meanings of the intonations, smiling more when the tone indicates approval and less in response to disapproval (Fernald, 1993). These findings show that infants not only attend to the speech around them, but also extract important meaning from it.

Locating Sounds

When we hear a sound, we often know its approximate location immediately, even when we are in the dark without visual clues. Only when a sound is extremely muffled, very low pitched, or heavily echoed do we become unable to locate its source. Even though we typically locate the source of sounds automatically and effortlessly, this is actually a complex task, especially given the great speed at which it is carried out. Such a skill takes considerable time and experience to develop. As we saw with face perception, infants may develop two systems to support sound localization: a crude early system and a more sophisticated later-developing system that provides a richer sense of auditory space (Muir & Clifton, 1985).

Newborns show some capacity for sound localization (Braddick & Atkinson, 1988; Muir & Clifton, 1985; Muir & Field, 1979; Wertheimer, 1963), but this early ability seems to be based on a fairly crude mechanism in the brainstem that does not provide a sense of objects' locations in an auditory space. Instead, newborns seem to rely on a simple system that registers differences in sound intensity between the two ears and then causes a reflex-like turn of the head toward the more intense sound. In this response, the infant does not seem to have a higher-level, perceptual expectation of finding an object near the location of the sound, and he does not seem surprised if he finds nothing there. At around 2 months of age, the head-turning response to sounds disappears, only to reappear at around 4 months. But at this point, the localization response has a different character. It becomes more accurate and precisely directed toward the sound's source rather than simply turning the head toward the correct side.

Sound localization abilities, then, present another instance of a U-shaped developmental curve. The infant shows a crude initial ability to localize sounds, which seems to decline briefly before reemerging in a more sophisticated form (Muir & Hains, 2004; Muir et al., 1989). Unlike the newborn, when the 4-month-old localizes a sound, he seems to have a clear expectation that something is "out there" in a particular location in space (Muir & Clifton, 1985). The development of this second, more accurate system depends not only on maturation of the relevant structures in the infant's brain but also on experience. Over time, feedback from touch and vision helps the infant to fine-tune the processing of incoming information about sounds' locations. Compared with the first system, the second system offers the benefit of increased accuracy and more explicit awareness; its costs include the additional time and experience it requires to become more accurate.

Both sound localization systems develop in close connection with infants' other perceptual abilities. In newborns, even simple, reflex-driven localization provides tremendous help in gathering information about the world. By triggering an immediate look in the general direction of a sound, this rudimentary ability enables even the youngest baby to begin learning which sights go with which sounds even before the system is fine-tuned by experience. Thus, right from the start, the infant starts to learn about objects by using several senses at once to achieve a unified perceptual experience, rather than focusing on one sense at a time. As we will see shortly,

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Cochlear Implants and the Question of Critical Periods for Auditory Processing

Although it has been known for some time that aspects of the visual system show critical-period effects, it has been more difficult to document such effects in hearing. Thanks to improving technology, researchers are now making advances in understanding critical-period effects on hearing. At the forefront of this research is work involving cochlear implants for very young children.

In response to incoming sound, the organ of corti within the inner ear stimulates the nerve cells that initially process auditory information. In most cases of total deafness, the organ of corti has been damaged. Cochlear implants are electronic devices that can be implanted in the ears to bypass the damaged organ of corti and cause stimulation of the auditory nerve fibers. The implant creates a form of hearing, the nature of which varies, depending on the age of the recipient.

As implants have been approved for younger and younger individuals, researchers have begun to ask whether there is a critical period for developing the ability to interpret the firing patterns of neurons as meaningful auditory input. Older recipients of implants are able to detect sounds through those implants, but can they learn to interpret those sounds in as sophisticated a manner as younger recipients? Or, analogous to the case of the girl whose vision was restored following cataract surgery, when the ability to receive auditory input is restored after early deafness, are there permanent effects of being deprived of auditory experience early in life?

In studies of cats that were born deaf, cats that received cochlear implants early in development showed better results than those that received implants when they were older. Those that got early implants gained higher levels of functioning in the auditory cortex, the brain area that processes sounds (Kral et al., 2002). Similarly, people who get cochlear implants in the first years of life can better distinguish between sounds than those who get the implants several years later.

Children who receive cochlear implants at younger ages usually have better outcomes (Pulsifer et al., 2003; Teoh et al., 2004a). "Younger" initially meant around 2 years of age, but more recent studies of children who get implants before age 1 suggest even better results than with 2-year-olds (Colletti et al., 2005; Dettman & Dowell, 2010; Niparko et al., 2010), suggesting a critical period in the development of some aspects of auditory perception. This critical-period effect may be largely caused by the brain's compensation plasticity (see Chapter 2). Recall that in blind people, areas of the cortex used for visual processing can become devoted to other sensory processes instead, resulting in more acute sensation in other modalities (such as hearing) to help compensate for the loss of vision. Or the visual cortex will show activation when subjects who were blind from birth or who became blind at a very early age read Braille by touching their finger to the letters (Gizewski et al., 2003). Similarly, if the auditory cortex does not receive auditory input, it can be "colonized" by other sensory functions, such as vision and touch, which help compensate for the hearing loss. By providing a different route for auditory input to reach the brain, cochlear implants may preserve the function of the auditory cortex for processing sounds (Teoh et al., 2004b).

Evidence is accumulating that the earlier the patient receives the cochlear implants, the more normal will be both her ability to distinguish between various speech sounds and her ability to articulate clearly; in fact, some neural circuits may show permanent declines in auditory and speech-processing abilities if implants are not present before roughly 4 years of age (Eisenberg et al., 2012; Kral & Sharma, 2012). (This connection between speech perception and articulation illustrates the kind of link between perception and action that we will see in more detail in Chapter 4.) Two concerns remain, however. First, the incidence of medical complications rises with implant surgery in younger and younger babies (Johr et al., 2008). Second, some members of the deaf community feel that any increased risk associated with the surgery is unacceptable, given that there is a rich and vibrant deaf culture that offers an alternative developmental path to many deaf children (Sparrow, 2010). Thus, even as the technology evolves and the critical-period effects are better documented, not all parents choose surgery for their infants.

Even adults who receive cochlear implants show some improvements that suggest an expansion of neural functioning in the auditory cortex. This pattern has been found both in adult cats (Klinke et al., 1999) and in adult humans (Teoh et al., 2004a). Thus, although it remains ideal to receive the implants as early in development as possible, they can still confer benefits to adults.

uniting the perceptual experiences from different senses may be one of the most basic ways that even the youngest infants begin making sense of the world. It is also intriguing that the second, higher-level localization system emerges around the same time that the infant becomes better able to visually perceive depth using stereopsis. As the visual ability to locate objects in depth improves, the auditory localization system seems to undergo a comparable shift.

Q: How is the sound localization ability of the newborn different from that of the 5-month-old infant?

To fully understand how sound localization systems become fine-tuned with experience, researchers need to systematically manipulate those experiences and measure the effects on a young organism's behavior and neural functioning. For ethical reasons, these sorts of experiments are not possible with human infants, which is why some of the most revealing work on the development of sound localization has been done in other organisms. For example, by studying barn owls, which are excellent at precisely locating sounds, researchers have constructed a detailed biopsychological model of the development of sound localization (Bergan & Knudsen, 2009; Knudsen, 1988, 2004). These owls localize sounds more accurately as they grow older, but even the youngest owls turn their heads in a roughly appropriate direction. This early ability suggests that they have an innate ability to infer the approximate visual location that corresponds to the sound's source. As we have seen in a number of systems, these innate abilities act as frameworks within which extensive fine-tuning of the skill occurs. For the owls, fine-tuning the sound localization system requires simultaneous experience in both vision and audition. This is the case even at the level of neurons; specific cells can respond to both auditory and visual inputs.

The fine-tuning process also demonstrates the importance of plasticity in the young owl's localization system. If the baby owl's visual or auditory experiences are distorted, either by plugging one of its ears or by placing prisms over its eyes that shift the visual world to one side (see Figure 3.27), the owl will gradually adapt and start localizing correctly again despite the distortion. When the earplugs or eye prisms are removed within a certain critical period, the owl will then initially turn its head in the wrong direction before readapting to its undistorted perceptions. By allowing the owl to adjust to perceptual problems or injuries, a plastic localization system offers real advantages over one that is fully hardwired and less responsive to feedback from the environment.

The research on barn owls has shown that there are **sensitive periods** for calibrating the system (Knudsen & Knudsen, 1990). If an owl younger than 60 days of age has one ear plugged, it will adapt and adjust the localization system. If the owl is still young when the earplug is removed, it will initially localize incorrectly but then gradually readjust, as previously described. But if the plug is not removed until the owl is 200 days old, the owl's system will become permanently inaccurate and unable to readjust. Interestingly, the sensitive-period during which the owl is able to adjust to distorted sound perceptions ends much earlier than the critical period in which the owl can readjust to its own *unaltered* perceptions. At the age of 60 days, the owl loses the ability to adjust to distorted inputs, but it can still recover from those distorted inputs for another 140 days. Readjustment becomes impossible only after around 200 days of distorted perception. The difference in these periods reflects a default bias toward the owl's unaltered perceptual experience. Owls show comparable sensitive-period effects in adjusting their visual perceptions to distortions from prisms, except that the ability to adjust to visual deviations declines more gradually than the ability to adjust to auditory distortions.

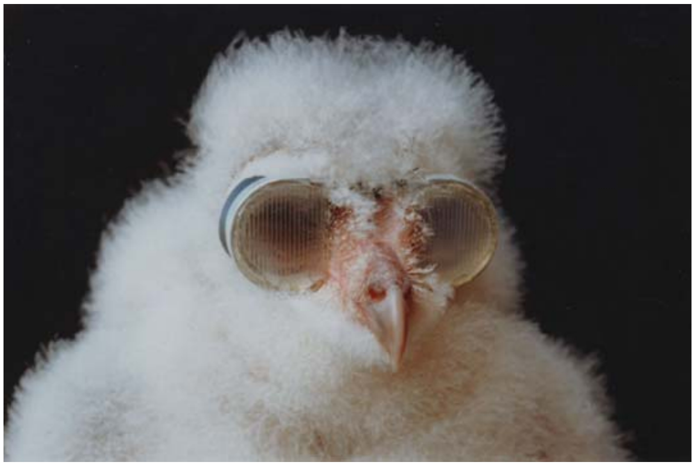

FIGURE 3.27 Effects of visual distortion on sound localization in owls. The owl uses vision to interpret auditory cues and adjusts its perception of where a sound is coming from based on what it sees. This baby barn owl is wearing prisms that make the world seem 20 degrees to the right of where it really is. If the owl wears these prisms beyond a critical period of roughly 200 days, it will have permanently "retuned" its localization of sounds based on the distortions caused by the prisms. If the prisms are then removed, the owl will forever mislocalize by 20 degrees. Because the barn owl's localization has been studied in great detail and has been linked to underlying changes in neural responses, it offers an excellent model of developmental change within a constraining framework.

Q: How does the development of auditory localization in the barn owl demonstrate both constraints on the development of this perceptual skill and its plasticity?

Perceiving Complex Sound Patterns

Some sounds, such as a bell or a snap of a finger, are relatively simple in acoustic terms. Others, such as human speech, are remarkably complex. A simple empiricist view of auditory development might propose that babies learn to perceive the sounds that are acoustically simplest first. If this were true, then to young infants, all speech sounds would initially sound the same: just an overwhelming confusion of sound components. Several decades ago, however, researchers learned that young infants seem to perceive quite a large amount of structure in speech sounds. Most dramatically, infants do not treat every different nuanced speech sound as unique. Instead, they tend to perceive discrete categories of sounds. Even though sounds' physical properties vary smoothly along a continuum, infants regard all the sounds within a category as very similar to each other and very different from the sounds in different categories. In short, infants are capable of categorical perception of speech.

Many elements of speech primarily differ from one another in terms of their values on a single dimension. For example, the sounds "ba" and "pa" only differ in terms of voice onset time (VOT), which describes the time lag between releasing your lips to define the sound and the beginning, or onset, of voicing the sound. A speaker saying "ba" voices the "ah" sound almost immediately after releasing the lips, but for "pa" there is a longer delay before voicing occurs. The average VOTs for "ba" and "pa" are shown in Figure 3.28, which also shows the similar wavelength continuum for color vision that we considered earlier.

The VOTs range along a continuum—from negative VOTs, with voicing before lip release, to positive VOTs, which occur as much as 0.2 second after lip release—but psychologically, we do not perceive these sounds as varying gradually. Instead, we group similar sounds into categories and treat the sounds within each category as basically the same. This means that to differentiate between "ba" and "pa," we hear a fairly large range of VOTs as "ba" and then, past a certain point on the continuum, we hear a large range as "pa." As Figure 3.28 shows, sounds that are within the "ba" region sound very similar despite having voice onset times 30 milliseconds apart. Yet, if two sounds on opposite sides of the "ba"/"pa" boundary are 30 milliseconds apart, they sound very different, at least to adults.

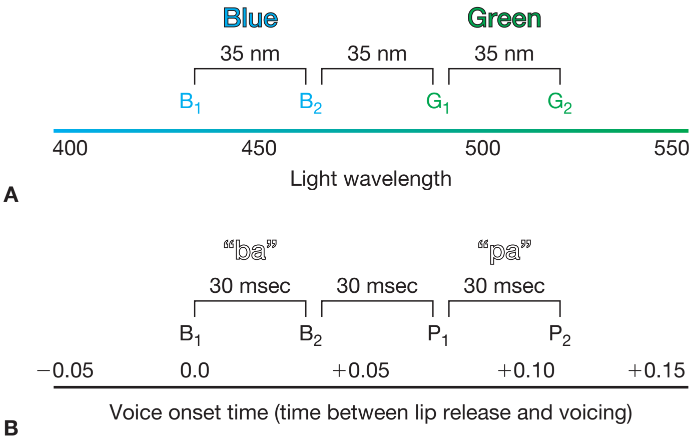

FIGURE 3.28 Categorical perception of speech. The categorical perception of speech can be understood the same way as the categorical perception of color **(A)**, except that, in this case, the physical continuum for perceiving speech **(B)** is the amount of time delay between lip release and voicing, called the voice onset time (VOT). Equal intervals of 30 milliseconds along this auditory physical continuum are not seen as the same psychologically. B_1 and B_2, both in the "ba" category, and P_1 and P_2, both in the "pa" category, are seen as much more similar to each other than B_2 and P_1, since they straddle the "ba" and "pa" categories. Even though physical distances are the same, the psychological distances are much shorter when they stay within categories rather than cross them. Even newborn infants show these categorical effects in their perception of speech.'

Q: How does the categorization of speech sounds help infants to perceive speech?

Studies of infants of all ages have attempted to understand more clearly how categorical perception of sound emerges and changes over the course of infant development. The first breakthrough study on the topic repeatedly presented the infants with an artificially synthesized "ba" sound (with a consistent VOT) whenever they sucked hard enough on a special pacifier that measured sucking intensity (Eimas et al., 1971). Over time, their sucking for that particular "ba" sound declined, presumably because they had become habituated to it. The infants would then hear one of two artificially synthesized sounds that were identical to the original "ba" sound except for differences in VOT. The two sounds differed from the original "ba" by an equal amount of VOT, but in opposite directions as shown in Figure 3.28. To adults, the sound with a shorter VOT would still sound like "ba," while the sound with the longer VOT would sound like "pa" because it falls on the other side of the category boundary. If infants had no preexisting biases to categorically perceive speech sounds, then both would sound equally distinct from the original "ba" and they would dishabituate equally to either of the new stimuli. But if the infants perceived speech sounds categorically, they would perceive the new, short-VOT sound as a second "ba," essentially the same as the first, and they would show little dishabituation to it. In contrast, they would perceive the new, long-VOT sound as "pa," and they would dishabituate more strongly. In fact, they tended to dishabituate, suggesting that very young infants do tend to cluster together speech sounds into categories, just as adults do (Eimas et al., 1987). They do not simply take in sensory data; they actively interpret sensory experience and group similar perceptions into classes, treating similar perceptions as essentially equivalent. Like adults, infants categorically perceive various sounds in the speech stream, including contrasts such as "d" versus "t" and "b" versus "g," as well as differences between vowels.

These studies were initially interpreted as indicating an innate language-processing capacity, since the infants categorically perceived speech sounds in particular. But two other lines of work soon expanded on these findings. First, researchers showed that infants also categorically perceive nonspeech sounds (Jusczyk et al., 1980, 1983). Second, researchers found that other species, such as chinchillas and macaque monkeys, also categorically perceive human speech, even though they obviously don't have brain structures specialized for it (Kuhl & Miller, 1978; Kuhl & Padden, 1982). The debate over how to interpret these findings is ongoing (Aslin et al., 1998; Gerken & Aslin, 2005; Goldstone & Hendrickson, 2010). Some researchers have proposed that infants' categorical perception of speech results from general properties characterizing most species' hearing systems (Kuhl, 1986, 2004; Samuels, 2012). Others have suggested that additional aspects of human infant speech perception support the argument for an innate speech-processing mechanism in humans, such as a special sensitivity to perceiving certain contrasts that are found only in human speech (Eimas et al., 1987).

It is clear that infants' early experience with a particular language heavily influences the way their categorical perception of speech develops. Initially, very young infants will categorically perceive a wide array of distinctions between sounds in all languages. Typically by around age 8 months, however, they lose the ability to make most of the sound discriminations that are not considered meaningful in their own native language (Kuhl, 2004; Werker, 1989). English-speaking infants, for example, lose the ability they once had to distinguish two different versions of "d" sounds that are meaningful in Hindi, while infants in Hindi-speaking cultures further sharpen that perceptual skill. Intriguingly, not all abilities to distinguish contrasts in unfamiliar languages disappear; the reason that some remain is a topic of active research and discussion (Aslin et al., 1998).

In general, experience in a given language fine-tunes the auditory perception system, so that the particular boundaries and categories that are meaningful within that language become most salient (Eimas et al., 1987; Gervain & Mehler, 2010; Werker & Tees, 2005; Werker et al., 2007). In many ways, this pattern is similar to the fine-tuning that we have seen in the development of abilities to recognize visual patterns and to localize sounds. The infant is not born with a fixed and unalterable set of categories and ways of processing them, but rather is endowed with a set of biases that are selectively fine-tuned by experience.

Above and beyond these biases, there may also be a component of speech perception that accords with a very general tendency to learn associations between stimuli that frequently occur together. For example, a critical accomplishment in the first year of life is to be able to pick out and recognize specific words in the speech stream. To see how difficult this is for the untrained ear, simply listen to a native speaker of a completely unfamiliar language; it is nearly impossible to count the number of words in any utterance. Yet, one line of work shows that by at least 8 months of age, infants start to pick out words from the speech stream solely on the basis of how often certain syllables occur together in the same order (Saffran et al., 1996a, 1996b, 2006). In these studies, infants listen to a steady stream of nonsense syllables separated by consistent time intervals and without stresses or larger sound patterns to emphasize syllable clusters. They nonetheless seem to perceive "words" in that stream if certain triads of syllables (for example, "bidaku") repeatedly occur in the same order ("bidakubidakubidakubidaku"). Quite remarkably, it only takes a few minutes of listening to such patterns for an infant to start picking out the three-syllable regularities. Moreover, they show the same ability to pick up on the syllable sequences that make up actual words in a real, but unfamiliar natural language (Pelucchi et al., 2009).

More broadly, we can see three distinct developmental patterns in the development of speech perception: (1) infants learn sensory patterns, (2) they develop universal aspects of speech perception, and (3) they develop language-specific elements of speech perception, starting at around 6 months (Kuhl, 2004). All infants start with the same general framework for interpreting speech, one that imposes considerable structure on the information in the speech stream. But soon they modify this original structure in ways that reflect the properties of their native language.

Categorical perception is not an oddity of perceptual development; instead, it may be the mind's normal way of handling an otherwise overwhelming amount of information. Even though our sensory receptors filter out vast amounts of information about the physical world, the information we do pick up varies in an extraordinary number of ways. Without

DEVELOPMENT AND SOCIAL POLICY

Legislating Early Stimulation

In 1998, following Governor Zell Miller's enthusiastic recommendation, Georgia's state legislature voted to supply a free recording of classical music to every child born in the state (Sack, 1998). The policy aimed to improve children's intellectual development through early stimulation. Miller was responding to research findings interpreted as showing that exposing infants to Mozart's music increased their intelligence and cognitive functioning (Rauscher et al., 1993, 1995). As other states took an interest in adopting similar programs, it became clear that these programs offered suppliers of the recordings substantial opportunities to profit. As a result, several companies sprang up offering musical recordings allegedly designed to enhance an infant's or toddler's intelligence with repeated listening. One enterprising company even trademarked the name "The Mozart Effect"—a reference to the research that inspired the trend—in an attempt to dominate the market.

The so-called Mozart effect had considerable intuitive appeal. It seemed appropriate that classical music, which most people view as cultured and sophisticated, would actually be good for the developing brain. Proponents of the effect even offered an explanation for the mechanism of improvement. Mozart's pieces had a rich mathematical structure (Hetland, 2000; Rauscher et al., 1993, 1995), and hearing the music's complex rhythms and patterns "exercised" brain circuits associated with spatial reasoning during a critical period of brain development. If these theories were correct, parents who deprived their children of such rich perceptual stimulation might be impairing their children's cognitive development, while parents and states that supplied Mozart recordings to all infants might have noticeably smarter children in later years. Even many years later, a cursory Internet search turns up all sorts of products making claims along these lines.

It might sound like a developmental psychologist's dream to see a policy designed and implemented in accord with developmental research. This research, however, was far less convincing than its advocates claimed. If listening to classical music has any effect on infants' cognition, it is small and short-lived, and it likely works through simply increasing the infant's alertness and attention—a property shared by lots of other stimuli, musical and otherwise. In fact, the claim that classical music, especially Mozart's, was unusually effective at enhancing intelligence was undercut by enthusiastic supporters of the effect. They claimed to find it even after exposing infants to sentimental popular music (Rideout et al., 1998), even though pop music does not seem to share the rich mathematical structure that supposedly boosts aspects of reasoning. Even worse, other researchers' attempts to replicate the initial findings of a "Mozart effect" generally have not succeeded (Chabris, 1999; McCutcheon, 2000; McKelvie & Low, 2002; Nantais & Schellenberg, 1999; Steele et al., 1999). These simple failures to replicate the findings, as well as demonstrations of a number of problems with the initial studies' experimental procedures, have repeatedly raised questions about whether the effect ever existed at all (Pietschnig et al., 2010; Schellenberg, 2005).

Although several U.S. states and some other countries proposed programs of distributing free classical music to newborns (see Figure 3.29), the proposals were rarely implemented, and Zell Miller's vision seems to no longer be part of Georgia's official activities. Yet, sales of music and videos touting the Mozart effect remain brisk, and many people firmly believe in the phenomenon. It might seem harmless, but from a public policy point of view, such misunderstandings incur real costs. Funds used to provide these materials to infants and toddlers might be better spent on more proven ways to improve their health. In addition, attempts to improve children's abilities through such "quick fixes" tend to give short shrift to educational problems that actually require much more long-term, structural support (Jones & Zigler, 2002).

FIGURE 3.29 **Newborns and music.** Newborns listened to classical music over headphones as researchers tested whether hearing music would stimulate the newborns' cognitive development. But early exposure to classical music did not lead to a significant increase in cognitive abilities.

sorting stimuli into groups that allow us to treat some inputs as roughly equivalent, we would never be able to generalize based on limited experience, recognize new but familiar instances, or otherwise process information effectively. Our perceptual systems have evolved to impose certain types of clustering that help the developing person notice important real-world differences.

Q: Why are young infants able to distinguish between some speech sounds that adults cannot?

The Chemical Senses: Taste and Smell

Although the visual and auditory senses dominate our perceptual world (as well as dominating the attention of researchers on infant perception), the chemical senses of taste and smell are also important to the way that infants perceive the world. Taste and smell are among the earliest emerging senses in the history of life, and in humans they may be functional even before birth.

Taste

Studies of the neuroanatomy and neurophysiology of fetuses in the womb suggest that taste perception functions well before birth (Beauchamp & Mennella, 2011). These studies, some of which involve physiological measures of the nerve bundles arising out of taste receptors, show that the fetus tastes the mother's amniotic fluid. The functional value that this ability serves is less clear, although it might be a way of starting to learn some distinctive things about that culture's diet, since fairly large taste-related molecules can pass from the mother's digestive system to the amniotic fluid. Thus, in some cases, the compounds that a fetus is exposed to in utero may make certain tastes more acceptable after birth. One study showed that newborn rats were more accepting of alcohol-laced liquids and other bitter compounds if their mothers were fed ethanol while pregnant (Youngentob & Glendinning, 2009). Thus, human infants whose mothers abuse alcohol may be more willing to ingest harmful compounds.

Adults are often said to have at least four basic taste categories: sweet, sour, salty, and bitter (Erickson & Covey, 1980), but infants may be less richly endowed. The ability to perceive all four of these basic tastes may take time and experience to develop. To assess taste perception in infants, researchers have adopted several strategies, which seem to converge on the finding that sweet substances play an especially important role in the life of the young infant.

Newborns and infants show a clear preference for sweet substances—not only sugar but also synthetic sweeteners such as saccharin—over other flavors. Infants can learn to suck in response to a sweet taste (Bartoshuk & Beauchamp, 1994), and sugar has a strong calming effect on very young infants, even acting as a kind of painkiller. Indeed, in the Jewish faith, it is common to have the infant suck on a rag soaked in sweet grape wine as a way of calming him during the ritual of circumcision. The practice dates back thousands of years and may reflect folk awareness of sugar's soothing effect (Blass & Hoppmeyer, 1991). As infants get to be about 1 month old, the effects of a sweet taste are amplified if the person providing the nutrition also makes eye contact with the infant (Zeifman et al., 1996). Since breast milk is quite sweet, this pattern suggests that infants' preference for sweet substances is closely linked to behaviors that calm them while nursing, which are obviously of great adaptive value.

Some assessments of early taste perception rely on correlations between facial expressions and sets of tastes. Adults clearly show distinct responses to sour, sweet, salty, and bitter (Steiner, 1979), and some evidence suggests that very young infants respond similarly (see Figure 3.30). Although we cannot know what these infants are experiencing, the relations between the substances they have tasted and their facial expressions imply that their experiences may resemble those of adults. Infants' facial responses to the four basic tastes also seem to emerge at different points in development. In line with the findings mentioned earlier, adults find it easier to identify newborns' responses to sweet substances than to bitter or sour substances (Rosenstein & Oster, 1988). It is not yet known whether newborns' less distinct responses to bitter and sour tastes reflect less ability to discriminate between these tastes or whether the infants fully sense the difference but respond with less taste-specific expressions.

The links between facial expressions and specific tastes may be evolutionarily quite old. When a wide range of primates are presented with sweet, sour, and bitter substances, they show facial responses similar to those shown by human infants (Steiner et al., 2001). It would be noteworthy enough if the great apes showed such expressions, but it is far more impressive that primates much more distantly related to humans, such as tamarins, also do. Primates more closely related to humans show more similarity to humans in their facial responses, but the overall pattern of resemblance is unmistakable.

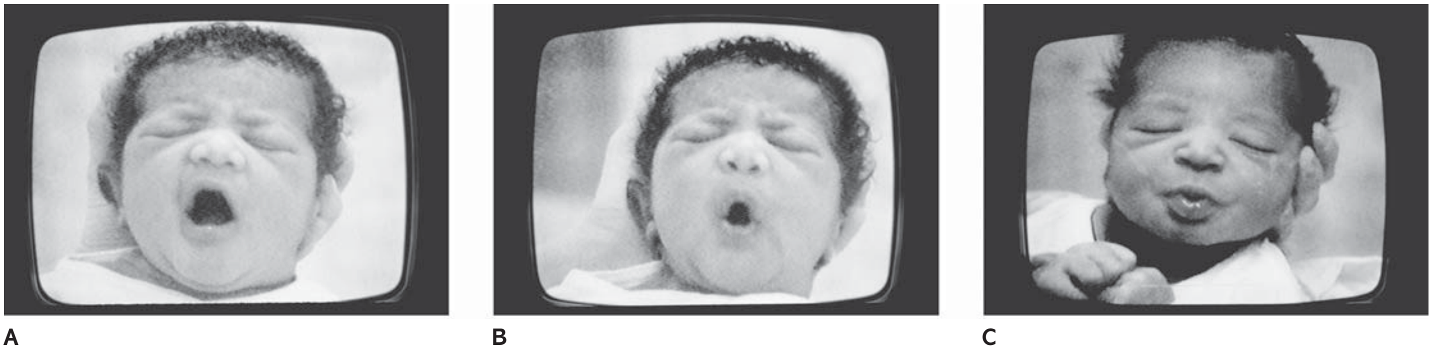

FIGURE 3.30 Facial responses to different tastes. Newborn facial responses to **(A)** bitter, **(B)** sour, and **(C)** sweet liquids. From Rosenstein & Oster (1988).

Even in the context of these evolutionary similarities, however, newborns' different facial responses to tastes should not be interpreted as evidence that links between tastes and expressions are fixed from infancy. Young infants can acquire new tastes just as adults can after experiencing new flavors. Thus, infants who drink a bitter form of synthetic formula in the first few months of life are likely to show a normal facial expression when they drink it at 7½ months. By contrast, infants who encounter that formula for the first time at 7½ months show a strong bitter reaction (Mennella et al., 2004; see Figure 3.31). Babies' ability to acquire new tastes from early experiences also suggests one possible consequence of feeding infants synthetic formulas. These formulas tend to have only one distinct taste, while breast milk has many tastes. As a result, formula-fed babies may become far less tolerant of alternative tastes (Mennella et al., 2004). Similarly, babies who are fed more fruits early on show much more tolerance for sour juices in their second year (Blossfeld et al., 2007). Above and beyond experience, babies also have some genetic dispositions either to tolerate or to reject some bitter substances such as alcohol or quinine. These dispositions interact with experience and may also be reflected in some cultural differences in diet (Mennella et al., 2005). Once again, now in the realm of taste, the complex interactions between initial genetic predispositions and the environment are essential to understanding development.

Q: To which of the basic tastes do infants seem especially responsive? Why might this preference have adaptive value?

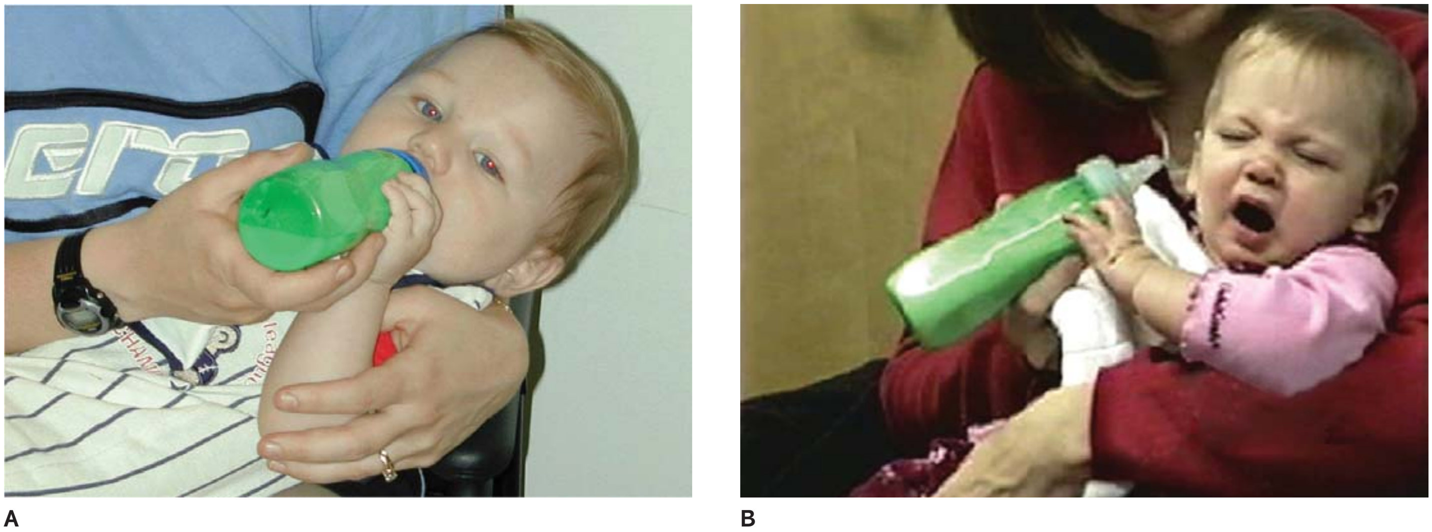

FIGURE 3.31 Acquired tastes. Quite young babies can come to have acquired tastes through early exposure. Beginning when they were 2 weeks old, infants were fed either a bitter-tasting synthetic protein formula or a milk-based formula. They were both given the bitter-tasting formula in a test procedure when they were 7 months old and had clearly different reactions. **(A)** The infant who had been fed the bitter-tasting formula over 7 months accepted the bottle without a problem. **(B)** The infant who was encountering the bitter formula for the first time made a face and pushed the bottle away.

Smell

Because there are many thousands of distinct smells, systematically studying infants' olfaction is much more difficult than studying their taste perception. Nonetheless, very young infants do seem to show clear sets of olfactory preferences (Porter & Winberg, 1999; Schaal, 1988). Within minutes after birth, newborns are particularly attracted to odors associated with their lactating mother's breasts (Porter & Winberg, 1999). Newborns also prefer the odor of breast milk to that of formula, and they show the preference by orienting more strongly to the breast milk (Marlier & Schall, 2005). Infants younger than 3 days old also clearly habituate to a wide variety of odors. One common method of studying infants' ability to differentiate smells looks at changes in their breathing patterns when they smell a novel odor and the reversion to a normal breathing pattern with habituation. Other studies have used near infrared spectroscopy (NIRS) to show that the newborn's olfactory cortex, a brain region that processes odors, is more active when the newborn smells an odor such as vanilla than when it is presented with an odorless liquid (Bartocci et al., 2000).

Taste and smell also interact powerfully during eating and drinking. For example, even though cherry Kool-Aid clearly seems to taste like cherry, it becomes indistinguishable from sugar water when its odor is blocked. Clearly, the integration of taste and smell is so automatic that it is common to misattribute the source of sensory information (Enns & Hornung, 1985). Research on the ways that taste and olfaction work together in infants is not yet far enough along to confirm the strong expectation that even newborns would seamlessly integrate information from these two senses. One intriguing study, however, potentially lends support to this idea. In adults, it is not only sweet *tastes* that have a painkilling effect; it turns out that sweet *smells* do also. The evidence that sweet smells have a similar analgesic effect on infants raises the possibility that infants also perceive sweetness with both taste and smell and, like adults, experience increased tolerance for pain in both cases (Prescott & Wilkie, 2007). These effects of sweet smells have yet to be studied directly in infants, however.

It seems likely that with further research, the sensory systems of taste and smell, which evolved long before vision and audition, will show many of the same powerful themes of perceptual development. First, the role of very early experience cannot be overlooked. Several investigators suggest that prenatal experiences with tastes and odors in the womb may heavily influence preferences at birth (Beauchamp & Mennella, 2011; Mennella & Beauchamp, 1997; Mennella et al., 2001; Youngentob & Glendinning, 2009). Furthermore, as with localization of sounds, increasing evidence at the neurophysiological level shows that experiences early in infancy serve to fine-tune taste and olfaction to different environments (Hill & Mistretta, 1990). The findings in perceptual research in other modalities also suggest some likely directions for future research in this area. With further study, categorical perception effects on early abilities to perceive tastes and smells are likely to be found. As we will see shortly with other senses, integration across sensory modalities, including taste and smell, is also likely to be found to emerge early.

Intermodal Perception

Much like the ability to visually locate a sound's source, the interactions of taste and olfaction in eating and drinking raise the more general question of how we come to perceive an object as the same thing regardless of which senses we use. When we simultaneously see and touch a hairbrush, how do we know we are acting on the same thing with both senses?

The empiricists' classic, associationist accounts would say that we gradually learn specific links, or associations, across the sensory modalities through experience (Helmholtz, 1884/1968; Spelke, 1987). According to this view, we would have to learn how the textures and contours associated with touching sharp-edged or flexible objects correlate with their visual features. The ability to use several senses to perceive a single, enduring object would take time and learning to develop—and until it did, the infant's experience of seeing an object would have no relation to the experience of touching that object. The feel of the hairbrush bristles would not lead the infant to expect a bristly appearance. By contrast, a nativist would embrace the idea that right from the start, infants might have specialized abilities to link up inputs from multiple senses to create integrated mental representations of objects.

It now seems that nativist views are more accurate and that **intermodal perception**, which fuses and integrates information across sensory modalities, may be as basic as perception itself. A newborn who turns his head to look at a novel sound is engaged in the simplest form of intermodal exploration. His response relies on neural circuits that are simultaneously tuned to visual and auditory inputs specifying location. A more dramatic demonstration of intermodal perception involves experiencing an object in one sense modality and then recognizing it using a different modality. After seeing a hairbrush among other objects on a dresser, you could easily pick out the brush from the other objects, even in total darkness. Since newborns do not tend to explore objects with their hands, they might seem likely to fail on this sort of task (Spelke, 1987). In fact, infants seem to integrate touch and vision quite well—even though they use their mouths as their primary means of touch-based exploration.

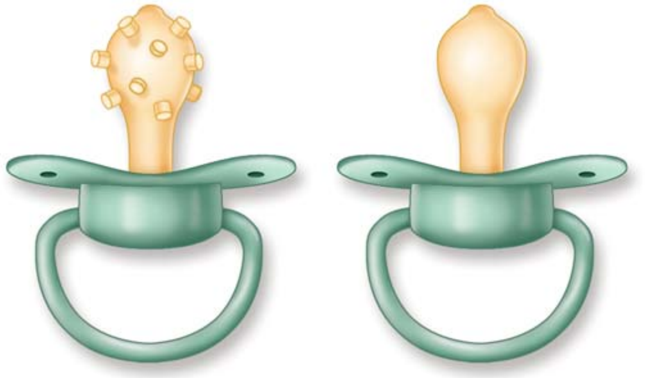

FIGURE 3.32 Integrating touch and vision. Newborn infants who mouth a particular object without seeing it, such as a nubby as opposed to a smooth pacifier, will then prefer to look at the same object they had previously mouthed when they see it for the first time. Adapted from Meltzoff & Borton (1979).

Anyone who has spent time with infants knows how quickly objects disappear into their mouths, a behavior that requires constant vigilance from parents and caregivers. This tendency may also serve as the basis of the infant's earliest intermodal perceptions. Researchers tested this possibility by having newborns suck on two textured spheres with pacifier-like handles (Figure 3.32). One sphere was smooth and the other was covered with bumps. Newborns were given one of these spheres or the other to suck on for a few minutes, but they were not allowed to see them. When researchers showed the objects to the infants and monitored their preferential looking, the infants looked longer at the object that they had previously explored with their mouth (Meltzoff & Borton, 1979). There are even some indications that despite their crude grasping abilities, newborns can integrate the feelings of objects in their hands with how those objects look (Streri & Gentaz, 2003). Interestingly, though, they may be more capable of visually recognizing an object that they previously held than of recognizing an object by touch that they previously saw (Sann & Streri, 2007). It takes several months before infants can "translate" accurately in both directions between touch and vision.

Q: Give an example of how infants use intermodal perception.

Using an experimental setup similar to the one with textured spheres, researchers found that when infants orally explore objects, they also develop expectations about how those objects move. In this case, the infants were allowed to suck and chew on disks that were either rigid or flexible and sponge-like. The researchers then showed the infants dynamic displays of two objects side by side, one moving without bending and the other flexibly deforming. Infants as young as 1 month looked longer at the object whose movement contrasted with the one they had explored earlier tactilely (Gibson & Walker, 1984). Note that unlike the study involving textured spheres, infants in this experiment looked longer at the novel object than at the familiar one. We will see that these sorts of shifts—infants sometimes looking longer at the novel object versus favoring the familiar one—are common in research on infants. Though they are curious, the infants' particular preference turns out to be less important than the finding of a clear, reliable relationship between the first experience and the preferential looking. This study also demonstrates that young infants can understand objects' different dynamic properties, such as rigidity or flexibility, even when their shape and texture visually appear identical.

Auditory-visual intermodal perception also has been explored extensively (see Scientific Research box). Many studies rely on infants' tendency to respond to a sound by looking at an object associated with that sound, even when the sound is actually coming from somewhere else. (Adults also do this; ventriloquism exploits this property of perception.) Infants turn out to be surprisingly sensitive to whether the sound they are hearing, such as a rattling sound, could plausibly be coming from the object they can see, such as a shaking glass with marbles in it. This is no small achievement considering the possible ways in which an event can be construed (Spelke, 1987).

The correspondence between sounds and their sources is not the only sound-vision relationship that interests infants. When they are as young as 5 months, infants look longer at happy faces than sad ones when a happy sound track is playing, and they look longer at sad faces while hearing sad sounds. This tendency is intimately related to sophisticated face perception; if the faces are inverted so the infants can't interpret the expressions, the infants no longer show the preference (Walker, 1982). Infants also seem to associate sounds with particular kinds of objects. When infants as young as 3 months were shown two clear cylinders side by side (Figure 3.33), they were able to link each one with the appropriate sound—the cylinder with one object making a "clunking" sound and the cylinder with multiple objects making a "clattering" sound—even though the cylinders were both turned at the same rate (Bahrick, 1988). Similarly, when infants as young as 5 months hear two qualitatively different sounds coming from behind a barrier, they expect to see two distinct objects; but when they hear two identical sounds, they have no clear expectations about one versus two objects (Brower & Wilcox, 2012). More subtle intermodal integrations, such as pairing a "clacking" with two wooden blocks banging together and a "splishing" with two sponges slapping

SCIENTIFIC METHOD: **Intersensory Perception at Birth**

Hypothesis:

Newborn infants can integrate sights and sounds for stimuli that they would not naturally encounter.

Method:

1. Newborn infants (1 to 3 days old) sat on an experimenter's lap and watched two videos of monkey faces without sound.
2. Infants then saw each of the videos with either the sound made by the monkey in that video (sound matched the video) or the sound made by the monkey in the other video. The sound came from a speaker between the two videos.
3. Experimenters recorded the infants' looking preferences when looking at the silent videos and when looking at the videos with one or the other monkey's vocalization patterns.

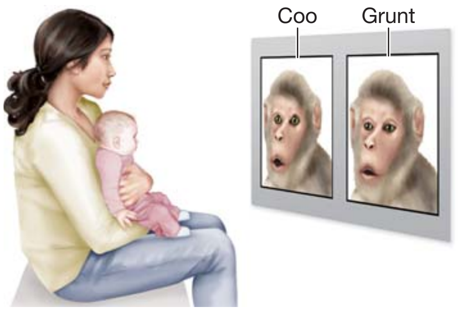
Results:

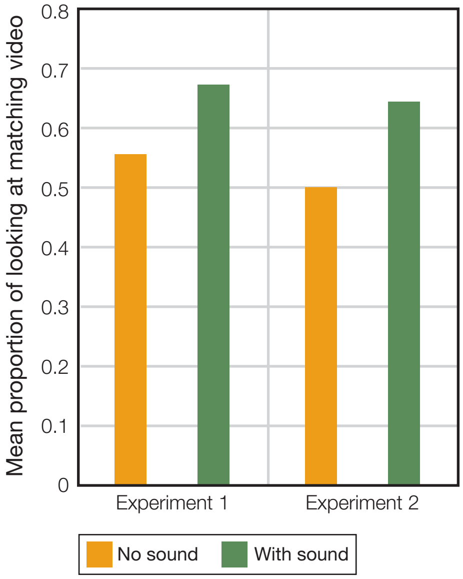
In experiment 1, newborn infants showed no significant looking preferences for either video without sound. But with sound, they looked longer at the video that matched the sound they heard. In experiment 2, they heard artificial sounds that were in synchrony with the facial expressions of one monkey and matched those as well.

Conclusion:

From the moment of birth, infants are able to map facial expressions onto sounds made by those expressions, even when they are nonhuman, suggesting a very general mechanism for matching visual events to sounds.

Source study: Lewkowicz et al. (2010).





together, take much longer to develop. They often do not appear until near the end of the first year of life (Bahrick, 1983). With more meaningful stimuli, however, such as the mother's face and voice, even newborns seem to engage in intermodal perception. Thus, when a mother's voice accompanies her own face as opposed to the face of an unfamiliar female, after just a few minutes of seeing and hearing the face, an infant will orient more to the image in which the mother's face and voice match (Sai, 2005).

Q: When do infants first seem to be able to link emotional expressions in faces to the corresponding emotional sounds?

From the broad range of examples given here, we see that even newborns integrate information across sense modalities. Based on the information they receive, they form expectations about how objects' properties go together and how an object perceived in one modality should seem when it is perceived in another. This initial integration ability also provides an essential foundation for learning more complex relations across senses. By the time they are 6 months old, for example, infants seem to know which kinds of noises an aggressive-looking dog might make as opposed to a nonaggressive dog (Flom et al., 2009). In some ways, newborns do understand and use aspects of the intricate relationships between touch and sight or between sight and sound, yet they clearly cannot perceive all of these relationships. A key question for future research is to specify the range of these earliest abilities more precisely and to learn how they are amplified and extended during early development.

Q: What is the value of intermodal perception in newborns?

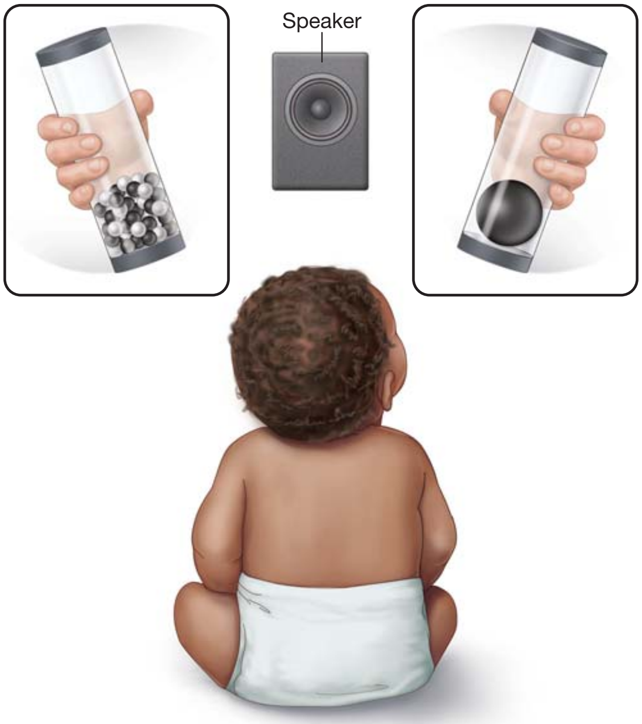


FIGURE 3.33 **Integrating sound and vision.** Even when both cylinders are turned back and forth at the same rate, 3-month-old infants know which one corresponds to a certain sound track. Adapted from Bahrick (1988).

Conclusions

We have consistently seen that infants have innate specializations within the different senses for perceiving patterns in the world, including those that integrate across the senses. These specializations do not emerge fully developed at birth. Rather, infants do a great deal of learning in order to perceive the world more accurately. One way to think about early perceptual development is that the newborn has a "head start" on understanding the informational patterns that exist in the world. This head start seems to affect all levels of processing, from experiencing sensory inputs to interpreting and integrating those experiences; but that innate capacity is not the same as having prior knowledge of the sorts of things we perceive. We are not like chickens with built-in hawk detectors, but neither are we blank slates. A basic, skeletal set of perceptual expectations guides further learning and development.

Perhaps the simplest way to characterize early perceptual development is to imagine that vision, hearing, taste, and the other perceptual systems function like curious individuals who first encounter the world with general hunches about what it is like. Since they recognize that their hunches are fallible, they initially hold only vague, sketchy expectations, and they constantly test those expectations to see how well they fit with aspects of the world. As time goes by, they adapt their hunches if they turn out to be incorrect, but they still show a bias to revert back to those hunches if information is unclear. Finally, the initial hunches are not infinitely flexible. They can be adapted to accord better with experiences of the world, but they cannot be changed in every way, shape, and form. For that reason, we and other animals are fortunate that the initial hunches capture enough of what is real about the world that they can become workable and useful. This metaphor of imagining perceptual systems as active agents helps us realize that from adults down to the tiniest infants, we are not passive perceivers of the world but active explorers. In the next chapter, we will look more directly at how the infant physically explores and interacts with the world.

STUDY AND REVIEW

SUMMARY

Vision

- Debates between nativists and empiricists in the realm of perceptual development can be understood in terms of the degree to which there are innate specializations for information beyond the processing of perceptual primitives such as brightness differences and lines and edges in the case of vision. Where specializations exist for more complex perceptual processing, such as for perceiving facial patterns, there is more support for nativist positions.
- To be able to explore questions about perception in preverbal infants, several important techniques must be used, most notably looking preferences and habituation/dishabituation paradigms.
- Even newborns have brightness discrimination abilities that serve as a foundation for higher-level perceptual skills. Their visual acuity is poor at birth, but it improves with age as the

eye grows and focuses light on the retina and as the brain areas' processing acuity become more sophisticated.

- Newborn infants have a "head start" at developing complex visual perceptual skills, such as perceiving color in terms of categories and perceiving objects in depth. This is because infants are born with a preverbal system that matures quickly to enable them to perceive universal, common color categories. They also are born with the ability to use some dynamic cues—for example, motion parallax—to perceive depth in the first month of life.
- As the early stages of depth perception illustrate, newborns undergo a great deal of developmental change as their perceptual abilities become more sophisticated. They begin to use binocular cues and then pictorial cues to more accurately perceive depth. Much of this development involves feedback loops between the developing organism and its environment. Flexible systems show plasticity and enable the organism to respond to its environment and to its own changing state over the course of development.
- Among the different types of perceptual development, the perception of visual patterns is perhaps the most complex, requiring a great deal of learning. At the same time, even newborns seem to have some basic expectations about certain visual patterns, especially the human face. A U-shaped developmental curve characterizes infants' face-tracking abilities. Some see this as evidence for an early rudimentary system of face perception in newborns that declines and then is replaced by a more sophisticated system.
- Infants prefer certain faces because they perceive them as more attractive than others, a behavior that may reflect a genetically predisposed awareness of average facial values.

Hearing

- Development of the ability to perceive sounds has many parallels to vision. Very young infants do not start out perceiving only the simplest, most basic auditory "primitives" and then combining them to perceive complex patterns, such as speech. Rather, infants can process complex speech sounds from the start, and their perceptual abilities become increasingly attuned to the types of sounds they typically hear.
- At birth, infants also have a crude system for localizing the sounds they perceive. This rudimentary early system is later supplanted by a much more precise system in yet another instance of U-shaped developmental changes.

The Chemical Senses: Taste and Smell

- Young infants can clearly distinguish between various tastes and odors, but the research in these areas has been less extensive than for vision or hearing.
- Taste perception begins in the womb and may affect infants' preference for certain tastes after birth. Newborns and infants show a clear preference for sweet substances, which calm them and can have painkilling effects.
- Newborns show preferences for certain smells, especially the odor of their mother's breast milk.

Intermodal Perception

- Right from the start, infants are able to integrate information across the senses. They seem to know how something that looks a certain way, such as bumpy, will feel. They also have been found to integrate sights and sounds. These findings provide strong evidence against extreme empiricist accounts of perceptual development because even very young infants show capacities for intermodal perception before they could have formed associations between specific sensory experiences.

THOUGHT QUESTIONS

1. What is the function of critical periods? Why should there be critical periods at all rather than continuous environmental sensitivity? Are there any functional advantages conferred on the developing organism, or are they incidental consequences of other aspects of development?
2. How does being born blind versus being born deaf affect a developing child? How do the developmental implications and challenges of being born blind differ from those involved in being born deaf? Compare both the immediate and long-term implications for the developing child.
3. What is the basis for a preference for attractive faces? Why might newborn infants have a preference for faces that adults regard as more attractive? What does such a finding tell us about how face perception develops?

Conclusions

Summary

There has been a surge of attention to the prevalence of obesity not only in children but also in infants. In 2010, U.S. First Lady Michelle Obama launched a national campaign to address what has been called an epidemic of childhood obesity. Around this time, the government of China also began voicing concerns about rising rates of childhood obesity. And in Europe, high obesity rates in infants and preschool children in some locales highlighted the large disparities among countries. Spain, for example, reported that up to 16 percent of 2-year-olds were severely overweight, while in Sweden, the rate was closer to 2 percent (Cattaneo et al., 2010).

There are many health problems linked to early childhood obesity. For example, overweight infants are more likely to eventually have diabetes, gallstones, fatty liver disease, sleep apnea, bone and joint problems, as well as a whole range of psychosocial problems (Lee, 2009). Most of these effects, however, gradually accumulate over many years and are not manifested until adulthood. It was not normally thought to be a problem if a baby was overweight; in fact, it was often seen as a sign of good health.

In one somewhat surprising way, however, researchers have found that obesity can influence an important aspect of infants' lives directly and quite dramatically—namely, their motor development. In one study of children between 3 and 18 months who were in the 90th percentile in terms of being overweight, researchers tested the infants' motor skills at frequent intervals. The overweight babies were almost two times as likely to show motor delays compared with normal-weight infants (Slining et al., 2010). For example, overweight babies tended to first walk at later ages than normal-weight babies, and the overweight babies had other delays in motor skills and coordination continuing for several months thereafter.

How could something as seemingly trivial as a little extra body fat cause substantial motor delays? Motor development is not simply a matter of a central motor control program maturing; instead, it involves interactions between central control patterns, physical properties of the limbs, and learning experiences. And as we will see, cyclical patterns and feedback loops play a critical role in these developmental processes.

In this chapter, we will explore the foundations on which early motor abilities are built, discussing such topics as reflexes, coordination of perception and action, imitation, critical periods, and conditioning. We will ask how infants progress from involuntary, reflexive actions to increasingly controlled and voluntary actions—for example, examining how infants become increasingly adept at reaching for objects and navigating space. We will explore how perception and action become increasingly integrated, asking such questions as: How do even the simplest acts of coordination develop in the infant, and how does the interplay between biological maturation and learning in infancy support the development of the fluid, effortless actions typical of older children and adults? In what ways are infants sensitive to feedback from the environment and from their own bodies as they attempt to act on the world? How do infants adjust their actions in response to feedback, and how do these adjustments occur within a set of guiding constraints? We will also see how changes in the body, such as the weight of the arms and legs, affect the emergence and coordination of motor skills. The intricate interactions between these factors enable infants to begin organizing their actions right from the start. And yet, just as we saw in the previous chapter, these rudimentary capacities are flexible enough to allow for fine-tuning, so that infants can develop their motor skills based on how their changing bodies are able to respond to what is happening in the world around them.

As we discuss each approach to the development of action, we will see that familiar themes emerge. We will consider the tradeoffs between specialization and plasticity, we will examine the extent to which different aspects of motor development depend on both innate maturation and external environmental influences, and we will discuss how feedback loops are central to the fine-tuning of behaviors.

Foundations of Motor Development

Even before birth, babies engage in clear and unmistakable actions. Virtually every mother feels her unborn child kick and move about, sometimes so dramatically that the movements are visible simply by looking at the mother's abdomen. At birth, an infant's behaviors are already quite rich and varied. A newborn can cry in a variety of ways that seem to suggest different levels of distress. He can also nurse from a nipple or bottle, albeit initially a bit clumsily. As we saw in Chapter 3, he can turn his head toward a sound and blink in response to a bright light, as well as show a variety of facial reactions to different tastes and smells. He can also imitate others' facial expressions, an ability explored in depth later in this chapter. At the same time, a newborn human infant is strikingly helpless compared with the newborns of many more precocious species. Whereas many newborn animals can walk immediately after birth, human infants cannot walk until they are around 1 year old. A human newborn cannot even roll over or lift up his head when lying on his stomach. How does a newborn progress from such an apparently helpless state to become an active toddler? What are the foundations of motor development? To begin with, infants are born with reflexes that enable them to react before they are capable of more directed action.

Reflexes in Infancy

Some of the most noticeable actions performed by the young infant are built-in **reflexes**, which are automatic responses to particular forms of stimulation (see Figure 4.1). Normal infants exhibit these reflexes so reliably that physicians routinely use them to monitor the development in the baby's nervous system and to diagnose possible problems. Some of the most common reflexes are the **patellar reflex**, or "knee jerk reflex," in which tapping a tendon below the kneecap causes the lower leg to kick; the **rooting reflex**, in which brushing an object against the face causes a newborn to move his mouth toward the object and attempt sucking; the **grasp reflex**, in which touching the newborn's palm causes him to grasp tightly; the **stepping reflex**, in which gently lowering the baby feet-first to a surface triggers automatic stepping movements; and finally the **Moro reflex**, in which experiencing a lack of support causes a baby's arms to move out to the sides (Moro, 1918).

These reflexes make adaptive sense for getting infants through their first year or so of life. The patellar reflex is thought to be essential for maintaining balance and posture by triggering a quick response when a tendon is suddenly stretched. When the doctor's tap—or more naturalistically, a quick change in leg angle—suddenly stretches the tendon, the leg muscles compensate for the stretch by contracting. The elbow and other joints show the same kind of reflex, which is common to most vertebrates. The rooting reflex helps the newborn "home in" on his mother's nipples and is widely shared among mammals. Without rooting and sucking reflexes, a newborn would have difficulty eating and surviving. The grasp reflex triggers newborns to wrap their fingers around an object after sensing contact, and many infants' grip is strong enough to support their own weight. This reflex is found early on in many mammals for which such a holding action is important to survival. In human infants, it disappears after a few months. The stepping reflex supports the development of the rhythmic alternation of the limbs for walking, not just in humans but also in species that walk on all four limbs. The Moro reflex is one of the newborn's more complex reflexes. One well-known way of eliciting it involves initially holding the newborn firmly with one hand under the center of his back and the other hand under his head, then dropping the hand under the baby's head. When the hand under the baby's head is abruptly dropped downward (but only a small drop so as not to injure the baby), the baby's arms fly out to each side and then return to the centerline of his body. A common interpretation of this action is that it causes the infant to reflexively grasp his caregiver if he feels himself suddenly falling. Although some reflexes may be just vestiges of responses that were adaptive to our evolutionary ancestors, most still serve important functions.

A distinctive feature of many reflexes in newborns, such as the Moro reflex and the stepping reflex, is that they gradually disappear in the first few months of life. In the first half of the twentieth century, some researchers interpreted this disappearance of inborn reflexes as evidence that key aspects of motor development depend entirely on changes in the brain. They proposed that as specific regions of the cortex mature, these regions increasingly inhibit the activity of lower-level brain structures, which they believed are responsible for early reflexes. In support of this view, they cited evidence that the brain grows considerably larger and its neuronal branching becomes more complex over the first year of life (Conel, 1939–1959). In particular, growth in the brain's frontal cortex and the increasing interconnectedness of regions such as the motor cortex and other structures related to reflexes were all cited as evidence that motor development is a matter of increased inhibition and greater control of reflexes.

But does motor development in infants actually consist of little more than bundles of reflexes waiting to come under the control of higher-level mental functions? There are several reasons to believe that this is not the case. As we will see in more detail in the next section, the reasons

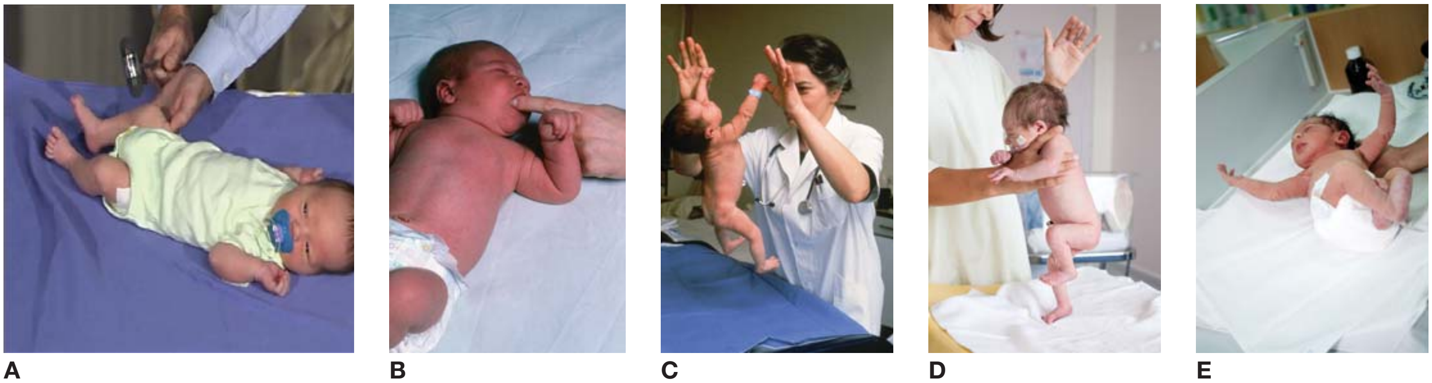

FIGURE 4.1 Reflexes in newborns. Healthy young infants show a wide range of reflexes. Some of these reflexes appear to vanish after the first few months of life, but in many cases they are still present in altered forms that are the result of changing anatomy. **(A)** Patellar reflex. **(B)** Rooting reflex. **(C)** Grasp reflex. **(D)** Stepping reflex. **(E)** Moro reflex.

that many early reflexes disappear have less to do with centralized developments in the brain and more to do with peripheral or bodily factors, like muscle strength or the size of the limbs, and the environment in which the infant is functioning. Furthermore, some reflexes may only seem to disappear, when they actually are still present but are being manifested in a different way, as we will see when we consider the effects of the changing weight of an infant's limbs as he matures. For example, researcher Esther Thelen demonstrated that contrary to the long-held belief that the stepping reflex ceases to exist, it actually becomes manifested in a different form as a "kicking reflex." By careful analyses of videotapes and measures of muscle actions in kicking and stepping by infants, she showed that they are essentially the same actions and that the movements change as a function of changes in the muscles and bones in the legs (Thelen & Fisher, 1982). We now turn to a discussion of theories of motor development to see more on how different researchers explain how infants become capable of various kinds of directed movement.

Q: Describe three reflexes that are present at birth, and explain how they change over the first few months of development.

FIGURE 4.2 Emerging motor skills. The infant's first steps are a highly precarious enterprise with failure and discomfort from falls being commonplace. That babies continue to try to walk suggests a powerful underlying motivation that overrides immediate negative consequences.

Theories of Motor Development

Imagine a 13-month-old toddling about her parents' house, carrying various objects—sometimes alarmingly heavy and fragile ones (see Figure 4.2). Two weeks earlier she couldn't take a single unsupported step. This dramatic change may appear to resemble a tadpole-to-frog metamorphosis in the sense that it seems to be driven by an internal timetable of maturation that is relatively uninfluenced by practice or experience. In reality, however, this classic view is largely incorrect.

One of the earliest endeavors in developmental psychology was to construct charts and tables showing the average ages at which children meet common motor development milestones, such as sitting up, crawling, and walking (Bayley, 1935; Dennis & Dennis, 1940; Gesell & Ilg, 1949; McGraw, 1943; Shirley, 1931). Traditional charts showed the sequence of milestones as pretty much the same across all children. Thus, they indicated that almost all children are able to roll over before they can sit up, and sit up before they can walk. They also showed all children as reaching each milestone at roughly the same average ages (for example, sitting with support at 4 months, sitting alone at 7 months, creeping at 10 months, and walking alone at 15 months; Shirley, 1931). More recent descriptions take care to show the age range in which particular motor skills normally appear in order to provide a sense of the typical variations, as well as the mean ages of these motor milestones (see Figure 4.3). They also recognize that not all motor developments necessarily unfold on the same, set timeline. A relatively late walker might not be a relatively late grasper of objects, because different factors, such as overall body weight (as noted in the opening to the chapter), might cause delays in development in walking but not in grasping.

Q: What is the normal sequence of motor milestones in the first 18 months of life?

The Maturational Account Even the early studies of motor development in the late nineteenth century showed that experience has relatively little effect on when motor skills first appear; certain skills always seem to emerge at around the same points in development. At that time, the explanation for this consistency closely resembled the brain-based interpretation of infants' "disappearing" reflexes. That is, the highly reliable timing of particular motor milestones suggested that motor development depends entirely on the increasing sophistication of the cortex and its ability to orchestrate the timing and intensity of muscle

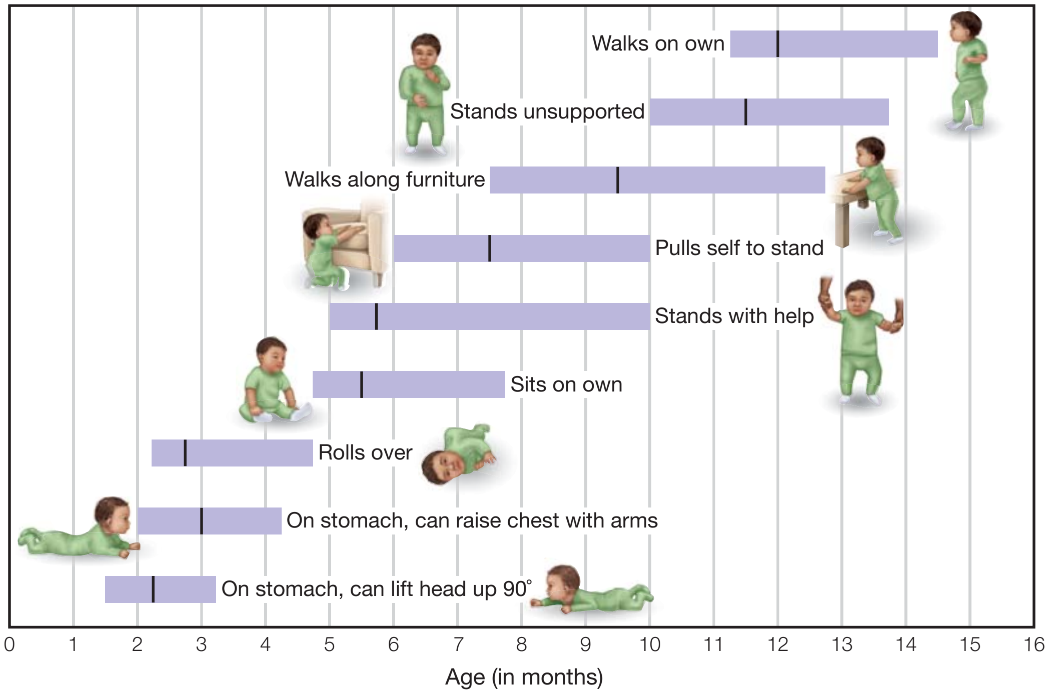

FIGURE 4.3 Motor milestones. Recent depictions of motor milestones show normal ranges within which each behavior appears. Each bar begins with the age at which the behavior has appeared in 25 percent of infants and ends with the age at which the behavior has appeared in 90 percent of infants; the vertical bar indicates the age at which the behavior has appeared in 50 percent of infants. In contrast to earlier views, these ranges reveal considerable variation in when a skill, such as walking alone, first appears. Adapted from Frankenburg et al. (1981).

movements. The first report along these lines was made by William Preyer, who, like many overeager parents, spent a great deal of time trying to teach his own son to walk before his son was a year old. Unlike most parents who have made similar attempts, Preyer wrote up the results of his labors, sadly reporting that not only did his son not walk any earlier than normal, but his final date of walking was actually a bit later than that of most other children (Preyer, 1888).

The proponents of the **maturational account** of motor development generally held that motor development depends on the increasing sophistication of the brain's motor programs for guiding more and more complex actions. They argued that a baby cannot walk before 1 year of age because the brain structures involved in guiding motor action are still too immature to coordinate the movements that enable walking. Training supposedly doesn't have much of an effect before a certain age because it has no functional cortical circuits to rely on.

The most influential advocate of the maturational account was Arnold Gesell. His landmark study involved the emergence of stair climbing ability in identical twin girls (Gesell & Thompson, 1929; see Figure 4.4). At the age of 46 weeks (about 11 months), one twin began daily practice at climbing five stairs. She made little progress for the first few weeks, but at around 50 weeks she quickly became able to climb the stairs, and by 52 weeks she could do it in less than half a minute. During this same period, the other twin had no practice. She was introduced to stairs for the first time at the end of 52 weeks—at which point she immediately climbed the stairs unaided, almost as rapidly as her sister. Similar studies on other early motor skills showed that extensive training before a child was "ready" had little or no effect. These sorts of findings led many researchers in the 1930s and 1940s to assume that motor development was largely a preprogrammed affair governed by maturational timetables and unaffected by experience.

Q: What was the conclusion drawn from Gesell's stair climbing studies with infants?

Additional evidence for the maturational account came from observational studies of infants who showed relatively normal motor development despite their **motor deprivation**—that is, their limited motor experience. One well-known study examined motor development in Hopi infants who were bound to a cradleboard for parts of the day, especially when they were asleep (Dennis & Dennis, 1940; see Figure 4.5). Although these infants had less motor experience than others, they showed almost no motor development delays. Subsequent to those studies, researchers have found that truly devastating environments, such as understaffed orphanages where infants are left lying in cribs all day (see Chapter 6), can cause extensive delays in motor development (Dennis & Najarian, 1957), but even these early impairments are typically reversible. In fact, there are some indications that tightly swaddling infants, a practice found across an enormous range of cultures over the course of history, may help them to sleep and protect them from the cold without negatively affecting motor development (van Sleuwen et al., 2007).

FIGURE 4.4 **Learning to climb stairs.** Gesell's twin studies suggested that the age at which children learn a new motor skill, such as climbing stairs, is mostly a consequence of maturation rather than learning.

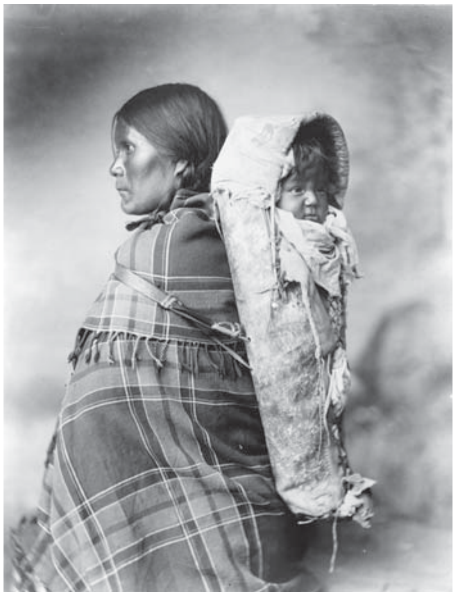

FIGURE 4.5 **Motor deprivation and motor development.** Native American infants were believed to spend much of their early lives immobilized on "cradleboards," raising questions about the importance of experience to motor development. Although they were immobilized during parts of the day, they were actually not immobilized most of the time and did not experience delays in their motor development.

Dynamic Systems Theory Since the 1970s, a new wave of research has largely replaced the maturational account. The new research was partly inspired by two new perspectives on movement. The first of these was developed by Eleanor Gibson (whose visual cliff studies were discussed in Chapter 3) and her husband, James Gibson. The Gibsons emphasized the constant interplay between perception and movement and the importance of this link for carrying out real-world actions. Thus, they believed that perception provides a context and a goal for an action, and the action then leads to the modification of a perception. You perceive your environment and then walk with the goal of maneuvering through that environment, so negotiating the environment is the action to be explained, not simply walking for the sake of walking. Similarly, you perceive a person who is running, and whether you are fleeing or pursuing that person significantly affects your own running. The Gibsons put motor development into the larger context of related changes in perception, attention, and the physical body, which work together to support more sophisticated actions.

The second perspective that helped launch the new wave of research arose from the work of the Russian researcher Nikolai Bernstein (Bernstein, 1967). Bernstein suggested that our actions are complex and orderly not just because of the brain's well-calibrated control of the body, but also because of the physical properties of our body parts and their interactions, including the size of the limbs, the way the joints work, and how different parts move together. In this account, the changes that occur in the shift from walking to running involve more than just implementing a different set of instructions from the brain. Instead, Bernstein argued, as the limbs move faster, the pattern of movements used to walk becomes unstable while the pattern of movements in a typical run becomes stable. There are strong constraints on the nature and organization of limb motion and on the speeds at which particular kinds of motions can stably occur. Notice, for example, the difficulty of running very slowly or walking very fast.

These two perspectives on movement led to a series of innovative experiments designed to explore how perception and action might be interwoven into one "dynamic system," in which each continues to affect the other, and how the parts of the body itself physically constrain and organize actions. Some developmental psychologists have therefore come to embrace what is known as **dynamic systems theory**, the idea that the development of complex behaviors should be understood in terms of the interactions among all the changing components involved in executing the behaviors, and not just as sets of instructions sent from the cortex and carried out by the body. Thus, we need to take into account anatomy at the levels of individual muscles and bones, limbs, and the body as a whole, as well as the involvement of the peripheral and central nervous systems, and finally the broader context in which an action is occurring, such as whether an infant is wearing bulky clothes, is lifting a heavy object, or has a particular goal. Taken together, all these components make up a dynamic system, which can result in seemingly rapid and qualitative changes in behaviors as small components of the overall system change.

One set of studies by Esther Thelen had a particularly dramatic effect on the view that emerging central motor programs are the prime determinants of walking (Thelen, 1995, 2001; Thelen & Fisher, 1982; Thelen et al., 1984). As mentioned earlier, Thelen focused on the disappearance of the stepping reflex a few weeks after birth. Traditionally, this disappearance had been attributed entirely to brain development. Recall that earlier researchers theorized that the reflex is governed by a simple, lower-level motor program and that as more complex, higher-level brain structures develop, they inhibit the initial reflex. Then, as the higher-level cortical structures become more sophisticated, they reorganize the stepping reflex and cause it to reemerge later as a component of normal walking.

In line with dynamic systems theory, Thelen wondered if physical properties of the limbs themselves also contribute to the reflex's apparent disappearance and whether the stepping reflex might actually have a connection with later, voluntary stepping. To see how the weight of the limbs might affect infants' stepping reflex, she conducted several studies that involved changing the weight of the limbs. One study involved 1-month-old infants, whose stepping reflex had disappeared. When the infants were gently supported in a walking position in a small tank of lukewarm water (see Figure 4.6), the buoyancy supported the weight of their legs, and they made reflexive stepping motions.

In addition, when younger babies who still showed the stepping reflex had tiny weights attached to their legs—approximating the additional weight of the limbs of older infants who lose the stepping reflex—these infants lost the reflex as well. This finding suggested that the reflex normally disappears as a result of changes in the physical dynamics of the limb, not because of changes in brain development. More specifically, Thelen discovered that the legs of older infants gained weight in fat without corresponding muscle increases. This line of research also explains the finding mentioned at the beginning of this chapter that obese infants walk considerably later than infants of normal weight. Even though the additional weight may seem inconsequential, an infant's motor development depends on just the right proportions of muscles and joint weights, so a little extra baby fat can cause substantial delays in walking.

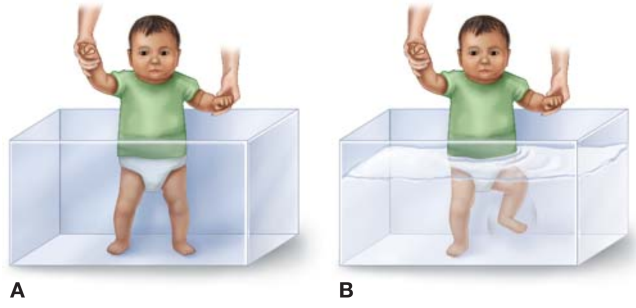

FIGURE 4.6 Physical constraints and motor skills. (A) When 1-month-old infants whose stepping reflex had disappeared were put in an empty tank and supported in an upright position, they did not make stepping movements. **(B)** When these same infants were supported in a tank of water, the buoyancy of the water lightened their limbs, and stepping and walking actions appeared spontaneously. These results suggest that physical constraints of the limbs, rather than central motor programs, may be a primary factor in the developmental changes of many motor skills.

Thelen analyzed the infants' dynamic patterns of leg movements, both during the stepping reflex and when they kicked their legs while lying on their back. In both cases, the timing and pattern of movements across muscle groups were nearly identical, suggesting that these two actions emerge from a common motor system, rather than granting the reflex a separate status.

Q: How does the weight of the limbs influence the development of motor skills?

Thelen's studies demonstrated that a complex action can be made to appear or disappear at many different times in infancy by simply changing the weight of the limbs. This finding makes the earlier maturational account—that an early reflex is inhibited by higher-level cortical developments only to reemerge when it is incorporated into a cortically controlled action—less plausible.

Following Nikolai Bernstein's thinking, Thelen felt that central motor programs are less important for explaining developmental change than the growth of the body parts that perform the actions (the bones, joints, and muscles) and their stable, coordinated patterns of motion. Thelen argued that babies incorporate particular motions into their voluntary actions if and when the timing pattern of the components is especially stable for a limb and its joints (Thelen, 1995). Just as it is difficult to run very slowly, Thelen argued that it is difficult to add certain motions to one's repertoire of voluntary actions until the various muscles are the right strength, the limb parts are the right weight, and the pattern of the movement is at the right speed.

Of course, Thelen's studies and others like them don't do away with the need for cortical structures that help guide actions. They just broaden the focus to include the developing body as well as the brain within a larger dynamic system. More generally, dynamic systems theory emphasizes the development of motor skills as a result of different interacting constraints: brain-based motor programs, physical properties of the body, features of the environment, and goals of the task at hand (Bertenthal & Clifton, 1998; Spencer et al., 2011; Thelen & Smith, 1998). In the development of action, the coordinated movements of muscles comprise just one part of a larger, integrated system.

Perception and Action

We have seen how the development of increasingly sophisticated motor routines involves the integration of several components involving both the brain and the body. In most cases, such actions are also integrated with perception of the environment and of oneself in that environment. An infant has to coordinate her actions with what she sees. Ultimately, she will become quite accurate at, for example, quickly putting her finger on a small object that she sees. Action and perception are intimately interwoven, and the infant has to learn to guide her voluntary actions by her perceptions and then to modify her perceptions based on her actions. Striking achievements in **perceptual-motor development**, which requires coordinating actions with perceptual information, depend on sophisticated systems to address complex developmental challenges. Perceptual-motor skills develop from the earliest moments of infancy and may continue to be refined to the highest levels of expertise, as in the dexterity of a concert pianist. Development and refinement of motor skills always involve feedback loops between actions and perception. You perform an action, perceive the result, and adjust your next action accordingly. Through this cycle, the action is refined and tuned. Even a single action, such as picking up a squirming puppy, can involve cycling feedback loops, as you adjust your hand position and arm motion to keep hold of the puppy.

Coordination in Changing Bodies

The squirrel jumping from branch to branch in a tree, the frog capturing a fly in midair with its tongue, and the child catching a ball in one hand have all developed a rapid, effortless coordination between vision and action (see Figure 4.7). All of them have developed these systems in bodies whose dimensions have changed dramatically over the course of their development. Consider a typical 13-month-old boy. He has yet to master many aspects of motor coordination, but he can quickly touch objects that he sees, no matter how his head is oriented or his body is turned. When he sees an object that is straight ahead of him, he moves his arms directly out in front of his body to touch it. When he looks over his right shoulder and spots another object, he does not move his arms in front of his body, but instead naturally and without hesitation reaches to his side and slightly behind his back to touch it. Infants engage with the world this way so often that we hardly stop to think about it. Yet, it involves coordination of the position of the eyes in the head, the head on the torso, and the torso with respect to the rest of the body. Meanwhile, all body parts must constantly update their locations with respect to the other body parts, and that information must be coordinated with information about objects' locations in space.

Infants successfully face the challenge of using their vision to rapidly locate objects in space and then use that information to direct motor actions at those objects. But infants accomplish an even more daunting feat: they coordinate vision and action while all their body parts continuously change. Think back to your clumsiest moments as a growing teenager. The challenge of coordination for infants is many times worse. Figure 4.8 shows how the proportions of the human body change from before birth to maturity. The adult's legs are three times longer than the newborn's. At the same time, the size and position of the head change considerably. A vast array of developing organisms must integrate perception with action under such changing conditions; very few, if any, main-

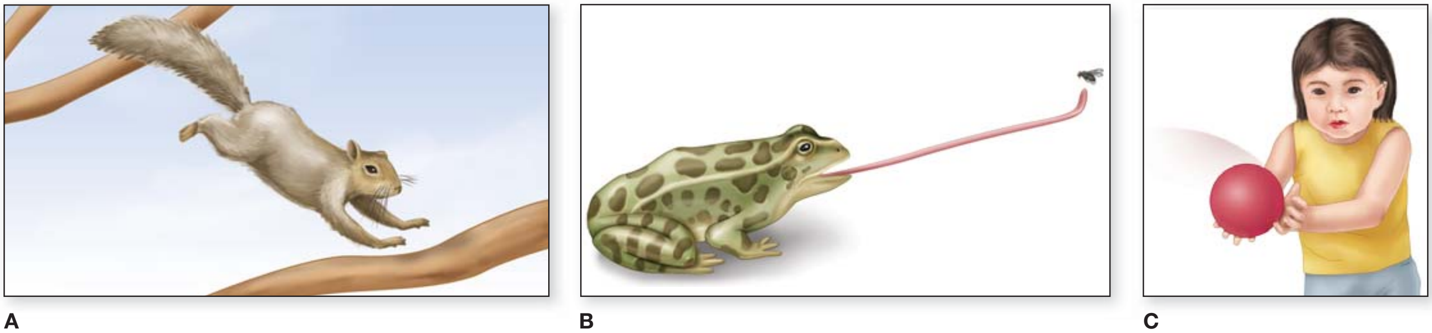

FIGURE 4.7 Perceptual-motor coordination. (A) A squirrel jumping from branch to branch in a tree, **(B)** a frog catching a fly with its tongue, and **(C)** a toddler catching a ball are all examples of perceptual-motor coordination.

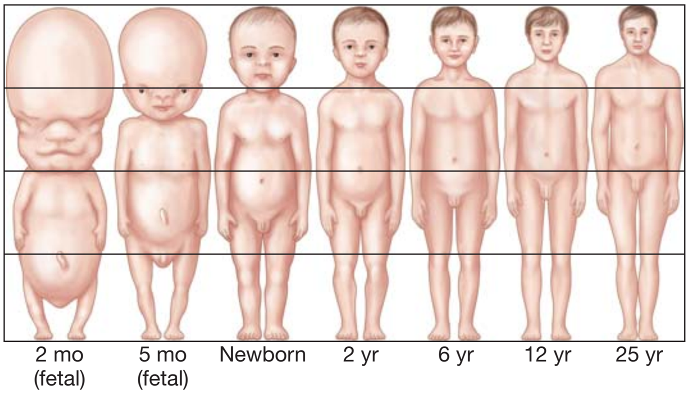

FIGURE 4.8 Changing bodily proportions. The relative lengths of body parts change dramatically with increasing age. An adult human's legs are one-half of the total body length, while a newborn's legs are about one-third of the total body length. A newborn human's head is more than twice as big relative to its body as is the adult head. In other animals, even more dramatic ratio changes can occur. Adapted from Robbins et al. (1928).

tain constant body proportions throughout development. To further examine the perceptual-motor system and the changing body, we now turn to a discussion of reaching and the development of eye-limb coordination.

Q: Describe the changes in relative size of body parts from before birth to adulthood.

Reaching

Many newborns do not touch much besides their own bodies, their clothes, and the bodies and clothes of their caregivers. Most of the time, both in experiments and in daily life, newborns fail to touch the objects they are trying to reach. These mostly failed attempts to touch objects are sometimes called **prereaching**. For example, infants younger than 2 months have trouble moving a hand horizontally across the front of their body (for example, moving the left hand to the body's right side). Researchers used to think that infants could not reach across the middle of the body because of an immature central nervous system or spinal cord (Provine & Westerman, 1979). But closer examination of infants who were reaching for objects with both hands suggested that infants start to reach across the middle of the body when they begin using both hands to try to hold onto larger objects, not because of a change in brain systems (Savelsbergh et al., 2003). That is, the goal of holding objects with both hands may provide a context for practicing and improving reaches across the body. Only at around 17 weeks are infants able to easily grasp an object with both hands at once. By 18 months, however, they are favoring one hand over another as they reach for objects based on genetic handedness biases (see Scientific Method box).

Empiricist View of Eye-Limb Coordination How do infants develop eye-limb coordination? The empiricist account would suggest that the infant starts out with no such coordination and develops it by learning from experience. In this view, infants would initially move their limbs without regard to what they saw. Then, gradually, learning through trial and error, infants would come to associate certain sensations in the muscles and joints with certain patterns of visual input and would start to be able to move their hands toward what they saw. This same idea underlies Berkeley's (1709/1901) account of depth perception described in Chapter 3, in which he proposed that infants learn to see depth by forming associations between different sensations of eye convergence and the particular muscle and limb sensations required to touch objects at different distances.

As mentioned in the previous chapter, if you casually observe a young infant, the empiricists would seem to be right. The infant's limbs seem to move completely independently of what she sees, and coordination seems to emerge gradually as if she were learning associations between perceptions and actions. But a closer look reveals subtle ways in which innate constraints influence perceptual-motor development.

Constraints on Links between Eye and Limb Although the limitations on infants' early actions make their arm and hand movements appear haphazard, there may be some structure to the seeming randomness. Researcher Claus von Hofsten has conducted some of the most elegant explorations of infant reaching by painstakingly observing infants' hand movements toward objects (von Hofsten, 1980, 1983, 1984, 2004; see also Chen et al., 2010). He found that infants' hand and arm movements are sometimes quite slow rather than the rapid jerks that we are prone to notice. Some of his experiments used a standard fishing lure—without the hooks of course!—which the infants found especially attractive. The lure was moved slowly back and forth in front of the infant, and the infant's hand movements were videotaped and carefully coded.

When researchers interpreted these experiments with infants' early coordination difficulties in mind, they found that infants as young as 4 or 5 months, and possibly younger, moved their hands to track and often anticipated the paths of moving objects (von Hofsten, 1980, 1984, 2004; see also Robin et al., 1996). Thus, 4-month-old infants clearly anticipate the path of a lure as they reach out to catch it on arrival (von Hofsten, 1980; see

SCIENTIFIC METHOD: The Genetics of Early Handedness

Hypothesis:

Genetic influences on handedness can be seen at 18 months of age.

Method:

1. Nineteen pairs of 18-month-old twins participated. Five twin pairs were MZ, six were DZ same sex, and eight were DZ opposite sex.
2. Infants were invited to retrieve attractive objects (A) from a tube (B) that encouraged use of just one hand.
3. Three different tube positions (C) were used relative to the infant's body: left, middle, and right.
4. Researchers recorded which hand was used.

Results:

Although there was a preponderance of right-handed reaching in all three groups, there was also some left-handed reaching, especially for tubes in the left and middle locations. Significantly higher correlations for the use of the same hand were found between MZ twins than between DZ twins in either same-sex or opposite-sex groups, especially when the tube was in the middle position (see Table 1).

Conclusion:

Handedness biases that are influenced by genetic factors can be found at 18 months of age, at which point more closely genetically related infants show higher correlations in the use of the same hand in a reaching task.

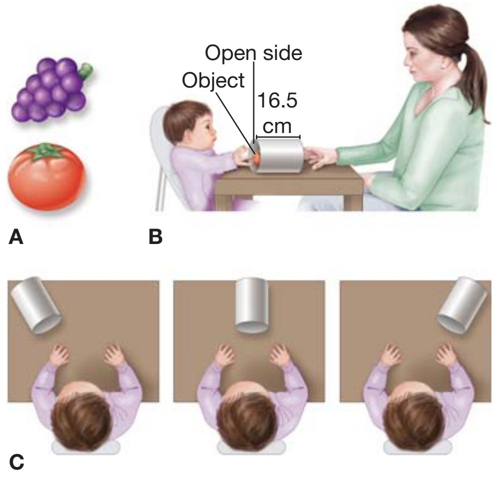

TABLE 1 **Correlations between members of MZ and DZ twin pairs and handedness biases**

	Left	Middle	Right	All Positions
MZ	.17	.66*	−.07	.64*
Same-sex DZ	−.54	−.45	.14	−.38
Opposite-sex DZ	−.41	−.15	−.22	−.18

MZ, monozygotic twin; DZ, dizygotic twin.
*significant correlations

Source study: Suzuki et al. (2009).

Figure 4.9). In reaching for stationary objects, even newborns seem to have a sense of where to move their hands. They reach in roughly the right direction, although they very rarely touch the object and are not able to easily grasp it (Bertenthal & Clifton, 1998).

While newborn infants may have difficulty grasping objects, they nonetheless can guide their arms in an intended direction. In one study, researchers passed a beam of light in front of infants in a darkened room. The light source was arranged so that each infant could see the beam only if her hand passed in front of the light, revealing a well-illuminated hand (van der Meer, 1997). The infants initially moved their hands into the ray of light at random, but they quickly learned to adjust the direction and speed of their hand movements to bring their hands into the light and keep them there. Similarly, newborns will move their arms toward objects they find appealing, even if they cannot grab them (von Hofsten, 1984).

If even newborns are able to guide their limbs toward the objects they perceive, then simple empiricist accounts appear to be in trouble. These very early abilities suggest that links between eye and limb that are already present at birth serve as a framework that guides learning during perceptual-motor development (von Hofsten, 1980, 2004). The critical question concerns how those links are influenced by experience.

Q: To what extent are newborns capable of guiding their limbs toward a desired object? How does that ability change in the first few months of life?

Within a perceptual-motor framework that is present from birth, one powerful way that human infants show

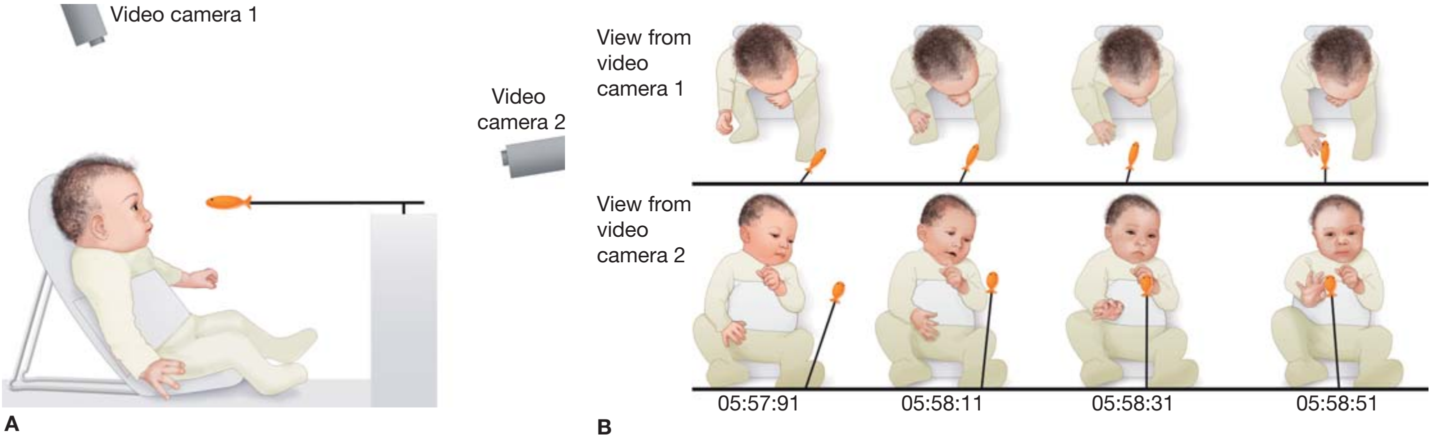

FIGURE 4.9 Reaching in young infants. (A) The setup in which an infant sits in a chair as an attractive object on a rod swings back and forth in front of him. Video cameras from above and straight ahead record the infant's reaching patterns, as well as his gaze and head movements. **(B)** Views of the infant recorded over time from above and from straight ahead as he reaches for the object when it moves in front of him. In this example, the infant is reaching in anticipation of making contact with the moving object. Adapted from von Hofsten & Lindhagen (1979) and von Hofsten (1980).

learning involves coming to understand that objects beyond a certain distance are not worth reaching for. Infants seem to understand this by the time they are at least 4 months old, as they are less likely to reach for more distant objects (Yonas & Granud, 1985). By 5 months of age, infants also modify the shapes of their hands to fit best with the shapes or orientations of objects that they are about to grasp (von Hofsten & Fazel-Zandy, 1984; see Figure 4.10). The purpose of reaching—to retrieve an object—is therefore integrated into an infant's perception and action from an early age. Another link between reaching and perception of distance also occurs with hearing. By 6 months, infants will reach less for objects they hear (in the dark) that are too far away (Clifton et al., 1991). Even more impressively, 10-month-old infants will adjust how they move their hands toward an object, depending on what they plan to do with it. Thus, they will reach faster to grasp a ball they want to throw than a ball they are going to stuff into a tube. Presumably the difference arises because the stuffing requires more dexterity and a more precise initial grip (Claxton et al., 2003).

Developmental improvements in reaching clearly are related to two kinds of changes in the brain: (1) changes to the neural circuits that directly enable action to become more sophisticated as the circuits mature, and (2) changes to the brain in response to learning new forms of actions. In addition, changes outside the brain are also important. In some cases, the infant's own body and posture may impose limitations, a pattern that fits with the tenets of dynamic systems theory. For example, 5-month-olds, who are not able to sit on their own, also seem to be quite poor at reaching for objects. But when these infants are propped up carefully with cushions, suddenly their reaching abilities become more sophisticated (Rochat & Goubet, 1995). Later, we will see that these kinds of peripheral limb-based constraints, so called because they involve bodily features rather than instructions to the body by the brain, may be especially prominent in learning to crawl and walk.

Navigating Space

Parents are often surprised at just how fast an infant can move, especially, it seems, when they look away for a moment. As infants grow older, they become increasingly adept at getting around, usually progressing from creeping to crawling to various stages of walking. During this progression, just as in the development of reaching, their movements are con-

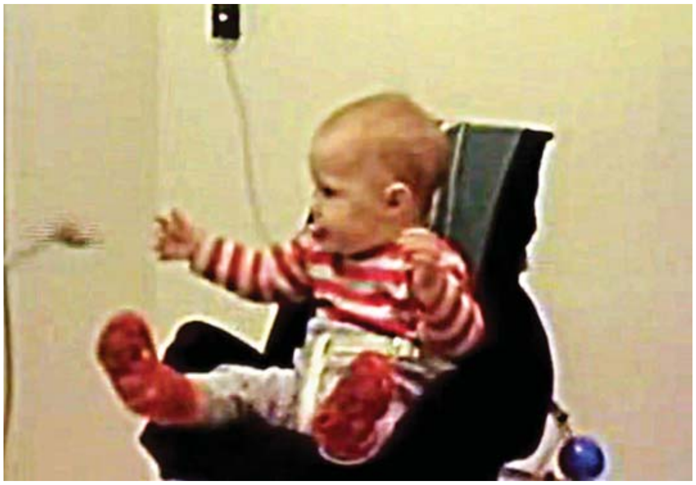

FIGURE 4.10 Reaching in older infants. This 8-month-old has become quite adept at both anticipating the trajectory of this rapidly moving object and also at adjusting her hand orientation and grasp width in such a way as to make effective contact with the object.

stantly guided by perceptual feedback. It is also important to note that not all infants go through the same sequence of learning to move around. Some never do much crawling and instead go from creeping to holding themselves up and moving about upright. It may be that medical recommendations for infants to sleep on their backs (so as to reduce the chances of sudden infant death syndrome) give them less of an opportunity to learn how to crawl on their stomachs.

Active versus Passive Visual Experience and Action

In learning a new action, how important is it to produce the action alone, as opposed to having someone else guide your movements? When a young baseball player learns to hit, how important is it for her to keep attempting to connect with the ball, rather than resting her hands on a bat swung by a coach? In both cases, she sees the ball moving toward the bat, then feels her arms move through space. Is the initiation of the action that important? To understand how perceptual-motor skills are best acquired, it is important to understand the different roles of active and passive visual motor experience and which kind of feedback most effectively supports the development of action. Only then can we make informed decisions about the kinds of activities that most benefit infants and young children.

An elegant approach to studying the role of feedback in perceptual-motor development was designed by Richard Held and Alan Hein (Held & Hein, 1963; see Figure 4.11). The researchers divided newborn kittens into two groups, active and passive. Both groups spent most of their time in darkness, where they were free to wander about as they pleased, and both groups were treated identically when in the dark. They saw an illuminated world only for the few hours each day that they spent in a special environment—a cylindrical chamber with identically spaced vertical lines on the wall. In this environment, the passive kittens were placed in a "gondola," a small container that carried them just a few centimeters above the ground. The active kittens were always placed in the harness that controlled the gondola. The mechanical linkages between the harness and the gondola were such that the passive kitten experienced the active kitten's every move. Thus, if the active kitten moved rapidly, both it and its passive partner would see the vertical lines on the chamber's walls rushing by at the same speed. When the active kitten stopped or turned, the passive kitten would also stop or turn, so that both kittens' visual experience would change in the same way.

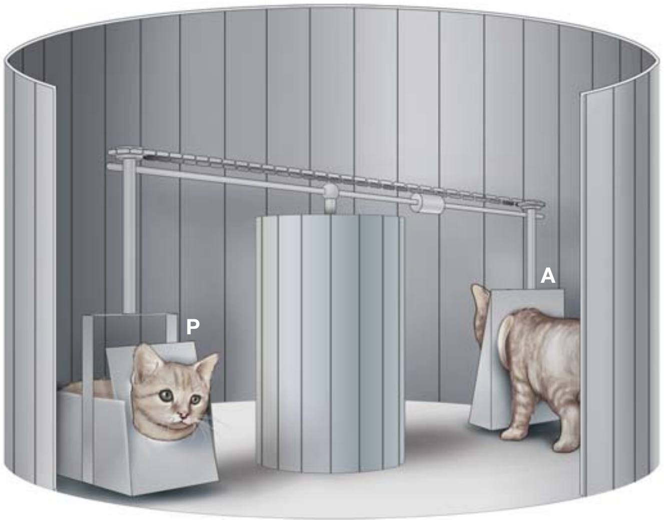

FIGURE 4.11 Active versus passive experience. The active (A) and passive (P) kittens in the Held and Hein study. The two kittens had nearly identical visual experiences due to the yoking of the passive kitten's gondola to the movements of the active kitten. Nonetheless, perceiving movement that is not the result of one's own actions resulted in many perceptual motor deficits for the passive kitten. Adapted from Held & Hein (1963).

In short, the combination of this special environment and the gondola arrangement eliminated all the differences in the perceptual-motor experiences of the two groups of kittens except for one. The passive kitten's visual experiences were never a consequence of its own self-produced motion; instead, they resulted from the motions of the active kitten.

After experiencing these conditions for 3 hours a day over the course of 2 months, the two groups of kittens were tested with several different tasks to see if being an active as opposed to a passive participant had any effect on perception or action. The researchers tested whether the kittens would put their paws out to land on a table as they were lowered toward it, as normal kittens do. As experimenters lowered the active kittens, they would put out their paws to meet the table's surface at just the right time. By contrast, the passive kittens were unable to link their perception of the approaching table to their own actions; they did not stretch out their forelegs to meet the surface. Instead, they usually let their forelegs hang until their paws grazed the surface, and then they would step up on the table, just as they normally did in the dark.

Q: How did the passively and actively reared kittens in the Held and Hein studies differ?

Passive kittens also seemed less sensitive to depth relations in other situations. When an object rapidly approached their faces, they were much less likely to blink, which was the active kittens' (and normal kittens') automatic response. The researchers also observed the kittens on a visual cliff like the one Eleanor Gibson used to test infants' depth perception (see Chapter 3). The passive kittens would wander off onto the deep side of the visual cliff, showing no ability to avoid the apparent drop-off (see Figure 4.12). Indeed, Held and Hein noted that if a passive kitten was placed on a

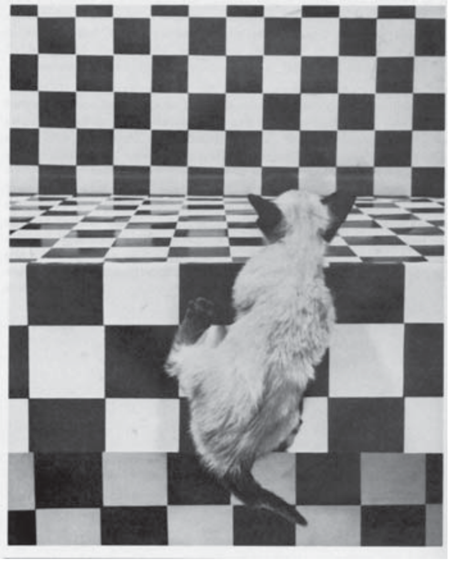

FIGURE 4.12 The visual cliff and active experience in kittens. Unlike this kitten, passively transported kittens in the Held and Hein studies were much more likely to wander off on the deep side of the visual cliff.

lab table for a moment, they would often have to rush over and catch it as it blithely walked off an edge. It is not clear whether the passive kittens were completely insensitive to these "cliffs" or whether they realized that a drop-off was imminent but did not know how to coordinate their actions with what they saw.

These studies and similar studies with other species, such as monkeys, show that it is not enough for the developing organism to have both unrestricted movement and unobstructed vision. The two must occur simultaneously so that the developing organism immediately sees the actions it produces and receives concurrent visual feedback; passive mimicry is not sufficient to support full-fledged perceptual-motor development. In the previous chapter, we saw that there seemed to be critical periods for the acquisition of some aspects of pattern recognition and auditory-visual localization. In contrast, there is no obvious critical period for establishing links between motion and vision. When the passive kittens were allowed to freely explore a normal, illuminated world, they quickly came to respond like the active kittens.

For obvious ethical reasons, no one has conducted a study like Held and Hein's with infants or children. But the importance of self-produced movement and concurrent visual feedback has been demonstrated in adults. In a version of Held and Hein's kitten study, an active participant and a passive participant both wore prisms, but only the active participant's visual experiences were directly correlated with self-produced movements. The passive participant rode along in a stand-up cart, seeing the same prism-distorted visual input as the active participant, but not experiencing visual feedback from his own actions. When both participants were later tested, the active person showed an adaptation to the prisms, while the passive person was relatively unaffected (Held, 1965). There are many other studies showing these results. For example, it is possible to learn to trace the path through a maze using only a mirror image for visual feedback, but only if you yourself do the drawing. Passively following the maze with your hand while someone else draws has little or no effect (Bedford, 1989; Held, 1965).

One study with human infants has interesting parallels to Held and Hein's (1963) study. Infants between 2 and 3 months of age were outfitted with mittens, some of which had Velcro that stuck to toys and some of which did not have Velcro and so did not stick to toys. The infants with Velcro mittens would touch the toys, which would stick to their mittens, and then transport them about as shown in Figure 4.13A. The infants with mittens that did not have Velcro watched as a parent moved the toys around in a manner that followed the infants' arm movements, without allowing them to actively transport the toys themselves (see Figure 4.13B). These two groups of infants had the same experiences for just a few minutes a day for 2 weeks.

Over subsequent weeks, researchers measured how much time the infants spent spontaneously grasping and reaching, both in the laboratory and at home. As Figure 4.13C shows, the active infants did much more grasping and reaching, suggesting that their early experience in short sessions of actively reaching and manipulating objects helped jump-start their learning about these motions (Libertus & Needham, 2010).

More broadly, these studies suggest that organisms can best learn about their environments in active, exploratory ways. They learn very little when they are forced to passively receive a stream of information. Even when the passive experience involves nearly equivalent information, an active, self-initiated experience seems to have a dramatically different effect on both the level of motor activity and on the ability to use vision to guide action. In later chapters, we will examine just how broad the benefits of active experience are. For example, most theories of education conclude that students learn more effectively when they actively practice new skills rather than being passively guided by teachers.

Q: How has active and passive experience been shown to differentially influence perceptual-motor coordination in humans?

Walking and Seeing Like most other motor activities—such as reaching and grasping—walking has important links to perception. Blind children who are otherwise healthy in

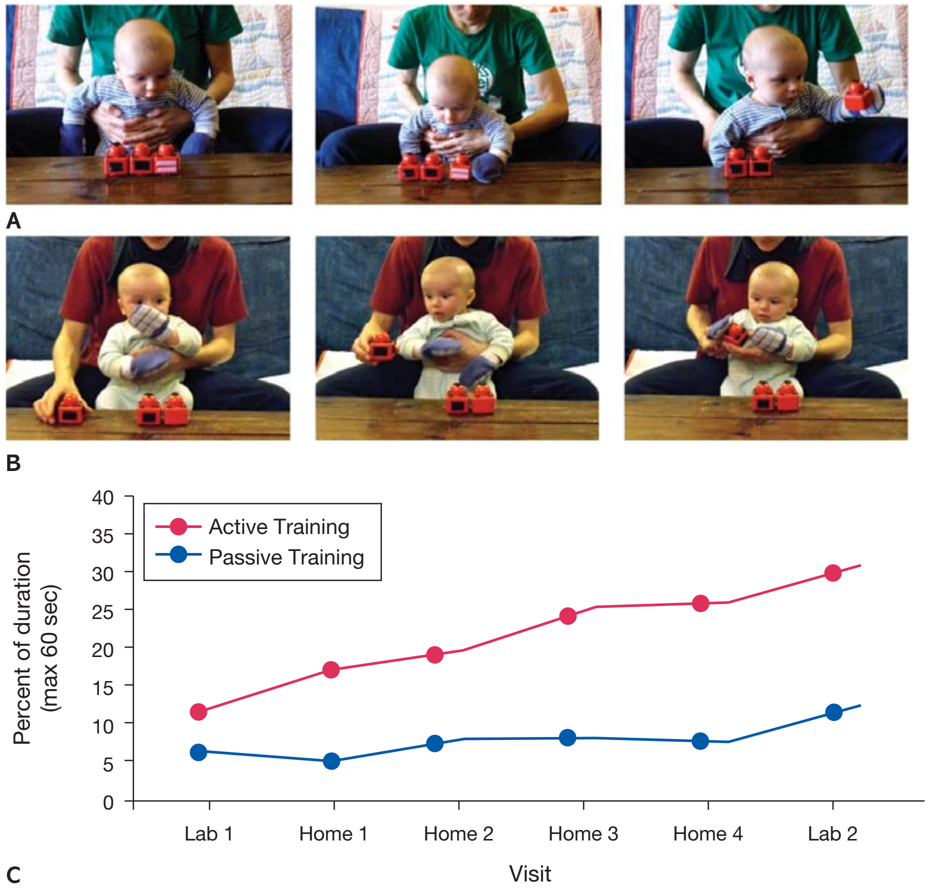

FIGURE 4.13 Active versus passive reaching and grasping. (A) Young 2- to 3-month-old infants who were given "active training" wore sticky mittens with Velcro and were able to "grasp" and transport toys. **(B)** Young 2- to 3-month-old infants who were given "passive training" wore mittens without Velcro and could not grasp or transport toys, but could only observe their parents doing so. **(C)** Infants given active training showed marked improvements in later weeks in time spent grasping and reaching, both in the lab and in the home, while infants given passive training did not show such improvements. Adapted from Libertus & Needham (2010).

all respects tend to start walking several months later than their sighted peers. Interestingly, the blind children's development of other motor behaviors before walking, including the ability to crawl, is not nearly as delayed (Adelson & Fraiberg, 1974). This suggests that vision is even more important to walking than to other motor activities.

Q: Why might blind children be delayed in walking?

One important way in which vision helps us walk is by providing us with information about how our body is moving through the environment. When we walk at different speeds, we come to expect certain visual patterns known as **visual flow fields** to stream past at appropriate speeds, and we use this visual feedback to adopt a well-balanced posture. Vision, in particular the visual flow fields around us, provides us with what amounts to visual "hand rails" that make it easier to get about in a steady and sure-footed manner. These flow fields can work even when children and adults do not fixate on any objects in particular and just observe the overall stream of the environment passing by them, as assessed by having wireless eye-tracking systems attached to their heads as they walk and run about (Franchak & Adolph, 2010). We are normally not aware of using this visual support while walking, but it quickly becomes obvious when we walk with our eyes closed. A series of studies vividly illustrated the extent to which toddlers depend on information from the visual flow field to maintain balance. In the studies, an unsuspecting new walker was placed in a room and allowed to stand for a few moments, at which point, even though the floor remained stationary, all the walls started to move in one direction as shown in Figure 4.14. Quite remarkably, even though the infant himself did not move, slow movements of the walls could "knock" the infants over by disrupting the coordination between their actions and their visual information (Bertenthal & Bai, 1989; Lee & Aronson, 1974; Stoffregen et al., 1987). Thus, if the wall was moving toward them, they felt as if they were moving toward the wall, tried to compensate by leaning backward, and lost their balance, rather than literally being knocked over by the walls. The same effect can be produced if an infant is walking instead of just standing still and the surrounding walls start to move in a manner no longer concordant with the walking. (Older children and adults are susceptible to these effects, too.)

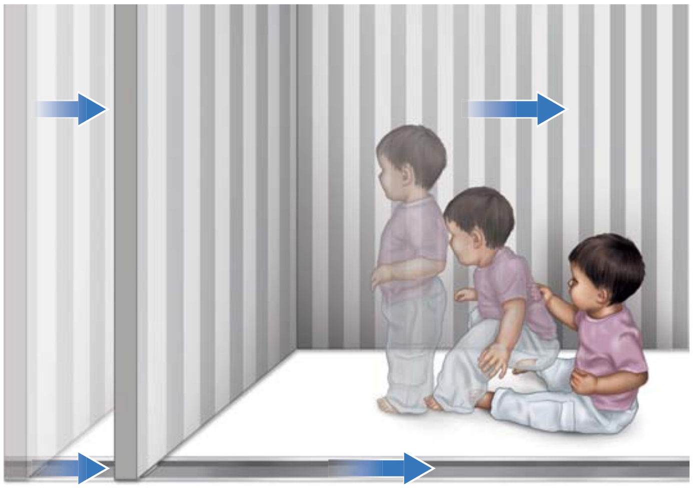

FIGURE 4.14 **Visual flow fields and balance.** Toddlers can be easily "knocked over" if the room around them moves in such a way as to suggest that they are moving when they are not. They rely on appropriate correlations between visual flow patterns in the environment and their own movements to help them balance. Here the walls are shown as moving toward the toddler, who feels as if he is moving toward the wall because of the visual flow patterns and compensates by leaning backward and falling over. Adapted from Bertenthal et al. (1997).

These studies demonstrate that visual information is not just a helpful support for walking. Rather, it is an intrinsic part of maintaining balance and therefore tremendously helpful in beginning to walk. Quite remarkably, this ability to use visual flow fields to control balance and posture is present in babies long before they have much capacity to use it. A newborn's head posture is responsive to the visual flow changes around her as early as three days after birth, even though her head still has to be carefully supported (Jouen et al., 1993; see Figure 4.15), and it becomes ever more responsive to small changes as the child grows older (Baumberger et al., 2004).

Besides guiding posture and balance, visual information is also critical for navigating the environment—and not just for avoiding large objects. Subtle changes in the visual flow allow us to adjust to dips and bumps in the walking surface (Vishton & Cutting, 1995; Warren et al., 1986). Watching a new walker manage to pick up on and adapt to irregular terrain makes it clear that visual information is used from the moment the toddler first starts to walk.

Q: How does the visual world we move through function as virtual hand rails?

A final way in which moving through the world is linked to perception is evident in studies in which Eleanor Gibson and her colleagues tested how readily infants would traverse novel surfaces (Gibson et al., 1987). The researchers arranged an experimental setup similar to the visual cliff in which infants were placed on a starting platform and encouraged to cross the surface in front of them (see Figure 4.16). The researchers tested responses in two conditions. In the first condition, the surface was a rigid plywood plank covered with black velvet. In the second condition, the surface was a soft water bed, also covered in black velvet.

Young infants who could crawl but not yet walk were about equally likely to venture out on both surfaces. They certainly perceived the differences in rigidity, but because they were already down on the surface and wouldn't be risking a fall, the consequences were relatively unimportant. In contrast, infants who were just learning to walk were much more reluctant to step out onto the water bed than onto the wooden plank. One common response was to explore the surface tentatively with one hand, and upon confirming that it was not rigid, to stay put. Even before having any direct experience, the young toddlers held back from crossing the water bed. If the experimenters dropped a ball on its surface or tapped it lightly to show that it was not rigid, this information was more than adequate to inhibit these early walkers.

Thus, young infants perceive the **affordances**, or possibilities for action based on the properties of the objects or surfaces on which the action will be performed. A nonrigid surface does not inhibit all kinds of movement across

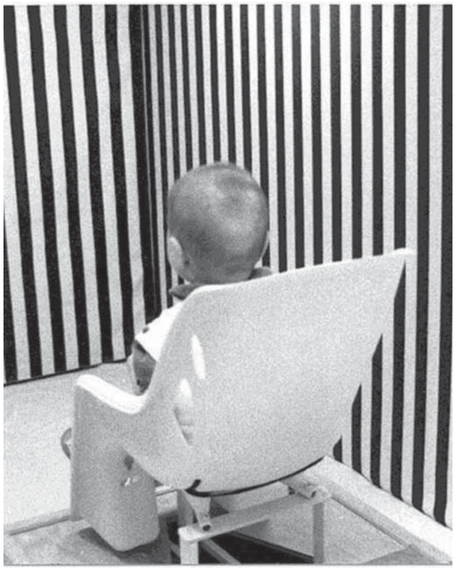

FIGURE 4.15 **Infants' responses to visual flow changes.** Babies will subtly move various parts of their bodies (for example, changing the position of their head and lower back) to compensate for movements in their environment. In this study, the room around the baby oscillated back and forth at different rates (based on movements of the side walls), and the 9-month-old baby showed corresponding back-and-forth oscillations of his body. Adapted from Bertenthal et al. (2000).

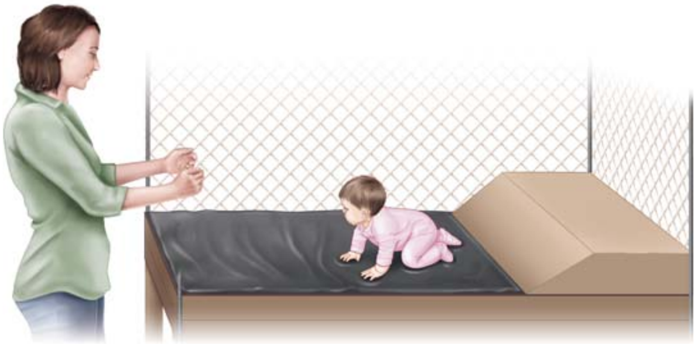

FIGURE 4.16 Perception and traversing novel surfaces. Gibson used a variant of the visual cliff to see how infants assessed traversability of a surface as a function of whether they were walkers or crawlers. The infant started down a ramp and then moved onto the main surface, which was either rigid or undulated like a water bed (as shown here). Crawlers happily ventured out on either surface, while walkers avoided the water bed. Adapted from Gibson et al. (1987).

it, only those that require maintaining upright balance to avoid falling. This is just one more way that the interaction between perception and action allows infants to respond flexibly to changes in their environment. Further studies have shown that infants are remarkably adept at adjusting their manner of locomotion, depending on the surface that they seek to traverse and taking into account the environment in many more ways than whether a surface is rigid or undulating. For example, if infants are put at the top of a downward-sloping ramp, the crawlers will proceed down it in much the same manner as they would cross a level surface, whereas young walkers will change their pattern of movement, often switching from walking to sliding (Adolph et al., 1993, 2003). More broadly, infants adapt their locomotion in highly flexible ways that are exquisitely sensitive to the particular environment in which they are put and to the ways that the environment poses specific biomechanical constraints on their actions, constraints that change as the toddler grows (Adolph, 2008; Adolph & Kretch, 2012).

These studies also highlight the finding that walking initially poses more risks and challenges than crawling. Given that walking is initially much slower and more difficult, what motivates expert crawlers to want to do it? After all, new walkers often drop to all fours when they need to move quickly. In addition, many fall frequently from the standing position, accumulating lots of bruises and bumps in the process of learning to walk. If walking is both slower and more painful at first, what motivates it?

One possibility is related to speculations about how walking evolved in the human species. Some theories suggest that the driving factor may have been the need to carry objects. As early hominins formed social groups in which they cooperated and shared resources, those who could more easily stand upright and use their hands to carry tools or gather larger amounts of food may have had a selective advantage (Lovejoy, 1981). Although still controversial, the notion that the infant first attempts to walk because it makes carrying things easier has considerable appeal. As I watched our own toddlers walk about, I was struck by how often they carried things from place to place with great delight. Shortly before taking their first steps, they attempted to carry things in their mouths, but this rather uncomfortable technique often failed. Walking upright, even in the earliest stages, enabled them to carry much heavier things much greater distances. Indeed, within his first few days of walking, our youngest son was discovered lugging a 5-pound jug of laundry detergent!

Infants are often able to carry or move objects even when crawling; for example, crawlers will support themselves with one hand while carrying an object with another, will use their mouth, or will slide an object along (see Figure 4.17). When they finally start to walk, however, their carrying behavior expands in important ways; they can more easily move large objects about and tend to do so more often and with greater speed (Karasik et al., 2012).

Q: Why should infants ever want to walk, given how uncomfortable and slow it is compared with their ability to crawl?

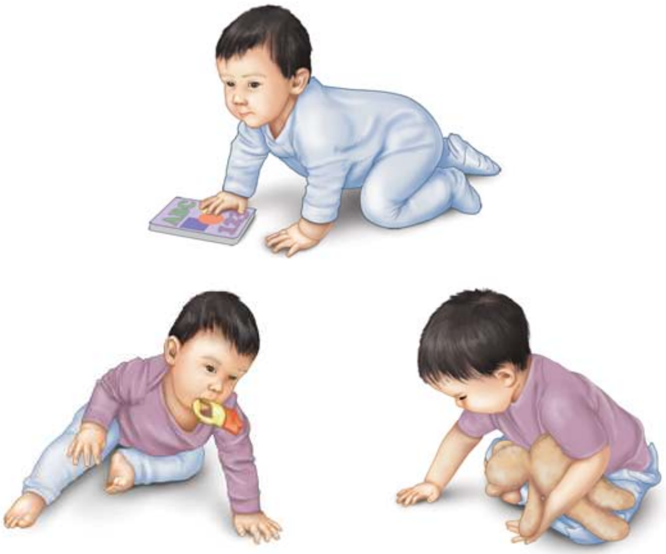

FIGURE 4.17 Carrying objects while crawling. Even before they can walk, infants have a strong drive to move things about and do so through several methods. When they start to walk, however, they tend to carry larger objects and do so with greater frequency. Adapted from Karasi et al. (2012).

Overall, early perceptual-motor development clearly illustrates that perception and action are part of an integrated system that enables infants to act on and get around in their world. Right from the start, there is a rough correspondence between what a newborn sees and hears and how she acts, and the integration of perception and action becomes much more refined in the months and years that follow. These refinements arise from several factors: the development of increasingly sophisticated neural circuitry, the growth and change in the size and proportions of the body, and the infant's ability to perceive the consequences of her own actions. This last factor is an excellent demonstration of the importance of feedback loops to the development of action. All these factors must be taken into account to understand how perceptual-motor skills develop.

Learning to Engage in Specific Actions

Up to this point, we have considered perceptual-motor skills such as walking, reaching, and grasping. These skills enable an infant to respond quickly to his environment and to begin navigating within it. Other kinds of actions require more specific and precise patterns of motion. These action sequences may require considerable learning, either by observing recurrent patterns in the environment or by experiencing environmental contingencies in response to one's own behavior. These sequences can range from an infant imitating a sequence of facial expressions to a dog learning a series of tricks.

The many ways of mastering such specific sequences illustrate the impressive range that organisms have for learning about the world while remaining subject to strong constraints and embedded in various feedback loops. We have already seen how cycles of action, perception, and adjusted reaction create the feedback loops that guide perceptual-motor coordination. Alternatively, an organism can learn about the consequences of its actions through feedback that involves being rewarded or punished. In the next sections, we will consider how these feedback systems, along with constraints on learning, guide the development of specific behavior patterns. To do this, we will examine three ways of learning specific action patterns: imitation, imprinting, and conditioning.

Early Imitation

Imitating others seems to come naturally—sometimes even unintentionally—whether it is imitating someone's gestures or even their manner of speaking (Pardo & Fowler, 1997). As we will see, even newborns can imitate simple facial expressions. Young toddlers often imitate older children and adults and, as many parents will admit, not always in desirable ways. Imitation is a part of all our lives, but its earliest manifestations in development were, until relatively recently, a mystery.

The Process of Imitation Much like reaching or walking, imitation might seem simple, but it is actually an intricate perceptual-motor achievement. To imitate a facial expression of another person involves perceiving the complex, dynamic patterns of facial movement, interpreting those movements in terms of your own facial muscles, remembering the pattern of facial changes after the model has stopped, and finally reenacting the neuromuscular event. Considering all these requirements, it is all the more remarkable that infants younger than 1 hour old can imitate the facial expressions of others.

Although researchers long believed that older infants could imitate facial expressions (Piaget, 1962), in 1977 Andrew Meltzoff and Keith Moore demonstrated the ability in newborns. The experimenters repeatedly made several different faces at newborns, in some cases within the first hour after birth, and videotaped the infants' facial responses. Observers then watched the videotapes, without knowing which expression the experimenter had been showing, and described the infant's expression. One of the acts the infants imitated most clearly was sticking out the tongue. As Figure 4.18 shows, the infants also imitated several of the experimenter's other acts, including opening the mouth in

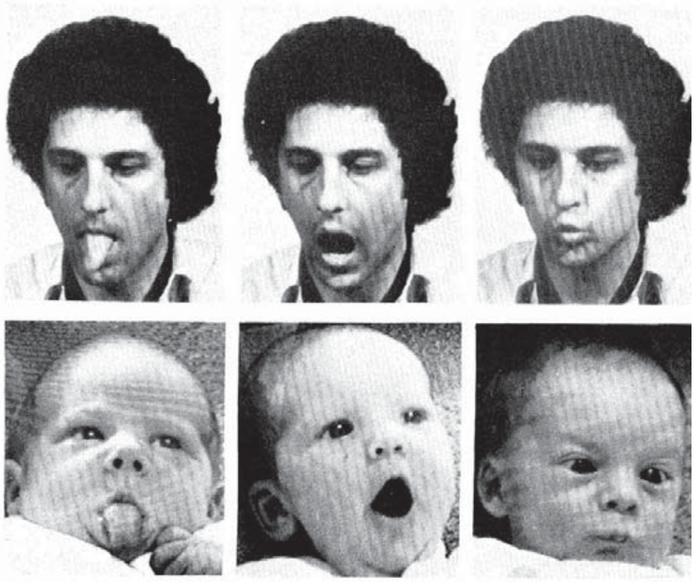

FIGURE 4.18 **Imitation by infants.** Infants between 2 and 3 weeks of age will imitate particular facial expressions (tongue protrusion, mouth opening, and lip protrusion) of an adult model. Normally, the adult must repeat the expression several times in succession with clear pauses between each display. From Meltzoff & Moore (1977).

a wide O shape and puckering the lips (Meltzoff & Moore, 1977).

These results were so remarkable that they were initially met with skepticism by those who thought that the accounts were exaggerated or perhaps had actually involved older infants. How could a newborn, who appears to be so helpless and, more specifically, so limited in terms of perceptual and motor abilities, possibly engage in something as sophisticated as imitating a facial expression? Although not all newborns imitate expressions consistently (or at all), and the imitation can often be subtle, their ability to imitate has since been confirmed in many carefully controlled studies (Abravenel & Sigafoos, 1984; Field et al., 1982; Meltzoff & Moore, 1989; Reissland, 1988; Vinter, 1986).

Q: What is necessary for infants to be able to imitate facial expressions?

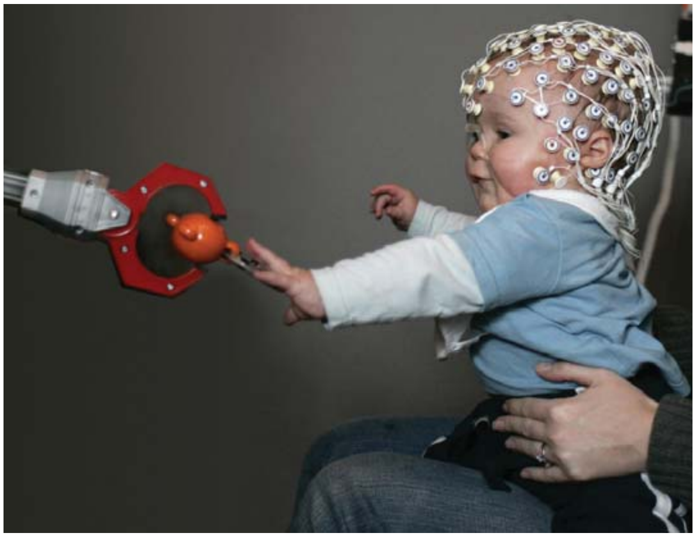

FIGURE 4.19 Brain activity and reaching in human infants. Infants show similar brain activation patterns when they are reaching for an object and when they observe others reach for an object. Southgate et al. (2009).

The fact that imitation is possible almost immediately after birth naturally raises questions as to its underlying mechanisms. Meltzoff and Moore suggest that for many human actions, including both facial expressions and hand gestures, the ability to perceive the action and the ability to produce it might be mentally represented in the same neural code. Thus, when an infant perceives an action, the code for the related motor sequence is activated as well. Although this specific proposal is still being investigated (see New Directions in Developmental Research box), it is clear that from a very early age, infants have a strong link between their perceptions and their ability to reproduce certain kinds of actions. This has been shown in studies that measure brain activity while infants are reaching and while perceiving others reaching for an object (see Figure 4.19).

Early imitation is not restricted to things that infants see, of course. They also frequently imitate sounds, in some cases as early as 10 weeks of age (Kuhl & Meltzoff, 1996). Moreover, imitation is a form of social activity; 5- to 8-week-old infants are much more likely to imitate humans than inanimate objects (Legerstee, 1991). For example, infants are more likely to imitate an adult sticking out her tongue than a long red object moving out of a white tube. Meltzoff and Moore (1994, 1999) argue that the various forms of imitation may also help infants recognize people, as if by imitating the other person the infant is saying, "I know you. You are the person who does this" (that is, sticks out his tongue or wiggles his arm a certain way). Indeed, infants will reenact an imitated action shown by a specific model when encountering that model in the future or when exposed to a cue (for example, hearing the model) that reminds them of the model (Meltzoff, 2005). Even 6-week-old infants seem to associate imitative actions with particular individuals. In one study, infants imitated an action by a specific adult whom they had seen performing that action 24 hours earlier. They readily imitated the familiar model, but were much less likely to imitate a new model. This is quite remarkable, given some claims that infants cannot recognize individual faces at that age. It also displays an impressive memory skill, which extends to several weeks in older infants (Meltzoff & Moore, 1994).

Newborns' ability to imitate facial expressions and actions is not uniquely human. Rather, imitation has a long evolutionary history in primates as a way of interacting that tends to bring individuals into similar emotional states (for example, feeling afraid). Thus, like human mothers, mothers of newborn macaques engage in making and imitating facial expressions with their infants (Ferrari et al., 2009a). This mother-infant facial feedback loop may help regulate their emotions so they can experience a shared emotional state and thus sense what the other is feeling. As Figure 4.20 shows, newborn macaque monkeys can also imitate human facial expressions, such as sticking out the tongue or showing a wide open mouth (Ferrari et al., 2006). This result is striking, given that the macaque newborns must be perceiving a representation of the human face that is generalized and abstract enough that they can use it to know which of their own facial muscles to move. Other studies of rhesus macaque newborns have shown that those that imitate most often also tend to develop more sophisticated motor skills later, such as those involved in grasping and reaching (Ferrari et al., 2009b). **Mirror neurons** are neurons in the brain that are activated both when performing actions and when perceiving them being performed by others. They are thought to support imitation and may be involved in the

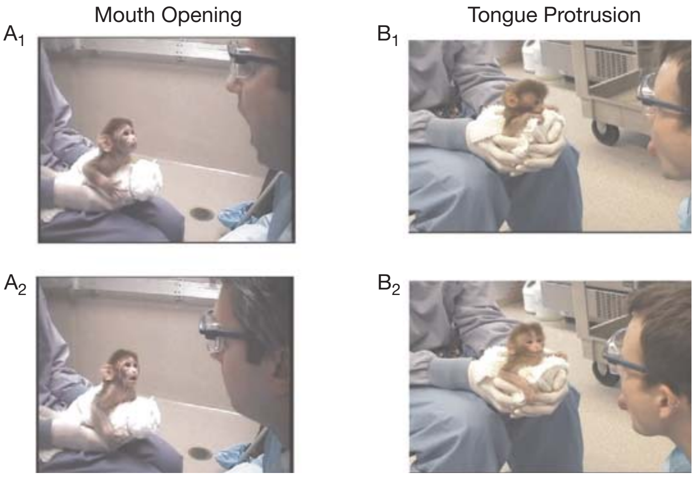

FIGURE 4.20 Imitation of facial expressions in newborns of other species. Newborn macaque monkeys will imitate the facial expressions of humans. From Ferrari et al. (2006).

process of learning new actions right from birth onward in monkeys (Ferrari et al., 2012).

Q: How have infant imitation studies influenced views of infant memory?

One of the most puzzling questions about the development of imitation concerns the boundaries that define what kinds of behaviors infants are likely to imitate. Even if we narrow the focus to actions made by human agents, infants clearly do not imitate everything they see. Part of what drives their imitative tendencies may be whether they perceive an action as intentional. They seem to require several repetitions of an action to want to imitate it—not because they fail to notice it, but perhaps because they need to know it was not simply an accidental action, like a sneeze. No one thinks that young infants fully understand others' intentions, but infants may find some aspects of intentional behavior especially salient, a topic we will return to in Chapter 5.

The Development of Birdsong: Variations on the Imitation Theme Humans and other primates are not the only creatures that attend to others' actions in order to reproduce them. In fact, the imitative feats of developing songbirds seem to exceed the imitative capacities of human infants. There can be large lags between when a bird first hears a song and when the bird first reproduces it. Unlike human verbal memory, immediate rehearsal is not necessary for birds to remember what they have heard. For example, starlings will sometimes reproduce for the first time songs that they have not heard for over 15 months (Chaiken et al., 1994). Many birds come to sing complex and beautiful vocalization patterns, using the songs to demarcate territory, attract mates, and identify themselves. But none sing full-fledged songs from birth, raising the question of how they develop these abilities. The answers have come from ethologists in the fields and meadows of the world and from neurophysiologists in their laboratories. Their findings illustrate some of the many different ways in which complex motor behaviors develop.

Among different types of songbirds, there are several different developmental pathways for learning to sing. Most birds imitate songs sung by older birds of their species. They hear a song, remember the patterns, and reproduce them. In addition, juvenile birds frequently are in a phase of overproduction of song components (somewhat like human infants' babbling), producing more "syllables" of songs than they will ever show as adults; they limit the components of their songs as they learn from older models. But songbirds also tend to be somewhat inventive and improvisational. They don't simply copy models' songs; they improvise in the specific style of the song they have heard. In most species, hearing good model songs enhances the quality of the songs that develop. For centuries, birdsong lovers in Japan would pay to have their young birds "tutored" by older prize-winning singers (Konishi, 1985; see Figure 4.21).

In some species, songs will emerge in relatively full form, even if the birds are reared in isolation, but the songs will typically be less rich and less tightly structured than those of birds reared in the company of older singing birds. Other species of birds, such as swamp sparrows, do much worse when they are reared in isolation. Although these birds do not simply stay silent, they only are able to develop a skeletal song that has the overall structure of the normal songs but that lacks details, including those that normally distinguish local groups of birds (Marler, 1991a, 1991b). Moreover, even more than listening to older singers, young songbirds must be able to listen to themselves. In general, if birds are deafened after they are born, their songs usually degenerate terribly. The feedback gained through hearing their own songs seems essential.

Finally, some songbirds, such as the zebra finch, show an innate bias to learn the songs of their own species, but if they are only exposed to the songs of a related species, they are also able to learn those songs. Nonetheless, learning another species' song tends to take longer than learning their own. In this way, the acquisition of birdsong by the zebra finch illustrates both learning within a set of guiding constraints (the framework songs of their own species) and also a flexibility in the learning process that allows them to transcend those constraints when the environment demands it (that is, when only other species' songs are available). This kind of pattern is often described as guidance by "soft constraints," which are said to provide a default bias toward a certain developmental pathway.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Mirror Neurons and Early Imitation

The remarkable ability of even newborns to imitate the actions of others has led many researchers to investigate the mechanisms that could support these surprisingly sophisticated behaviors. A recent series of findings in neuroscience on mirror neurons has resulted in some provocative suggestions about the neural basis of imitation (Lyons et al., 2006; Meltzoff & Prinz, 2002; Nakahara & Miyashita, 2005; Rizzolatti & Craighero, 2004). Some of the most intriguing findings initially came from studies of the neural basis of imitation in monkeys. Neuroscientists implanted electrodes in the monkeys' premotor cortex, the brain area involved in guiding actions, to monitor the firing of individual neurons. They recorded the firing patterns of premotor neurons, both when monkeys performed object-directed actions (including grasping, placing, and manipulating objects with their hands) and when they observed other monkeys performing similar actions. In several cases, the same neuron fired both when a monkey was performing a specific action on an object, such as grasping a block on a table, and when the monkey was watching another monkey engaging in the same action (Gallese et al., 1996, 2004). The neurons that fired when the monkey grasped the block did not fire when the monkey saw the block when it was not being grasped by a hand or when the monkey watched the experimenter simulate grasping the block when it was not present. Because these same neurons fired when the monkey either performed or observed a particular action on an object, they came to be called mirror neurons.

Interestingly, while the mirror neurons associated with a particular object-directed action did not fire when the action was performed in the absence of the object, they did fire when the monkey watched a robot perform the action. This suggests that the activity of mirror neurons is associated with the overall goal of the action rather than with the necessary limb movements (Gazzola et al., 2007; Rizzolatti & Sinigaglia, 2010). There may be a common code both for perceiving and for performing many kinds of actions. Researchers have documented what seem to be different populations of mirror neurons for hand movements, for facial movements, and for eating (Rizzolatti & Craighero, 2004).

It is relatively easy to document the activity of mirror neurons in monkeys, but it is far more difficult to do so in humans, because implanting electrodes in human brains solely for the purpose of experiments is unethical. Nonetheless, evidence from a variety of noninvasive measures of brain activity, ranging from electroencephalograms (EEGs; Altschuler et al., 1997) to functional magnetic resonance imaging (fMRI; Grèzes et al., 2003), suggests that the same brain regions responsible for object-directed actions are also active when people observe similar actions being performed by others. Studies involving people with intractable epilepsy have also offered more direct confirmation. These individuals already had deep electrodes implanted in regions of their cortex to help guide neurosurgeons attempting to treat the epilepsy. They were shown to have mirror neurons in several locations, some of which were analogous to the brain areas where they have been found in monkeys (Keysers & Gazzola, 2010). Other studies with 9-month-old infants used a net of scalp electrodes to detect mirror neuron–like processes in the motor control regions of the brain. These areas show similar electrical activity patterns when infants grasp an object themselves and when they anticipate that someone else's hand is about to grasp the object (Southgate et al., 2009, 2010). Thus, the motor region is activated when thinking about another's goal of grasping, not just by observing actual grasping.

It has been argued that the sort of imitation found in humans and higher primates is unique and that it represents a highly advanced evolutionary achievement (Rizzolatti & Craighero, 2004). Mimicry in other sorts of animals is argued to involve different kinds of processing and no mirror neurons. If this claim is correct, it raises the question of whether newborns' ability to imitate might arise from the presence of functional mirror neurons at birth. This question can only be answered with a detailed understanding of mirror neuron function, which can then be contrasted with other systems that might support mimicry. The more precise functions of mirror neurons remain a topic of considerable debate. Besides their role in imitation (Jeannerod, 1994), they may contribute significantly to attending to the details of others' actions (Wilson & Knoblich, 2005), to understanding the meanings of those actions (Gallese et al., 2004), and to social understanding and empathy (Baird et al., 2011; Meltzoff & Decety, 2003). It remains unclear, however, whether the activity of mirror neurons provides a basis for inferring others' thoughts, feelings, and intentions by neurally "simulating" their actions (Saxe, 2005). Thus, imitation may be the mirror neurons' core purpose or only a kind of side effect of their activity.

FIGURE 4.21 **Imitation of birdsong.** For centuries, songbirds have been prized in Japan, and juveniles were often exposed to "expert" adults for "tutoring" in the nuances of particular songs.

The zebra finches also illustrate an intriguing interaction between critical periods and environmental input. Most songbirds have a critical period in which they are best able to learn from listening to older singers. These periods can vary in length from a few months to over a year, depending on the species (Hensch, 2004). The start and stop times of the periods can also be environmentally influenced. Thus, if zebra finches do not hear good model songs during the normal developmental time frame for this period, they are able to postpone the critical period's onset by several weeks. Then, if an appropriate model comes along a bit later, they can learn just as easily. The length of the critical period for this species does not change; its start and stop dates simply seem to get postponed in the absence of a good model (Mooney, 1999).

The development of birdsong illustrates that there are many developmental paths for learning complex motor behaviors from models. Among songbirds, the particular role that songs play for a given species likely influences which developmental course is favored (Slater, 1989). The development of birdsong also draws together many of the themes of this book. Most songbirds show critical or sensitive periods for learning the skill from their elders. Perceptual-motor feedback is also essential, as most species will develop inadequate songs if they cannot hear their own efforts. In addition, a framework of biases toward learning and producing species-typical song elements, such as certain patterns of vocalization and repetition, is usually present at birth and guides further inputs. Moreover, the more complex the species' song patterns are, the more likely that the birds will depend heavily on input received from others and not just on a set of rote singing routines. Many of these same patterns also characterize imprinting, another behavior in young birds that has revealed important developmental principles.

Q: What are some different patterns of birdsong development and what do they tell us about different ways of learning to imitate others?

Imprinting, Action, and Critical Periods

Young organisms sometimes learn in a powerful and seemingly irreversible manner known as **imprinting**. Imprinting is most common in birds, such as chickens, ducks, and geese, and its main function seems to be to ensure that young birds learn to stay close to their mothers. Newly hatched chicks will initially approach a wide range of objects. If they repeatedly encounter a particular object during the appropriate critical period, normally during the first few days after birth (Nakamori et al., 2010), however, they will continue to approach and follow it eagerly, often for the rest of their lives. In the natural world, this object is almost always their mother, but in the laboratory, young birds have imprinted on a host of other objects and even on the researchers themselves (see Figure 4.22).

A key aspect of imprinting is that the size, shape, and contrast of the object, as well as the manner of movement and many other factors, all influence the ease with which the chick will imprint on it (Honey & Bateson, 1996; Horn, 1990; Sluckin, 1972). Thus, as one researcher put it, the chick's brain is not "a tabula rasa on which experience makes it mark" (Horn, 1990). Outside the lab, where a newborn chick would likely encounter other chicks and perhaps the chicken coop itself during the critical period for imprinting, these innate biases greatly improve the chances that it will still imprint on its mother. A second feature of this kind of learning is that even when the chick simultaneously encounters two objects that are equally likely to cause imprinting, the chick will not imprint to both; instead, it will come to follow only one. The imprinting system does

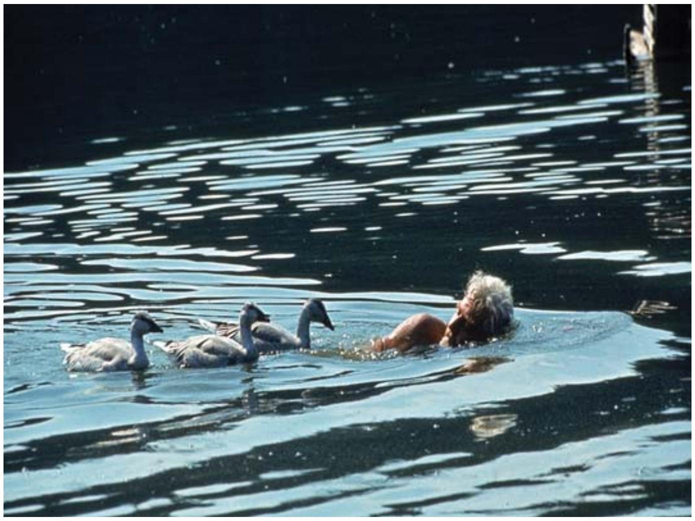

FIGURE 4.22 Imprinting. A group of goslings swimming in a pond with ethologist Konrad Lorenz. Ducklings and goslings can imprint on a person (or on some part of the person, such as his boots) and will follow that individual as if he were a parent. These unusual imprintings require unusual environments in which the real mother is not present or only minimally so. The human would never win out over the real mother if they were both amply present in the environment, reflecting a natural bias to imprint on the mother, all things being equal.

not seem to allow imprinting on two distinct objects. This feature of the system also makes excellent sense for survival. Since no wild chick would need to imprint on two mothers, a double imprinting could become dangerously confusing for a young bird.

In the chick's brain, imprinting seems to occur in a region known as the intermediate medial hyperstriatum ventrale (IMHV), which is in the chick's forebrain. If the IMHV is lesioned before imprinting occurs, the chick will be unable to imprint. Moreover, lesioning this area after imprinting will erase what was learned with the imprinting. The same lesion will not block forms of learning unrelated to imprinting (Horn, 1990). And yet, while an IMHV-lesioned chick can no longer imprint on an artificial object such as a moving block, it will still follow a chicken about. How can we resolve this contradiction?

It turns out that in chicks, two independent systems are involved in behaviors like following, imprinting, and recognition. One system, which is present throughout the lifespan and does not involve the IMHV, consists of a general tendency to notice and follow other chickens. This system does not allow the chick to recognize another chicken as an individual. Rather, it is more like a general chicken detector that tends to make the chick orient toward others of its species and follow them.

The second system, which is in the IMHV region, governs the ability to recognize specific individuals rather than categories. This system, which is most receptive to learning during a critical period spanning the first few days after birth, is where the phenomena of imprinting occurs. It can support imprinting on an enormous range of objects and individuals, including many that do not look like chickens. Yet, in the natural environment, the coordination between this system and the other, earlier-emerging chicken detector system almost inevitably results in the chick imprinting on its mother (Bateson & Horn, 1994). We see here yet another example of the coordination of perception and action in development. The chicken-detecting-and-following system influences the chick's imprinting system and greatly increases the odds that the chick will imprint on the appropriate target.

As we saw in Chapter 3, this two-system model has inspired a similar model of infant face perception. In that model, the initial system orients the infant toward human faces as a general category. Then the experience the infant gains by attending to faces helps get the second system—the one for recognizing individuals—up and running. Imprinting in chicks and face perception in human infants demonstrate how the challenge of learning to attach to a specific individual might be solved in strikingly similar ways in two very different species. They also illustrate how the ability to recognize a general category and the ability to recognize a single individual both play important roles and can work together.

Imprinting is a highly constrained learning process involving a sequence of actions and perceptual discriminations that almost always emerges in the same way within a set time frame. In contrast, conditioning is a more flexible form of learning that can result in a variety of complex and variable behaviors. We will see, however, that these dramatic variations in conditioned learning still occur within a framework of constraints.

Q: What is the evidence for two distinct systems in the development of imprinting?

Conditioning

Two of the most powerful and best-studied ways to elicit actions in infants involve classical and operant conditioning. The general theory of conditioning attempts to explain how organisms learn to respond to environmental events. In this theory, learning involves three components: awareness of stimuli, awareness of the environment, and awareness of consequences of actions. In the simplest kind of learning, the organism becomes aware of a stimulus. This is typically observed in instances of *habituation* and *dishabituation* (see Chapter 3). In the next level of learning, the organism must

DEVELOPMENT AND SOCIAL POLICY

Can a Toddler's Motor Development Be Accelerated?

Some affluent parents worry about how to give their children a competitive edge at the earliest age. In response to these kinds of concerns, enrichment programs for preschoolers, including programs to boost motor skills, have become commonplace in many cities and towns. But can these programs really deliver on their promises?

Imagine that a nationwide chain called Power Toddler claims that its 2-year program enhances the athletic skills of children aged 1 to 3 years old through early practice with motor skills. For a hefty fee, retired gymnasts, basketball players, and other athletes coach the toddlers for 2 hours each day, training the children to balance on beams, perform simple gymnastic movements, catch and throw balls, and do a variety of other simple athletic activities. Power Toddler's brochure says that perceptual-motor development largely depends on prior experience and that by enriching this experience for its students early on, its program confers a lifelong athletic advantage. It even cites some studies in which perceptual-motor skills seemed to be influenced by training (Boucher & Doescher, 1991; Laszlo & Sainsbury, 1993). The brochure goes on to refer to studies in Kenya that suggest that certain kinds of parenting practices might boost children's early motor development (Super, 1976). It even mentions some research arising from Esther Thelen's studies that shows that changes in muscles and other physical properties of the limbs can bring dramatic changes in motor abilities (Thelen, 1995; Vereijken & Thelen, 1997). On this basis, Power Toddler argues that through early exercise, toddlers can strengthen their muscles, which will enable them to achieve impressive new levels of motor activity.

As Power Toddler centers spring up across your state, the Consumer Protection Agency becomes concerned that the chain may be fraudulently promising parents more than it can deliver. The agency then turns to developmental psychologists for advice about the effects of intensive perceptual-motor instruction for children aged 1 to 3. It wants to know whether the Power Toddler program could really provide long-lasting benefits. Based on the information in this chapter, what does research on the development of action suggest about whether Power Toddler is using false advertising?

In considering this question, think back to Gesell's classic studies, such as the 11-month-old twin sisters who learned to climb stairs. These experiments involved younger children and far shorter durations of training than Power Toddler's 2-year program, but their findings suggested that extra training made no difference—all that seemed to matter was maturation (Gesell & Thompson, 1929). Here the question is: Do findings like Gesell's extend to later ages and longer periods of training?

Also consider how the evidence cited in Power Toddler's brochure relates to its promises of lifelong athletic benefits. While those studies and others—including the one described earlier that utilized Velcro mittens to accelerate infants' grasping and reaching (Libertus & Needham, 2010)—may well show how specific perceptual-motor experiences can improve early motor skills, this is not the same as providing evidence of more general, long-term benefits. Perhaps Power Toddler's program temporarily speeds up the development of perceptual-motor abilities but then other children catch up within a few months. Or perhaps Power Toddler's students regress back to normal levels when the program of constant practice ends.

This imaginary case is not far from real ones, and it illustrates how research on motor development might influence legal decisions about certain advertisements. In the hypothetical case of Power Toddler, the value of the program for physical prowess is probably quite modest. As long as young children have ample opportunities to engage in a variety of gross and fine motor activities, it is unlikely that special programs provide any additional and lasting athletic advantage. Participating in group activities with other children may confer some social benefits, but as a general rule, there is no evidence that toddlers who receive professional coaching are more likely to become skilled athletes.

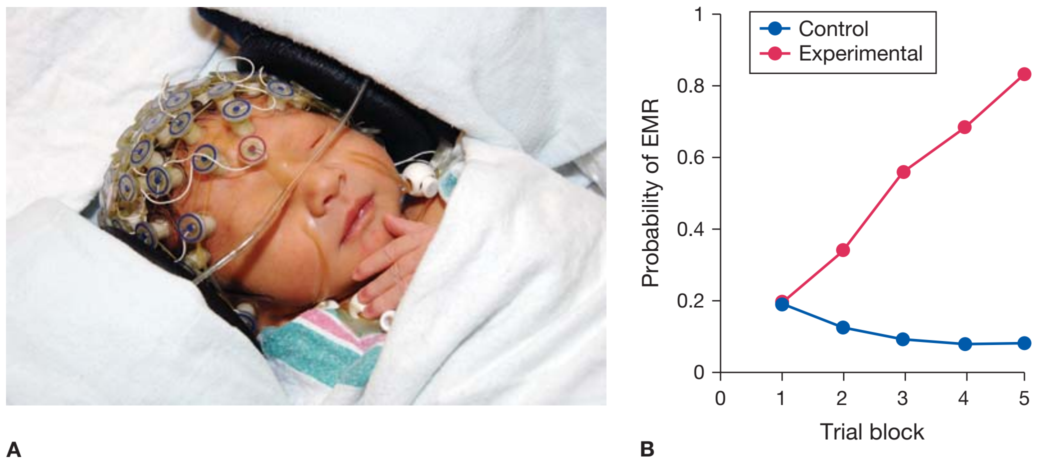

FIGURE 4.23 Classical conditioning in sleeping newborns. Newborns can be classically conditioned to associate a tone with a puff of air to their eyes. They soon learn to blink when they hear the tone alone. **(A)** By monitoring sleeping infants' eye movement responses (EMRs) during this kind of classical conditioning, **(B)** researchers have found that sleeping infants who were conditioned show more EMRs than infants who were not conditioned. Those who experienced the classical conditioning also showed more brain activity suggestive of learning the association compared to infants in the control group. Adapted from Fifer et al. (2010).

learn how stimuli are related; this level of learning is seen in *classical conditioning* (or Pavlovian conditioning). In the final level of learning, the organism learns about the consequences of its actions, where the stimulus usually takes on the role of a positive or negative reinforcer. This level of learning is known as *operant conditioning*. Let us now turn to classical and operant conditioning in more detail.

Classical Conditioning For over 100 years, since Pavlov's groundbreaking studies on dogs, it has been known that an enormous range of organisms can be classically conditioned. In **classical conditioning**, an initially neutral stimulus that does not normally elicit a response comes to do so through the repeated pairing of the neutral stimulus with a stimulus that would naturally elicit the response. To begin with, an **unconditioned stimulus (UCS)** has a preexisting relationship to an **unconditioned response (UCR)**. In Pavlov's dogs, meat powder (UCS) led to salivation (UCR). In a young infant, a puff of air to the face (UCS) will elicit an eyeblink (UCR) without any prior learning. If a tone is repeatedly paired with the puff of air, infants as young as 10 days will learn to blink (**conditioned response**, or **CR**) when they hear the tone by itself (**conditioned stimulus**, or **CS**), having learned the association between the two stimuli through classical conditioning (Little et al., 1984). Similarly, when infants are given a sweet solution (UCS), they will automatically show increased sucking (UCR). If a gentle stroking of the forehead, the conditioned stimulus (CS), is repeatedly paired with a sweet solution, even newborns will soon start to engage in anticipatory sucking (CR) in response to stroking alone (Blass et al., 1984), just as Pavlov's dogs came to salivate (CR) at the sound of a bell (CS) alone after the bell had previously been repeatedly paired with the meat powder (UCS).

Interestingly, infants can learn from classical conditioning even when they are asleep. (It is not uncommon for newborns to sleep 18 hours a day, which would leave less than 6 hours for learning if the infant needed to be wide awake to learn.) When a tone is consistently paired with an air puff delivered to sleeping newborns (see Figure 4.23), they will soon show more eye movement in response to the tone than other newborns who hear tones at random that are not paired with air puffs. In addition, only the infants who experience the air puff–tone pairings show increases in cortical activity that suggest that they are processing new memories (Fifer et al., 2010). The ability of infants to be classically conditioned whether they are awake or asleep enables them to learn as much as possible about important patterns in their world. In contrast, sleeping adults are not thought to be capable of classical conditioning. The ability to learn this way while sleeping may be a special adaptation of infancy because of the enormous amount of time infants spend asleep. Forming associations through classical conditioning is one way that infants begin adapting to their environments right from birth.

Q: What are some examples of classical conditioning in infants?

Early in the study of classical conditioning in infancy, J. B. Watson and his associates conducted a dramatic demonstration of this form of learning (Watson & Raynor, 1920). A 9-month-old infant referred to as "Little Albert" was brought into the laboratory, where he eagerly approached furry animals, such as rabbits. The child was then shown

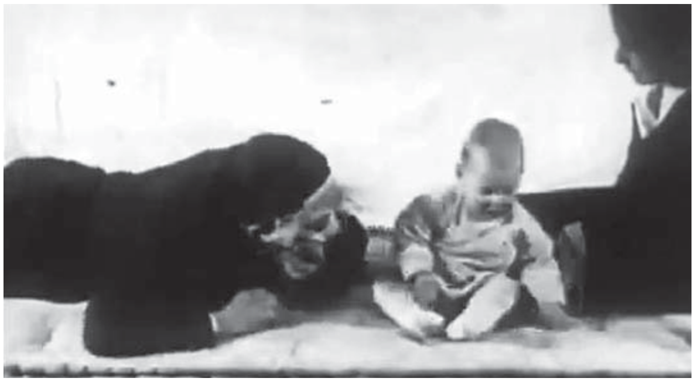

FIGURE 4.24 The Little Albert study. The demonstration of classical conditioning in a child with the pseudonym "Little Albert" was used by James Watson to argue for an entire program of child rearing. Here Watson is pictured wearing a mask to see if Albert's fear of rats would generalize to a person wearing a furry mask.

a white lab rat. Initially, he seemed interested and unafraid as he reached toward it. In later trials conducted over 2 months, just as Albert touched the rat, a researcher behind him hit a steel bar with a hammer to make a sharp, loud noise (the UCS), which startled Albert and made him cry (UCR). After Albert had experienced several pairings of the rat with the noise, the researchers found that the rat alone (CS) could elicit a fearful response (CR). Whenever Albert saw it, he crawled away from it. This fearful response was then shown to generalize to other furry objects, such as rabbits (see Figure 4.24). Clearly, the current ethical restrictions would forbid this sort of study on infants or young children. The study has also raised considerable controversy over the years among those who disagree not only with its ethics but also with its methods (Paul & Blumenthal, 1989). In addition, it appears that contrary to Watson's claims that Albert was a normal healthy infant, he in fact had neurological impairments that raise questions about the extent to which the specific findings would extend to healthy infants (Fridlund et al., 2012).

The conditioning of fear, as in Albert's case, is interesting because it starts to illustrate some of the hidden complexity of classical conditioning (Rescorla, 1988). In the traditional view of classical conditioning, the conditioned response and the unconditioned response are supposed to be quite similar, with the conditioned response perhaps a bit weaker—for example, less salivation (CR) when the bell rings (CS) in the case of Pavlov's dogs, or not quite so active sucking (CR) by a human infant when her forehead is stroked (CS). But in the case of conditioned fear, the conditioned response is quite different from the unconditioned response (LeDoux, 1998). After Albert had been conditioned to fear the rat, he didn't startle and cry when he saw it as he had in response to the loud noise. Instead, he tried to avoid the rat in anticipation of hearing the loud noise. The conditioned behavior was clearly adaptive and, in a sense, purposeful, rather than being limited to a simple association of a conditioned stimulus with an unconditioned one. Classical conditioning also relies on developing aspects of memory (Rovee-Collier, 1986) and on emerging expectations about future events (Fagan, 1993).

As we saw in Chapter 1, **behaviorism** is the notion that all behaviors can be instilled through conditioning, using combinations of punishments and rewards in association with sets of stimuli. Such conditioning makes certain actions more likely and others less likely. For many years, behaviorism and different forms of conditioning were thought to be the only scientific way to discuss learning, both in adults and throughout development. Behaviorists believed that infants come into the world as a **tabula rasa**, or blank slate, with little or no innate associations, and that any association can be conditioned through experience. Because they focused on the overt behaviors—that is, the *actions*—that resulted from the conditioning of these associations, behaviorists viewed most variations in behavior as a consequence of differences in the ways individuals were conditioned to act.

Classical conditioning models of learning were the first wave of behaviorism, with Watson being one of the strongest proponents of this point of view. The second wave arose with B. F. Skinner, a dominant figure in psychology in the mid-twentieth century. Skinner worked out the details of another way of modifying behavior known as operant conditioning (Skinner, 1938).

Operant Conditioning Compared with classical conditioning, **operant conditioning** (also known as **instrumental conditioning**) is more directly concerned with the way an organism learns to operate on its environment in response to either positive reinforcements that reward that behavior or negative reinforcements that punish that behavior. Skinner developed highly efficient methods for getting a wide range of species to exhibit specific behaviors. In one of the processes he used, called **shaping**, the researcher begins by rewarding spontaneous actions that resemble the desired behavior and then continues rewarding only behaviors that are increasingly similar to the desired response. As a result, the responses gradually change to become the desired behavior.

This technique was often used on pigeons in tightly controlled learning environments known as Skinner boxes (see Figure 4.25). Suppose an experimenter wanted the pigeon to peck a certain button whenever a green light in the box was illuminated. She might carefully observe the pigeon in the box and provide a reward, such as food pellets, whenever the pigeon happened to be facing toward the button while the green light was illuminated. After several trials, she would up the ante and only reward the pigeon when it was both oriented toward the button and standing near it while the green light was lit. When the pigeon had

FIGURE 4.25 Skinner boxes and pigeons. A "Skinner box" in which a pigeon's behavior is shaped through operant conditioning. Many researchers saw the Skinner box as promising a technological revolution in behavior modification—a revolution that was thought to ultimately provide a full explanation of human behavior as well.

learned this response, the reward might become contingent on actually touching the button while the green light was on—and so on, until the pigeon learned that it could earn a reward only by pecking the button while the green light was on.

What role does operant conditioning play in infant development? It can be a useful way for infants to learn to adapt to changes in their environment. It can be as simple as learning to change lip movements while nursing in response to positive reinforcement from the improved flow of milk. Likewise, 3-month-olds can learn to vocalize more in response to parents' smiles and other positive cues (Rheingold et al., 1959; Weisberg, 1963). Other studies have shown how infants at 6 weeks and older can learn to smile more often and more intensely through operant conditioning (Brossard & Decarie, 1968; Zelazo, 1971) and how infants who are at least 2 months old can be operantly conditioned to kick their legs more often when it causes a mobile (loosely tethered to the baby's leg) to move, providing a rewarding visual stimulus (Rovee & Fagan, 1976; Rovee-Collier & Giles, 2010; Watson & Ramey, 1972). In all these cases, the infants learn to adjust their actions to make a pleasant event occur more often. The infants are more likely to repeat these learned actions later in contexts highly similar to the ones in which they originally learned them (that is, in situations with the same stimuli and in the same setting). Infants will also make similar adjustments to reduce occurrences of unpleasant events (Sajwaj et al., 1974), though for obvious ethical reasons, there have been more studies of positive reinforcement of human infants than negative reinforcement.

Yet, most contemporary infant researchers have not used operant conditioning to shape desired infant responses. Instead, they have taken an easy, well-established infant action, such as sucking, and taught infants to associate it with a stimulus, such as a visual pattern, through operant conditioning. The researchers can then measure the infant's operant sucking response to see whether he can discriminate between the learned visual pattern and another one. (This technique is similar to the use of sucking as a measure of habituation, which was discussed in Chapter 3.)

Hundreds of studies have now shown that from birth on, infant behavior can be modified through both classical conditioning and operant conditioning. Infants can come to associate some stimuli with other stimuli, and they can alter their actions as a result. They also can be shown to change their actions as a result of positive and negative reinforcements. But those capacities do not necessarily support the behaviorists' key contentions about development: (1) that the infant comes into the world with few or no preformed associations, (2) that any pattern of associations can be learned from experience, and (3) that actions are simply learned responses to environmental contingencies. While learning and environmental influences clearly matter in infant development, several lines of research have greatly refined our understanding of both their contributions to development and their key limitations.

Q: What are some examples of operant conditioning in infants?

Constraints on Learning It has now become abundantly clear that neither humans nor other animals associate all stimuli equally easily and that some stimuli can become associated in particular contexts but not in others. Thus, if a rat repeatedly sees a light and hears a noise at the same time prior to receiving a shock, it will respond fearfully to either the light or the noise. If a rat is repeatedly presented with a light prior to a shock and then later the noise is added, however, the noise alone will not cause a fearful response (Rescorla, 1988). Intuitively, it seems obvious how this **blocking** of the noise-to-shock association occurs; the formation of the first association interferes with the formation of the second association. The rat that has received light alone first has learned that the light is the critical determinant of the shock and therefore regards the subsequent noise when paired with the shock as redundant and uninformative. In effect, a decision is made about the likely informative value of the noise. The rat seems to engage in some form of cognition that goes beyond association.

Studies of human infants suggest that they experience similar blocking effects as early as 6 months of age (Sobel & Kirkham, 2006, 2007). The first association can be construed as a form of context that then influences the learning of a second association. Infants learned to look at either sequences of visual events in certain locations or visual events followed by sounds in specific locations. When the researchers measured infants' anticipatory eye movements to each location in response to these series of patterns, they found that the initial associations influenced the infants' later associative learning in ways that the classical laws of association could not explain, but which were quite similar to blocking phenomena found in other species.

A second important constraint on conditioned learning is that for particular species, some associations are easier to form than others. That is, considerable evidence across many species shows that organisms are **prepared** (through natural selection) to learn some associations and not prepared to learn others (Seligman, 1970). In Pavlovian conditioning, this can be seen where an animal will tend to associate some stimuli more strongly with certain outcomes than with others. Thus, a rat can more readily be classically conditioned to associate a sound (or a visual stimulus) with the pain of a shock than to associate a particular flavor with a painful shock. On the other hand, the rat is prepared to associate feelings of nausea with a prior flavor rather than with a certain sight or sound that preceded the feeling. The likelihood of associating nausea with a flavor tasted earlier remains high even when the rat experienced the taste several hours before feeling ill and the sound directly preceded the nausea (Garcia et al., 1974, 1985; Rozin & Kalat, 1971). The effects of preparedness on learning can be just as striking in operant conditioning. Thus, it is easy to train a pigeon to peck a button to get food or to flap its wings to avoid shock (see Figure 4.26). But trying to shape it to perform the opposite associations—pecking to avoid a shock or flapping its wings to get food—will try the patience of even the most dedicated experimenter.

The pigeon and rat examples offer intuitive examples of why associations aren't formed in an unbiased manner. Many behaviors, especially those that appear earliest in an organism's life, are organized in ways that make functional sense for an organism in its normal environment. Thus, pigeons have evolved a set of escape behaviors that involve flapping their wings when they are in unpleasant or painful situations. Likewise, they have evolved a set of behaviors in seeking food that involve pecking at the ground (Woodruff & Williams, 1976). An animal's behavior is therefore intimately related to its typical environment, resulting in behaviors that are adapted to that environment, just as physical adaptations, like an animal's fur or webbed feet, are adapted to that environment. Thus, action is rarely arbitrary, but rather is directed by an organism toward solving certain problems in a particular environment.

We will see in Chapter 7 that the development of fears in human infants fits the idea of having prepared responses to certain stimuli. Human infants seem predisposed to develop a fear of snakes and spiders, but not of flowers or frogs (DeLoache & LoBue, 2009; Rakison & Derringer, 2008). These fears can form rapidly in infants who have never had negative experiences with snakes or spiders. In addition, monkeys reared in controlled settings where they never saw any snakes show a similarly strong bias to learn to fear them. In short, human infants seem very much like other primates in the ways they are prepared to associate some creatures with fear.

These constraints on conditioning—on both the context in which conditioning takes place and the ease or difficulty of forming particular associations—serve as a reminder that all actions, even those motivated by negative and positive

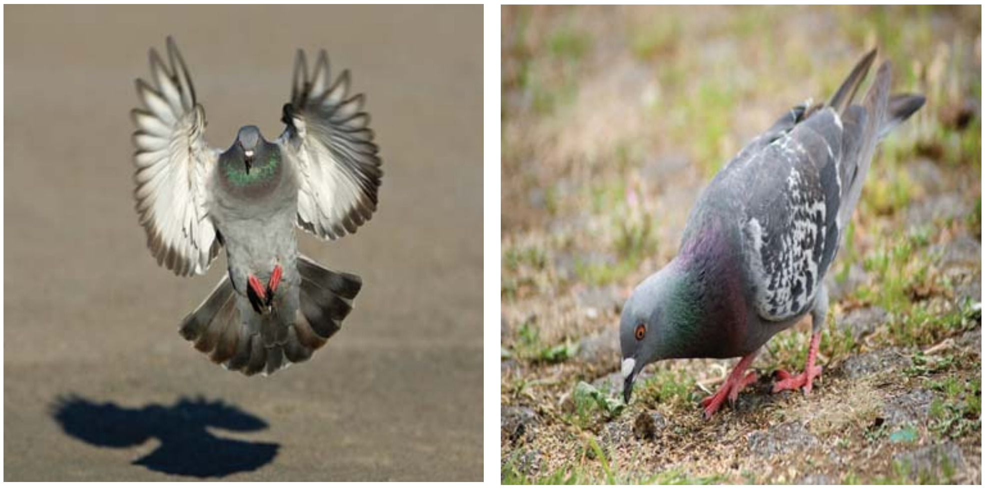

FIGURE 4.26 Prepared learning. Pigeons' tendencies to flap their wings and to peck are "prepared" to be associated much more strongly to some classes of events than others. It is much easier to train pigeons to flap their wings (and attempt to flee) to avoid shock than it is to get food, while the opposite is true for pecking.

reinforcements, develop within a framework of constraints. Those constraints do not necessarily specify which actions will develop. But they do make some kinds of associations, and therefore some kinds of behavioral responses, far easier to learn than others.

Q: How are both classical and operant conditioning constrained such that not all associations are treated as equal?

Conclusions

Action does not develop in infancy either as a purely internal set of motor control programs or as a passive reflection of the pushes and pulls of various environmental contingencies. Instead, it arises from an interplay between dynamic properties of the body, the environment, and some elements of motor planning. The physical properties of a baby's limbs interact with specific environments, such as a tank of water or a ramp, in ways that become more than the sum of the individual elements. More broadly, action is an example of how much of development consists of dynamic interactions between distinct subsystems, whether they are perceptual and motor systems or different forms of information, such as spatial layout and number.

Across a wide range of approaches and topics, we have seen that the infant is constantly coordinating action with perception in ways that are critically dependent on the simultaneous feedback of self-produced movement. The feedback loop between a developing organism and its environment is an essential part of the developmental process and perhaps most easily seen and understood in cases of the development of action. As we saw in the discussion of perception and neural development in Chapter 3 and as we will see in later chapters, infants, children, and other developing organisms are often best understood in terms of their continuous cycles of interaction with their environment. We have also seen that an animal's actions are tailored for particular interactions with its specific environment, as in the linking of pigeon pecking to food-acquiring behavior. We have begun to think about constraints on development, leading to the idea that human infants (and infants in other species) are often endowed with preexisting frameworks that make certain actions more likely but do not predetermine them. This was particularly vivid in the development of birdsong, but it applies to many other cases as well. In Chapter 3, we saw some signs of preexisting frameworks in perceptual development, such as a schema for perceiving faces, but in this chapter we have gone beyond the perception of information to see how behavior itself conforms to different types of constraints. In later chapters, we will broaden this idea further to look at constraints on cognitive structures, on language, and on social behavior and emotions. In general, this chapter paints a picture of the infant as a dynamic, exploring, willful agent who is trying to make sense of and gain mastery over the world, much as we saw in Chapter 3. In Chapter 5, we turn to closely related questions about how the infant tries to make sense of that world.

STUDY AND REVIEW

SUMMARY

Foundations of Motor Development

- Newborn infants are endowed with many reflexes right from birth, including the patellar reflex, the rooting reflex, the grasp reflex, the stepping reflex, and the Moro reflex. Some of these reflexes disappear in the first few months of life. This is no longer thought to be solely a consequence of their inhibition by higher-level cognitive control, but rather is thought to reflect the changing properties of infants' muscles and limbs and the features of the environment in which they act.
- Psychologists have long documented various milestones in motor development, such as a sequence that proceeds from rolling over, to sitting, to crawling, to standing, and finally to walking, regardless of experience. It used to be thought that these sequences were merely consequences of increasing brain maturation. This view is now replaced by a view that emphasizes ranges and variation as to when normal behaviors appear, based on dynamic systems.
- Dynamic systems theory emphasizes the interactions between many components involved in executing behaviors and not just instructions being sent as one-way messages from the brain. Feedback loops are a central part of such an approach. The components include the physical environment, the physical properties of the body (especially the limbs), the properties of the brain and nervous system, and how the environment is being perceived.
- Dynamic systems theory has been supported by studies showing that minor changes in the limbs (for example, small weights attached to the limbs) or in the environment (for example, a ramp or a tank of water) can cause radical changes in motor behavior in the developing infant.

Perception and Action

- Action is often linked to perception, as in the case of reaching for an object. There are considerable challenges here, as the infant's body is undergoing dramatic changes while she is learning to guide her hands to an object.
- Through careful video analysis, it is possible to show that even newborn infants can crudely move their arms to reach in the direction of an appealing object or display. Their very early abilities serve as a framework that guides learning during perceptual-motor development.
- As infants grow older, they are able to use feedback from their perception of their own actions to fine-tune their movements to more and more accurate actions. But to do so, infants must perceive the consequences of their self-produced actions in real time. If they are made to be passive observers of actions made by others, they will not learn to fine-tune their actions. This effect has been well documented in kittens and increasingly in human infants.
- Walking might seem to be a skill that develops merely because of increasingly sophisticated signals coming from the brain. It is instead dependent on visual feedback of how the world is flowing by and on feedback from the infant's muscles and touch receptors. It also depends on the properties of the limbs, such that heavy babies take longer to walk because the walking system is so fragile that a little extra baby fat is enough to interfere with early walking.

Learning to Engage in Specific Actions

- One of the most dramatic early actions is imitation. Newborn infants will imitate several different facial expressions, as will newborn monkeys. Remarkably, the monkeys will imitate faces of another species, namely humans. Imitation requires a sophisticated mapping between perception, memory, and action, and it may involve a special set of neurons known as mirror neurons.
- The development of birdsong showcases several important patterns pertaining to the development of action. The variation across different species of birds shows that there are many possible developmental pathways for learning complex motor behaviors from models. Birdsong development illustrates critical periods and the great importance of perceptual-motor feedback in learning songs. The different patterns of birdsong development also illustrate how a framework of innate biases guides learning species-specific song elements.
- Imprinting is learning that seems to occur during a special time period, after which it becomes irreversible. It is most notable in many birds that normally imprint on their mothers but can be tricked into imprinting on a wide variety of other moving objects. It seems to involve an initial tracking system that makes moving objects of roughly maternal size the most salient, and an independent system known as the IMHV that leads the chick to imprint onto a particular individual, usually its mother, during a critical period.
- In conditioning, organisms learn to produce actions in response to environmental contingencies. Through classical conditioning, an organism learns how stimuli are related; through operant conditioning, an organism learns the consequences of its actions.
- Classical conditioning consists of identifying a preexisting stimulus-response relationship and then associating a new

stimulus with the first stimulus, such that the new stimulus now produces an action similar to the original response. Originally demonstrated in dogs by Pavlov, it has been demonstrated many times in infants from birth onward, and it can occur even when infants are sleeping. John Watson used the phenomenon of classical conditioning, as demonstrated with Little Albert, to make broad claims about child rearing from the viewpoint of behaviorism.

- Operant conditioning is concerned with how organisms learn to operate on their environments in response to positive and negative reinforcements. Through the technique of shaping, in which the researchers reward spontaneous actions that come closer and closer to resembling a desired behavior, it is possible to get animals to produce chained sequences of novel behaviors, a technique that was greatly refined by B. F. Skinner, another proponent of behaviorism.
- Both classical and operant conditioning occur within a framework of constraints that can sharply limit what associations are learned and what behaviors are elicited in response to a stimulus. Organisms are prepared by natural selection to make certain associations and certain stimulus-response pairings that have adaptive value for those organisms in their environmental and ecological niches.

THOUGHT QUESTIONS

1. How can imitation be related to empathy? Infant imitation has often been described as a way of setting up feelings of empathy with another. Empathy, however, can have several forms, ranging from simple emotions to understanding another's point of view. Consider what forms of empathy would and would not likely be facilitated by infant imitation.
2. Why would imprinting behavior be selected for in the evolution of some species but not others? How might a species' developmental growth patterns, its relations to other members of the same species, and its niche be relevant?
3. Why are prepared associations useful? You have read how rats and pigeons are "prepared" to make certain associations more than others and that humans may be "prepared" to associate certain organisms with fear. What other associations might humans also be more prepared to form?
4. Can infants display early indications of exceptional motor skills? In several countries that have strong government support of Olympic development programs, scouts try to find evidence of extraordinary motor skill at younger and younger ages. If you were such a scout, what evidence, if any, would you use to identify infants under 1 year of age who are gifted with such extraordinary motor skills?

Conclusions

Summary

Well before the end of their first year of life, each of our three sons had made many dozens of trips to the lake near our house. By the lake, we would throw stones that skipped along the surface and then sank and disappeared. The small waves lapping at their feet, the bobbing driftwood near the shore, the trees' leaves fluttering in the wind—all were objects of great fascination. What crossed their minds as they watched the world so avidly? Did they think that the stones that disappeared under water ceased to exist? Did they have a sense that the lake water was anything like the water in which they bathed? Did they understand why the leaves fluttered or that they even needed a cause to move? When they saw a duck out on the water or waddling on the bank, did they think of it as a living being with different capacities from an inanimate object? When they saw two pieces of wood drift under the dock, did they expect to see two pieces emerge on the other side? More broadly, as young infants, did they think about the world in qualitatively different ways than older infants or children think about it; or was there much more continuity to their cognitive development? These same kinds of questions pertain to the mental lives of infants throughout the world. This chapter examines how developmental psychologists have explored such questions scientifically.

In Chapters 3 and 4, we considered how the infant comes to perceive and act on the world. Coming to understand that world and hold specific beliefs about it is quite another task, even as it intimately depends on perception and action. In this chapter, we will consider infant cognition—that is, the capacity of infants to think, reason, and use knowledge about the world. We will see that considerable complexity lies beneath an infant's cognitions. But because infants can't explain their thought processes to us, developmental questions about their minds often revolve around whether their thoughts and knowledge are explicit or implicit. **Explicit cognition** involves having an awareness of knowledge or of a thought process, usually in a way that can be described in words, such as knowing that Paris is the capital of France or knowing the rules for solving a crossword puzzle. **Implicit cognition** works outside of awareness and may be difficult to describe in words. It might include the thoughts underlying the sense that an animal is sick, even if you can't say why, or the knowledge that helps you ride a bicycle, even though you can't fully explain the skill. We will see that recognizing the difference between explicit and implicit cognition plays an important role in understanding early cognitive development, often with the initial assumption that the cognition of young infants and other animals is mostly implicit.

We will explore cognition in several areas of infant development. In particular, we will consider how infants understand an object's physical properties (for example, its solidity or its continued presence when out of sight) and the causal relationships between interacting objects, as well as how they understand different numbers of objects. We will also look at how infants think about physical space and how they come to view objects as members of categories (for example, knowing that a poodle is a dog and that a dog is an animal). Finally, we will consider how infants distinguish social agents that act (and react) on their own from inanimate objects.

Throughout the chapter, we will draw on some familiar developmental themes. We will investigate whether infant cognition is just a simpler version of older children's or adults' thinking or whether it is qualitatively different. Moreover, when infants show marked cognitive change, does that change seem to occur globally, affecting all kinds of thought and understanding, or does it seem limited to one kind of cognition, such as thinking about spatial relationships or understanding numbers? And in what ways is the infant's mind adapted, or receptive from the start, to think about the world in particular ways?

We will begin by exploring the work of Jean Piaget, the twentieth century's most influential developmental psychologist. In this chapter, we will discuss Piaget's general approach and his theory of infancy, along with the recent surge of research that suggests that infants have greater cognitive capacities than Piaget believed possible. In later chapters, we will consider Piaget's theories of childhood.

Piaget's Approach

It is impossible to fully understand Jean Piaget's approach to development without knowing a little about who he was (see Figure 5.1). Born in 1896 in Neuchâtel, Switzerland, Piaget showed an early scientific bent and was particularly fascinated by biology. His first publication came early—at the age of 10—and was followed by more than 20 additional biological papers by the time he was 21. When this impressive record earned him an offer to become a curator at a Geneva museum, he surprised the museum officials, who had assumed he was much older, when he declined the job because he had not yet finished school (Flavell, 1963; Piaget, 1952a).

In the following years, Piaget became increasingly interested in psychology, always taking what he considered a biological perspective. He did not focus on the inner biological mechanisms that lead to behavior but instead used biological concepts such as adaptation to the environment, relationships between the structure and the function of particular adaptations, and the developmental unfolding of structure over time to explore cognitive development. When he was roughly 24, he began working in Paris in the laboratory of Alfred Binet, a researcher whose studies of school-age children led him to develop the first workable standardized intelligence test. In Binet's lab, Piaget began interviewing large groups of children

FIGURE 5.1 **Piaget.** Jean Piaget (1896–1980) is the undisputed giant in the history of the study of cognitive development. His work over a span of several decades revolutionized the study of the developing mind.

and became fascinated with the kinds of mistakes on experimental tasks that children commonly make at different ages. To Piaget, these changes suggested a series of stages in normal cognitive development. Piaget returned to Switzerland, where he held a variety of academic posts and remained actively engaged in research until his death in 1980.

The scope of Piaget's work is breathtaking. He wrote more than two dozen major books and hundreds of articles on topics ranging from children's understanding of time, space, and number to topics in biology and philosophy, and he inspired an extraordinary range of studies in developmental psychology. Especially in the 1960s and 1970s, as the influence of behaviorism declined and researchers began reincorporating the workings of the mind into their explanations of behavior, there was a renewed interest in Piaget's work. It offered a way to bring cognition back into developmental psychology. Because his body of research is so vast, our goal here is to outline its most important trends and their place within developmental psychology. We will then present some of the more recent research that has challenged some of Piaget's assumptions and explanations.

Piaget's Theory of Cognitive Development

Piaget's theory describes several processes of cognitive development. To characterize those processes, Piaget thought of the child's knowledge and behavior in terms of schemes. A **scheme** describes a child's pattern of interacting with her environment; it includes the child's internal knowledge and interpretations and also the behaviors that arise from them. Children are constantly engaging in a process of **adaptation**, by which the child better fits her schemes with new experiences in the environment. The two most basic forms of adaptation through which the child tries to achieve a better fit between her schemes and the world are known as *assimilation* and *accommodation*.

Assimilation is the process in which the child interprets something new and unfamiliar in terms of preexisting schemes—that is, behaviors and concepts that are already familiar to her. The result can often be a distorted or severely narrow view of that aspect of the world. Thus, if a 1-year-old has talked to relatives on a cell phone, she might first think that a television remote is somewhat like a cell phone, and after pushing its buttons, she may try talking into it. She has assimilated the remote control into the richer knowledge she already has about cell phones, but she has distorted her understanding of the remote control in the process. In contrast, **accommodation** occurs when the child alters her schemes—that is, her behavior or understanding—to better fit something new she has encountered. If our 1-year-old adjusts her knowledge of cell phones and how to use them in a way that incorporates the differences between the remote control and a cell phone, she has used accommodation. Through this process, she may realize that she does not need to speak into the remote, but it does help to point it at the television. As a result, she has differentiated her understanding of the cell phone and the remote.

Piaget suggested that we rarely see pure cases of accommodation or assimilation; rather, the two almost always work in concert to achieve the best fit between the child and the environment. There may be cases where assimilation dominates, but usually some small adjustments of behavior and knowledge are also needed. Similarly, there may be cases where accommodation dominates, but in order to relate the new scheme to the world as we know it, some assimilation must also occur.

This process in which both accommodation and assimilation work together to foster a better cognitive fit with the environment is known as **equilibration** (see Figure 5.2). We can think of equilibration as the child's tendency to achieve a dynamic balance between her schemes and her environment. Piaget conceived of a continuous and active interplay between the child's schemes and the phenomena in the world. In Piaget's terms, equilibration describes the process of achieving a closer correspondence between the environment and the child's thoughts and behaviors. This correspondence is never perfect, but for Piaget, improving it is the motivating force behind cognitive development. Thus, the 1-year-old girl who has never before seen a TV remote control has a mismatch between her existing cognitive structures and processes, or schemes, and how well they can be used to understand the remote control—so she strives to find a better match. This is equilibration.

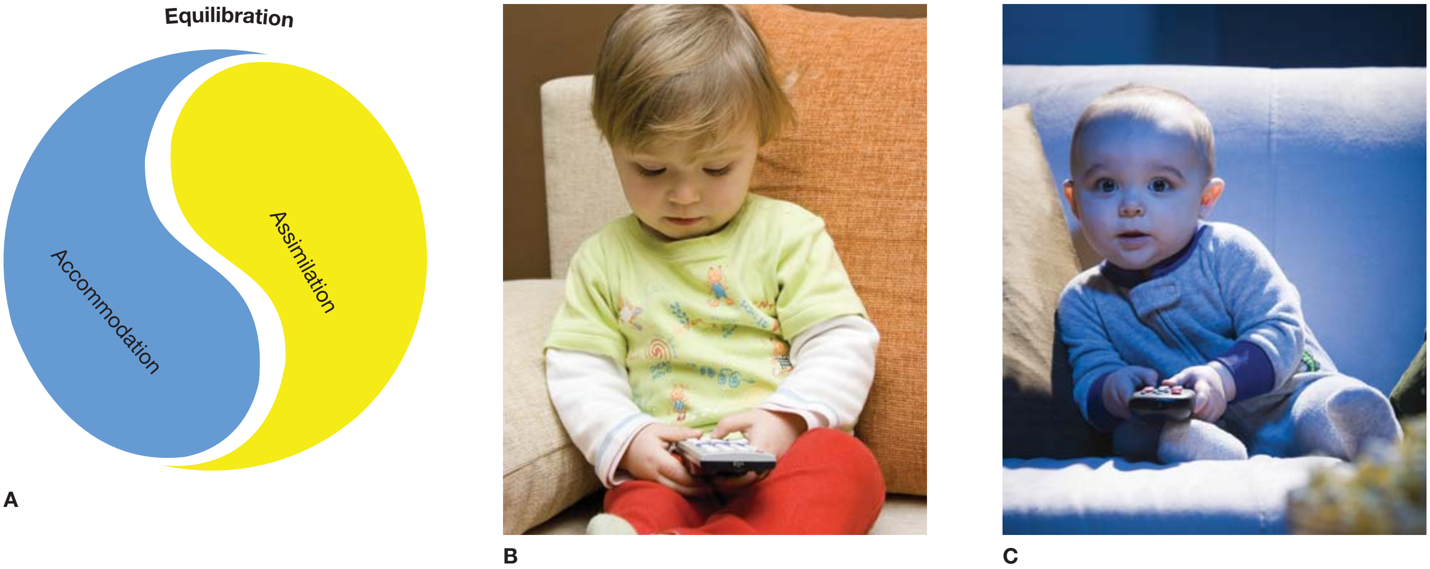

FIGURE 5.2 **Equilibration and its two components: assimilation and accommodation.** **(A)** Equilibration is seen as composed of two complementary processes of assimilation and accommodation. With assimilation, the child interprets new and unfamiliar things in terms of existing mental structures and concepts. With accommodation, the child adjusts her behaviors and concepts to better fit the environment. **(B)** When an infant first encounters a TV remote control, she may cognitively assimilate it into the more developed mental representation that she has for a wireless phone. **(C)** Somewhat later, she may accommodate her mental structures and behaviors for the remote control in ways that more closely relate to the unique properties of the remote control.

Q: What is equilibration? What are the two processes that make up equilibration?

In Piaget's view, infants and children use various schemes to interact with their environment. Since these schemes are never perfectly matched with the aspects of the environment that they seek to interpret, children use equilibration to bring their schemes into closer alignment with the world they encounter, doing so through the complementary processes of assimilation and accommodation. As the schemes are adjusted through accommodation, their structure changes, perhaps modestly at first, but over time they may be completely reorganized.

A distinctive aspect of Piaget's theory is its emphasis on discrete periods and stages of development. Piaget is known as a stage theorist because he believed that assimilation and accommodation of many schemes lead to qualitative changes in cognition, which is evident in children's major leaps in understanding at certain points in development. In contrast, some approaches view development as a more gradual process of continuous, incremental change—quantitative change—as described in Chapter 1.

Piaget envisioned four periods of development across the lifespan: the *sensorimotor period*, from birth to roughly 2 years; the *preoperational period*, from roughly 2 years to 7 years; the *concrete operational period*, from roughly 7 years to 12 years; and the *formal operational period*, from roughly 12 years on. Table 5.1 outlines these four periods. We will discuss each of these periods in the appropriate chapter. Here we will discuss more general aspects of the stage theory before exploring the sensorimotor period in depth.

By dividing cognitive development into four periods, Piaget was proposing distinct, qualitative changes in the child's thinking about the world. During each period, the child acquires many new schemes—until she accumulates enough new understanding to trigger a transformation in her thought processes, leading her into the next period. Piaget believed that each period operates in a domain-general way; that is, during each period, the child uses certain characteristic ways of thinking to develop schemes about all aspects of the world—not just about one specific area, such as social agents. The only way to proceed from one period to the next is to accumulate enough new knowledge from experience to cause a reorganization of the schemes. Piaget observed that the specific ages associated with each period vary from child to child. By contrast, he believed that the order of the periods never changes, since each period provides a necessary foundation for the next one.

Q: Describe Piaget's four periods of cognitive development and the distinguishing features of each.

Period of Cognitive Development	Age	Hallmark
Sensorimotor period	Birth–2 years	Infants learn to distinguish their own bodies and actions from the external world around them.
Preoperational period	2–7 years	Children can use symbols to mentally represent objects, but they fail to use mental operations that enable them to see the quasi-logical relations governing phenomena.
Concrete operational period	7–12 years	Children can apply quasi-logical operations to concrete information, but they fail to think abstractly or in hypothetical terms.
Formal operational period	12 years on	Children are able to think logically about things that are not immediately present and about abstract and hypothetical ideas.

TABLE 5.1 **Piaget's four periods of cognitive development.** Each of Piaget's four periods describes a qualitatively distinct way of understanding the world. The associated ages provide rough guidelines and can vary considerably across children.

Where would Piaget fall along the nativist/empiricist continuum? His view of infants and children as striving to understand the world better through assimilation and accommodation stresses an active, exploratory developmental process. While he clearly disagreed with the empiricist view of the infant as a passive vessel or blank slate, his emphasis on the domain generality of cognitive development and his notion that all knowledge is built up through experience made him an empiricist. Although he certainly was concerned with the mind (unlike a behaviorist) and with complex cognitive structures (rather than the simple networks of a classic associationist), he was nonetheless deeply at odds with the nativists' central tenets. Unlike the nativists, he never proposed that the mind has any innate biases toward particular areas of thought. Thus, while Piaget believed in innate schemes that work in ways that go beyond mere associations, he did not believe in the nativist view that there are innate domain-specific constraints for understanding such areas of knowledge as spatial layout, number, or the properties of physical objects. To better understand the details of Piaget's approach to infancy, we will turn to his description of the sensorimotor period.

Q: Is Piaget's approach more compatible with nativism or empiricism?

The Sensorimotor Period in Infancy

Piaget called the first 2 years of life the **sensorimotor period**. As he did for each of the four periods of cognitive development, Piaget further divided the sensorimotor period into smaller stages that give it texture and depth. He proposed that there are six distinct stages within the sensorimotor period (Piaget, 1952b). His evidence for these stages was especially personal, coming almost exclusively from detailed observations of his own three children.

Piaget saw a great deal of activity going on in infants during each of the six sensorimotor stages. This overview briefly characterizes each stage, focusing on the infant's understanding of physical objects, a form of understanding that Piaget called the **object concept**, an idea central to his overall theory of the sensorimotor period. Piaget's account of the object concept focuses on **object permanence**—how the infant comes to think of objects as things that still exist even when they are out of sight and not being used or acted on.

Stage 1 (Birth to 1 Month): Use of Reflexes Piaget believed that the very young infant interacts with the environment by means of relatively fixed, innate routines, or reflexes, which Piaget viewed as the simplest early versions of schemes. Among Piaget's examples of these infant reflexes, the most commonly mentioned are those related to breastfeeding, such as the sucking reflex, which is present from birth. In Piaget's view, these reflexive behaviors are not completely fixed, however. Rather, by interacting with the world, infants learn—through the processes of assimilation and accommodation—to modify the simple schemes that influence their reflexive behaviors. For example, Piaget repeatedly observed that his own children became increasingly proficient at finding their mother's nipple and at maintaining active sucking while nursing (thus modifying the sucking reflex through accommodation). The sucking reflex changed in ways that were directly related to the object it acted on, the breast. Thus, the infant "fine-tuned" the preexisting sucking reflex to make it more optimal for recovering milk from the breast. Similarly, one of our sons initially had trouble breathing while he was nursing, since he would bury his face in the breast and cover up his nose while sucking vigorously until he would come up for air. As the days passed, however, he began to show accommodation as he learned to breathe while nursing by turning his head to the side and by not pressing so hard. Through these kinds of modifications of schemes related to early reflexes, infants are able to change their behaviors and eventually integrate them into more sophisticated actions. In this way, according to Piaget, the infant's reflexes form the building blocks for more complex behaviors.

Piaget believed that the infant experiences the world in a radically different way than older children and adults do. In Sensorimotor Stage 1, infants have no awareness of objects as being "out there," independent of their own actions (see Figure 5.3). Instead, they understand objects only in the context of their own ways of routinely interacting with the world. In the breastfeeding example, the infants are focused on sucking and have little awareness that the breast itself is a distinct object; if the infants saw the breast from another angle rather than the close-up nursing position, they would not recognize it as the same object involved in nursing. This concept of the infant's experience is at odds with the research on intermodal perception described in Chapters 3 and 4, in which infants showed very early abilities to integrate information from different perceptual systems, such as vision and touch. As we will see, Piaget's view is also at odds with the more recent research on infant cognition.

Q: What role do reflexes play in Piaget's first sensorimotor stage?

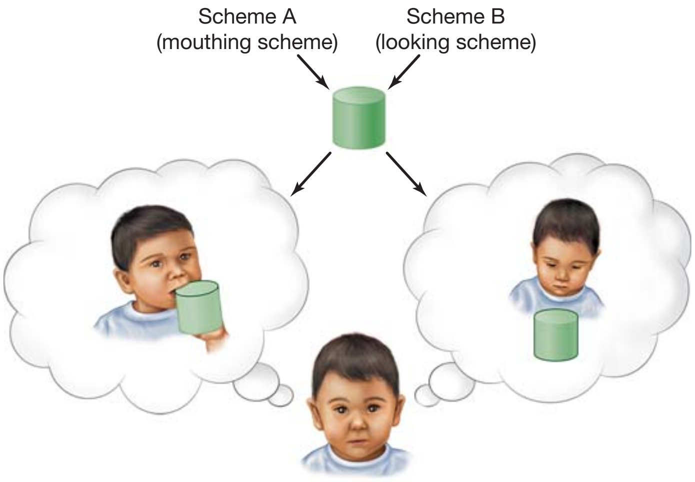

FIGURE 5.3 Multiple schemes and understanding objects. According to Piaget, the young infant can have very different impressions of the same object when understood through different schemes. In this case, looking at a cylinder from one particular angle confers a distorted perspective, whereas mouthing the cylinder distorts it by focusing attention on its edge. According to Piaget, an infant would not even realize that the same object was involved, but later research raised doubts about this notion.

Stage 2 (1 to 4 Months): Emergence of Primary Circular Reactions

In Sensorimotor Stage 1, infants begin modifying their reflexes into more effective behaviors, or motor schemes. In Sensorimotor Stage 2, Piaget saw infants using and modifying their schemes in increasingly flexible ways to get better at stimulating themselves. The hallmark of this stage is the **primary circular reaction**, in which the infant discovers by chance that she can use her motor schemes from the first stage to interact with "new objects"—specifically, new parts of her own body (see Figure 5.4). If the infant finds that new action pleasing, she will try to reproduce it. Then, as these attempts lead to small adjustments in the original behavior, she will accommodate her original scheme to include the new body part and the new action. Since schemes cannot be changed completely, her original scheme partly shapes her understanding of the new behavior, so assimilation also occurs.

Infants can also create new schemes through primary circular reactions, but only schemes discovered accidentally and directed toward parts of their own bodies. Piaget offered an example in which his son, in the process of sucking, happened to have his tongue protrude beyond his mouth and touch his lower lip. He discovered that this was a pleasing sensation and attempted to repeat it. As he gradually became better at quickly licking his lower lip, he built a new scheme for lip-licking. Accommodation occurs here because as the licking scheme develops, it changes in ways related to the sensations of the lip. Assimilation is also involved because the infant's understanding of his lip is heavily influenced by learning about it through his lip-licking scheme.

The schemes developed by primary circular reactions are therefore routines in which infants learn to stimulate themselves better and better. In this context, Piaget argued that infants' understanding of objects remains largely unchanged from Sensorimotor Stage 1 to Stage 2. The infants still do not understand objects (including parts of their own bodies) as existing independently, but rather they see them as embedded in particular behavioral schemes. Thus, as infants in Stage 2 learn to interact with their own bodies in new ways, they remember only the actions and the effects they produced, not the objects that the actions involved.

Piaget recognized that even the most careful observations of his own children were not enough to build a theory of the sensorimotor period, so he developed predictions based on his observations and set out to test whether they held true for other infants. Some of his most interesting predictions concerned the object concept. For instance, as we have seen, Piaget believed that infants in Stages 1 and 2 cannot represent objects as existing independently and that the infants can only understand objects as parts of an ongoing scheme. The objects would vanish when the scheme was no longer being used. Piaget thus predicted that infants in Stages 1 and 2 would not search for an object once it was out of

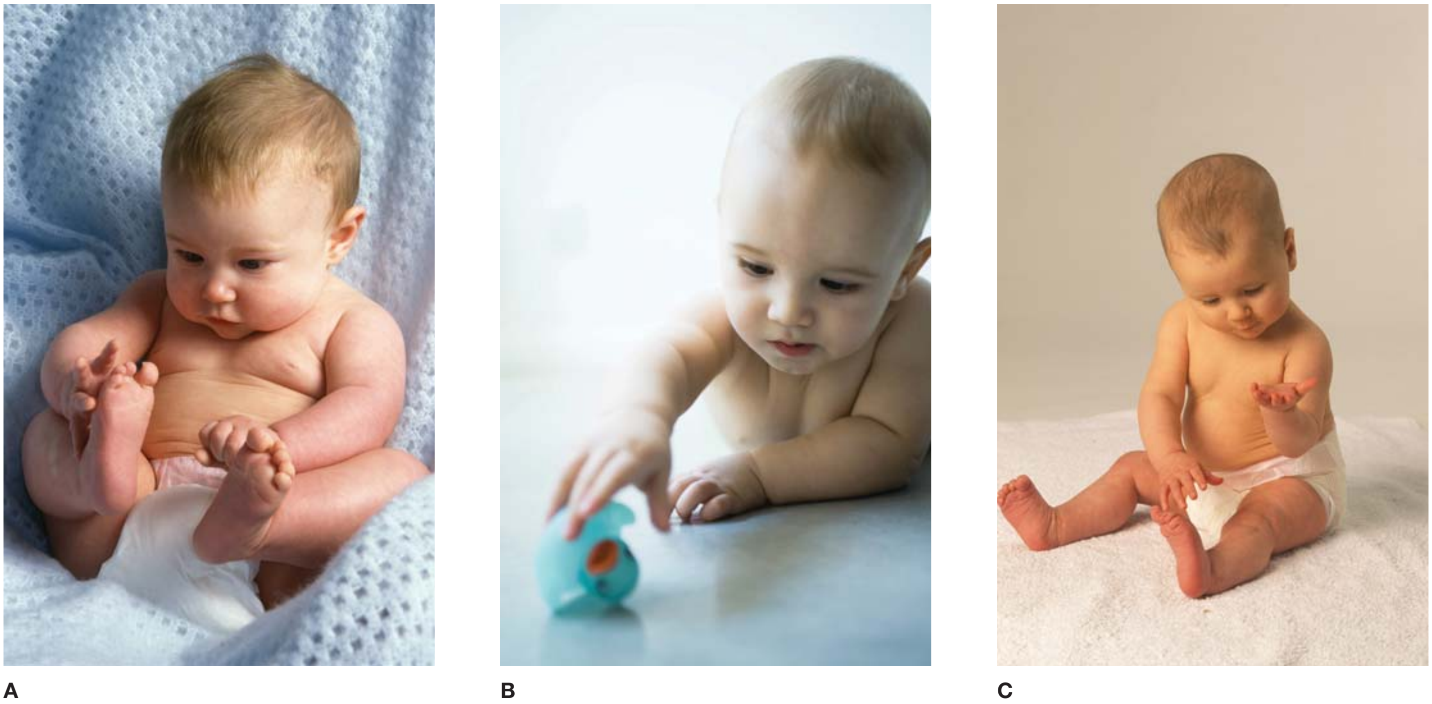

FIGURE 5.4 The developing object concept. As seen in these photos, young infants will scrutinize with apparent concentration many objects, including parts of their own bodies. Researchers on infant cognition are trying to understand how the infant thinks about those objects, such as whether he thinks that they are whole enduring entities that exist when out of sight.

sight. For example, if an infant playing with her favorite rattle accidentally dropped it between the folds of a blanket, she would not search for it, since she would not realize that the rattle continued to exist when she lost sight of it. For the same reason, Piaget believed that infants would not understand that an object's properties can change. For example, if an object is moving, the infant would watch it with a "tracking scheme"; but if the object suddenly stopped moving, the infant would continue tracking along the path the object would have taken if it had continued to move. Piaget based this prediction on the idea that because a moving object and a stationary object require different schemes, the infant is unaware that the stationary object is the same one that was moving a moment before.

Q: According to Piaget, how do infants in Sensorimotor Stage 2 understand objects?

Stage 3 (4 to 9 Months): Appearance of Secondary Circular Reactions In Sensorimotor Stage 3, the infant further expands and modifies his set of schemes, most notably through the process of **secondary circular reactions**. Secondary circular reactions represent a major advance over the primary circular reactions of the previous stage because they involve applying new schemes to external objects, not just to the infant's own body. Although younger infants do act on objects other than their own bodies, Piaget held that in Stage 3 they develop new schemes specifically for interacting with external objects. This is the first small step toward developing limited notions of an external world. But at this point, infants still recognize objects only in terms of the schemes in which they are embedded, rather than viewing them independently.

Like the primary circular reactions, secondary circular reactions initially happen by chance; then, if the behavior is pleasing, the infant reproduces it. The key advance in Stage 3 is that the infant acts on something other than his own body (see Figure 5.5). He might shake a rattle and find the noise interesting, then shake it again to repeat the sound. Over time, he would become more efficient at making the sound, producing a new rattle-shaking scheme. All three of Piaget's children showed secondary circular reactions to mobiles suspended over their bassinets. Each one discovered by chance that leg movements caused the mobile to move. As they sought to repeat this effect, they became increasingly efficient at integrating schemes: moving their legs while simultaneously watching the mobile. With time, such schemes become increasingly sophisticated. For example, an infant might modify the scheme of the mobile by performing an abbreviated and simplified version of the full scheme as a kind of shorthand way of recognizing it. Thus, an infant might give a brief perfunctory leg shake on recognizing a mobile, a leg shake that is a shortened and smaller version of the original that actually moved the mobile and made it exciting.

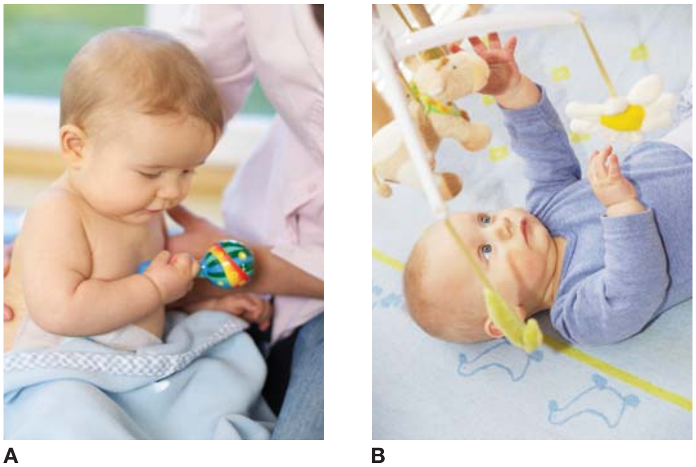

FIGURE 5.5 Secondary circular reactions and interactions with external objects. Infants in the 4- to 9-month-old age range start to explore objects, such as **(A)** the rattle and **(B)** the mobile, with ever more attention to the objects' unique properties. The infant in Sensorimotor Stage 3 initially discovers the sound of the rattle or the movement of the mobile by chance and then uses secondary circular reactions (shaking the rattle, setting the mobile in motion) to act purposefully on the object.

Q: How can a Sensorimotor Stage 3 infant develop actions tailored for an object but not really know that the object exists in its own right? Give an example.

As he did for Stages 1 and 2, Piaget tested predictions about how Stage 3 infants would respond to particular ways of manipulating objects. For example, he predicted that in Stage 3, objects completely out of sight are still "out of mind." But he thought that infants in Stage 3 would sometimes retrieve an object that had been partially covered, because their schemes were sophisticated enough to act on just part of an object, such as a rattle's handle. Piaget also predicted that if a blanket were placed in front of a Stage 3 infant's face, she would push it aside to reach for an object, but if the same blanket directly covered an object that she wanted, she would not remove it. Piaget maintained that the infant would move the blanket away from her face not to get at an object that she couldn't see, but rather to allow the looking scheme to operate. Once the looking scheme could again operate, seeing the object would then trigger a reaching scheme, and the infant would reach for the object. On the other hand, when the blanket covered an object, the infant could still use her looking scheme, but there would be no object visible to elicit it.

Integrated Representation

FIGURE 5.6 Integration of secondary schemes. As infants enter Sensorimotor Stage 4, they transition from seeing each object differently, depending on their schemes for using it, to a more integrated set of schemes that can support a more objective, scheme-independent understanding of the object. Thus, in Stage 3, each scheme involves a different representation of the object. After the transition to Stage 4, the schemes are unified into an integrated representation, and the infant's understanding of the object is no longer "embedded" in any one scheme.

Stage 4 (9 to 12 Months): Coordination of Secondary Circular Reactions

Stage 4 is perhaps when the most significant transitions in the sensorimotor period occur. Although there are no new behavioral hallmarks, such as the circular reactions, the infant is now integrating his vast array of relatively independent schemes into a smaller number of more complex and flexible schemes (see Figure 5.6). A key process for the infant in Stage 4 is interacting with the same object in various ways or, in Piaget's terms, applying multiple schemes to the same object. Through this process, the infant begins to get a sense that the object has enduring properties and that it exists independently of his actions. "Viewing" the same object from the contrasting vantage points of several different schemes starts to bring the objective qualities of the object into relief. Consider again the infant's rattle. If an infant starts to put together the rattle-shaking scheme with a rattle-mouthing scheme, a rattle-hearing scheme, and a rattle-splashing scheme, she will start to understand that certain properties of the rattle persist across these different schemes. These properties start to emerge as ways of characterizing the rattle independently from any particular scheme. Thus, infants in Stage 4 undergo a dramatic transition as they start to integrate schemes and come closer to realizing that distinct objects exist "out there" in the world.

Even though infants at Stage 4 are beginning to use more integrated schemes to understand objects, they still do not truly appreciate objects existing apart from schemes. Infants in this stage will now retrieve a fully hidden object, but according to Piaget, they will not fully represent the object when it is out of sight (see Figure 5.7). In support of this idea, Piaget showed that although infants at this stage will retrieve a fully hidden object, they tend to make a particular type of mistake in their searching, known as the **A-not-B error**, or the **place error**. Infants make this error when an object has been repeatedly hidden for them to discover in the same spot (place A), but then the object is hidden in a new spot (place B) while the infant watches. Infants making the A-not-B error will again search for the object in place A, where it was previously hidden, even when other cues, such as a bulging cover, strongly suggest the new location. Piaget believed that by repeatedly finding the object hidden in the same spot, Stage 4 infants develop a particular scheme for retrieving that object at a particular location. He interpreted the A-not-B error as a consequence of the infant's inability to apply a new scheme to the object in its new location, since the object is still embedded within the older scheme.

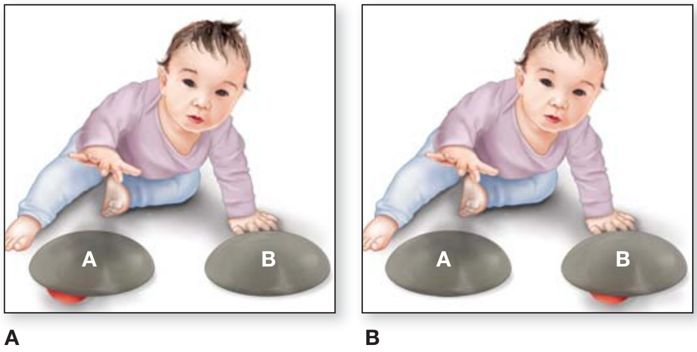

FIGURE 5.7 **The A-not-B error.** The Stage 4 infant searches for the hidden object under cover A, where it was initially hidden and recovered several times, even though it was last hidden in location B. (In the actual experiment, the hidden object is not at all visible.)

Q: What is the A-not-B error, and why is it also known as the place error?

Stage 5 (12 to 18 Months): Appearance of Tertiary Circular Reactions An important new milestone in Stage 5 is the appearance of **tertiary circular reactions**, in which infants use schemes intentionally. In this stage, infants begin intentionally coordinating their use of schemes in innovative and creative ways to actively explore the world. And unlike infants in earlier stages, infants in Stage 5 finally understand objects as existing independently from their schemes. Piaget commented on several cases where his children would experiment with different ways of acting on objects. For the first time, a baby might play with a bath toy by looking for the effects that dropping has on the object rather than focusing on the dropping action itself. Thus, while a Stage 4 baby might release the toy after holding it in the air and focus on the releasing action, the Stage 5 baby would drop the toy so as to make the biggest splash or to make it sink. Piaget referred to this as "the discovery of new means through active experimentation"(Piaget, 1952b), meaning that the child is constantly and intentionally discovering new ways of learning about objects.

There is, however, one critical way in which Stage 5 infants still have an immature object concept. Although they no longer commit the A-not-B error (they can find objects that were hidden while they were watching), they are unable to think about the objects as changing location while out of sight. This inability comes to light in their failure to understand **invisible displacement**, in which a hidden object is moved to a new hiding spot. In the simplest kind of invisible displacement, commonly known as a "shell game" (see Figure 5.8), an infant is shown an object being put under a cover, which is next to another cover of the same type. The two covers are then moved very slowly, in full view of the infant, so that they trade places. When the infant is asked to find the hidden object, she will usually reach for the cover at the location where the object was originally hidden. Apparently, she is unable to mentally keep track of the object's movement while it is hidden.

Q: What are invisible displacements, and why doesn't the infant in Sensorimotor Stage 5 understand them?

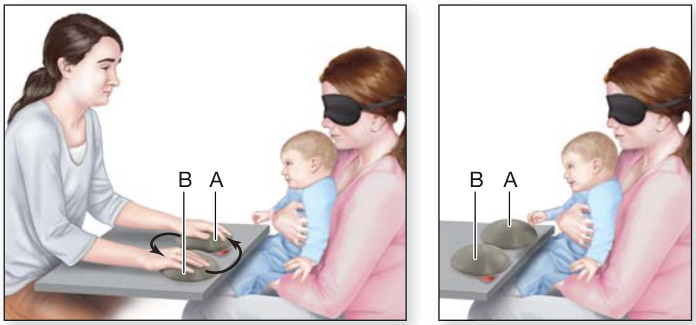

FIGURE 5.8 **Invisible displacements.** The error of invisible displacements occurs when an infant watches an adult hide an object under a cover and then watches the adult move the cover so that it slowly changes places with another cover. The infant searches where the object was initially hidden (place A) rather than at its new location (place B). (In the actual experiment, the hidden object is not at all visible.)

Stage 6 (18 Months to 2 Years): Invention of New Means through Mental Combinations In Stage 6 of the sensorimotor period, the child can flexibly use schemes and can more powerfully represent objects and their relations. She knows that objects continue to exist apart from schemes and regardless of whether they are hidden or moved. And she can solve invisible displacements because she not only can represent an object in her mind, but can also manipulate her mental representation. The emphasis on more powerful cognitive representations and thought processes is also linked to a much broader array of changes in children during this period. Most notable is the emergence of language, which Piaget took to be the most easily observable manifestations of a new competence in symbolic thinking—namely, the ability to use structured sounds (words) and relations (sentences) to stand for real-world things. For Piaget, language does not emerge as an independent skill following its own developmental course; it is inextricably linked to the ability to think symbolically, which also signals the transition out of the sensorimotor period.

Table 5.2 summarizes the six stages of the sensorimotor period and the significant developments found at each stage. As with Piaget's broader stages, the ages can vary across children. But Piaget believed that the stages themselves emerge only in one order. The significant developments focus on the object concept, which is where Piaget put his primary emphasis and where the most empirical support for his ideas is found.

Key Aspects of Piaget's Theory

Piaget's theory of cognitive development in infancy is an extraordinary account for several reasons. First, it offers a dramatic view of infants as experiencing a very different world from the rest of us. In this view, younger infants cannot differentiate between objects and the actions they perform on those objects, and thus they do not understand that there is an external world separate from themselves. Quite unlike adults, young infants have no awareness beyond the schemes they are currently using.

Sensorimotor Stage	Age	Significant Developments
1. Use of reflexes	Birth–1 month	The infant's actions are mostly reflexive, but even at this stage, the infant learns to modify actions that began as reflexes.
2. Emergence of primary circular reactions	1–4 months	The infant discovers by chance the application of motor schemes to self and modifies schemes. The first acquired adaptations appear.
3. Appearance of secondary circular reactions	4–9 months	The infant now applies schemes more directly to other objects and modifies schemes accordingly. The infant discovers procedures designed to make interesting sights last.
4. Coordination of secondary circular reactions	9–12 months	The infant now links schemes together and starts to get a more objective sense of objects, but still interprets objects in terms of each specific scheme and not as objects per se. The infant now applies schemes to new situations.
5. Appearance of tertiary circular reactions	12–18 months	The infant now uses schemes intentionally to actively explore the world, and schemes are now truly subordinate to objects. The infant discovers new ways of acting on objects through active experimentation.
6. Invention of new means through mental combinations	18 months–2 years	The child can symbolically represent objects and their relations.

TABLE 5.2 **Piaget's six stages of the sensorimotor period.** Piaget's theory of six sensorimotor stages forms an essential backdrop for all later research in infant cognitive development. His ideas motivated many studies on infant cognition, the majority of which focused on infants' understanding of objects, and much of that work eventually challenged Piaget's theory.

Second, this view offers a detailed model of development that was one of the first to explain the mental states and processes underlying behavioral changes. Piaget theorized that higher-level cognition develops out of an inevitable progression of structures. Starting with reflexes, infants begin modifying those behaviors, allowing them to develop even more flexible schemes. These schemes are used first in self-directed actions, then applied to external objects, then gradually integrated into increasingly complex schemes that help the child gain an objective sense of what is "out there." This is a more sophisticated empiricist account than the early ones described in Chapter 3, in which infants begin life with only basic sensory capabilities and the ability to form associations. In Piaget's view, infants also have modifiable reflexes through which they begin learning about the world.

Third, this view stresses domain generality, in which stage changes affect everything that the infant does and thinks about. Thus, regardless of the cognitive domain, the transition to a new stage influences thinking and reasoning on all tasks in which a child is engaged. Whether the domain is number, spatial representations, or language, changes in a stage will fundamentally change how a child thinks in each case.

Finally, Piaget left us with lots of observational and experimental data. Much of his data revolved around the infant's object concept, which Piaget used to illustrate many aspects of his theory of sensorimotor development. Piaget's studies suggested that young infants can think about objects only in terms of currently active schemes and not as objects in their own right. Only by gradually elaborating and integrating schemes can infants finally become able to understand independent objects well after the first year of life.

Piaget's account of infancy is so comprehensive and compelling that it was considered mostly correct for many decades, and his work continues to motivate many studies. Since Piaget's time, however, researchers have come to question significant aspects of his theory, and clever experiments have revealed new insights about how infants think. Building on our exploration of Piaget's sensorimotor theory, we next turn to more current views of how infants understand the world, beginning with a new look at the object concept.

Examining the A-Not-B Error

Many studies have challenged Piaget's idea of the object concept. As early as 1971, researchers asked whether there were alternative explanations for the errors that Piaget observed young infants making. They hypothesized that infants might be aware of objects' independent existence but have other cognitive limitations that cause the errors (Bower, 1971, 1974).

The A-not-B error is one observation that has been explained differently in more recent research. Recall that infants make this error when, after repeatedly finding an object hidden in the same place, they then watch it being hidden in a new place but still search for it where they had found it before. Piaget considered this a failure to apply a new scheme to the object. But some researchers believe that infants' diligent searching for the unseen object may be evidence that infants are indeed mentally representing the object, in spite of their failure to correctly locate it (Ruffman et al., 2005). In one study, experimenters used the standard procedure, repeatedly hiding an object at place A, then obviously moving it to place B. But instead of using the infants' reaching to assess their understanding, experimenters observed the infants' reactions when they saw the object that had clearly been hidden in place B retrieved either from A, the "impossible" location, or from place B. They found that even infants who reached for the object at place A were more surprised when the object was found there, indicating that, despite their reach, they had expected to find it at place B (Ahmed & Ruffman, 1998). In other studies that used more hiding places, a similar pattern of results emerged: although they reached for the object at the wrong location (A), infants would also look at the correct location (B) more than at another location (C) (Cummings & Bjork, 1983; Diamond et al., 1994). These studies pointed out difficulties with Piaget's account, but they still did not fully explain what causes the errors.

Studies in both humans and other primates suggest a different account of the place error, one that suggests that infants can understand an enduring external world but are not yet fully competent in certain cognitive and motor skills to act successfully on the external world. As we have seen, Piaget believed that infants make this error because they cannot fully mentally represent unseen objects. The most prominent alternative account focuses instead on the reaching action involved in retrieving the hidden object. As discussed in Chapter 4, several of the earliest reflexes appear to be more robust in younger infants. Two of these, the grasp reflex and the avoidance reflex (a tendency to pull a limb back from sharp objects or edges), may interfere with retrieval when the object is hidden next to a barrier or anything else that could brush against the infant's hand. Even brief contact can trigger the infant to either reflexively grasp the barrier itself or to withdraw his hand (Diamond, 1985, 1991). Frame-by-frame video analyses suggest that these reflexive actions, triggered by a barrier, typically prevent the infant from retrieving the object from its new hiding place. If the object is instead placed to reduce the infant's likelihood of accidentally touching a barrier, the infant is much more likely to succeed (Diamond, 1991).

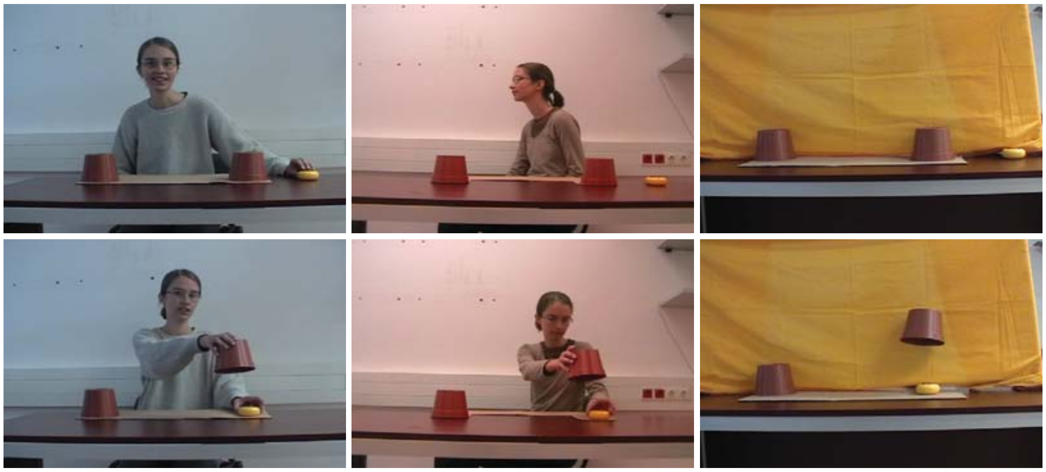
These findings suggest that younger infants may know that the concealed object exists, but they may only be able to engage in successful retrieval actions for some object-barrier configurations. Thus, at this point in their development, their ability to retrieve hidden objects may depend on the specific object-barrier configuration. Put differently, covers and barriers pose obstacles to the goal of retrieving an object. Younger infants have difficulty overcoming these obstacles without being distracted by them. But by around 8 months of age, infants start to be able to inhibit these reflexes and to control their actions more voluntarily.

Another contributor to the A-not-B error seems to be infants' tendency to try to make sense of what they see as if it involved intentional acts of communication. In all the traditional versions of this task, the experimenters look at the infant and clearly indicate that they are demonstrating something to the infant. That intentional, communicative component may have a strong influence on the infant's reasoning. In one series of studies, 10-month-olds saw either an agent deliberately communicating with them while covering and uncovering the object, an agent who performed the same actions while clearly *not* communicating, or an inanimate object that performed the actions (Topál et al., 2008; see Figure 5.9). In the communicative condition, the demonstrator established eye contact, talked to the baby ("Hello, baby, look here!"), and then hid the object in location A while looking back and forth from the object to the baby to clearly draw the baby into shared attention to the object. When the adult provides these rich communicative cues, roughly 80 percent of 10-month-olds commit the search error, while only about 40 percent make the error in the other two conditions. The authors suggest that younger infants may interpret the communicative cues as a way of teaching, as if the adult is trying to convey that "this is the hiding place for this object." The infants may then internalize that message in a way that usually overrules the fact that the object was hidden elsewhere on the last trial. Some tendencies to perseverate, or to repeat past actions, may also be at work, since 40 percent of the infants in the noncommunicative condition still commit the error, but these tendencies may not be the primary reason infants look in location A in the normal task.

Performance on the A-not-B task depends not only on the infant's ability to inhibit his reflexive actions, but also on his memory. Although infants may stop making the A-not-B error as early as 8 months, when there is no delay at all, their ability to do so depends on the length of the delay between when the object is hidden and when the infant is allowed to retrieve it. After a delay of several extra seconds, infants who normally pass the A-not-B task will fail. Many studies have also found that the more times infants find the object at location A, the more likely they are to make the error (Markovitch & Zelazo, 1999).

Q: What is an alternative way of understanding the A-not-B error?

It seems as if infants have difficulty "letting go" of the practiced action of searching in place A, which interferes with, and can even overwhelm, competing actions (Munakata et al., 1997). This observation suggests that younger infants may simply be less mature in the brain regions necessary to inhibit the practiced action, specifically the dorsolateral prefrontal cortex (see Figure 5.10). Support for this idea comes from several sources. First, anatomical studies of human infants demonstrate relative immaturity of the dorsolateral prefrontal cortex compared with more posterior brain regions. Second, adults with damage to this brain area exhibit similar errors. Even after correctly indicating which card they should select from a group, they may be unable to select it by reaching (Diamond, 1991; Milner, 1964). Finally, adult monkeys with lesions in the dorsolateral prefrontal



Communicative Noncommunicative Nonsocial

FIGURE 5.9 Pragmatic factors and the A-not-B error. Many infants who normally fail the A-not-B task in the communicative version pass it in the noncommunicative and nonsocial versions. This may be because in the communicative version, the infants believe that the adult is intentionally communicating to them that they should look for the hidden object in the location on the right. From Topál et al. (2008).

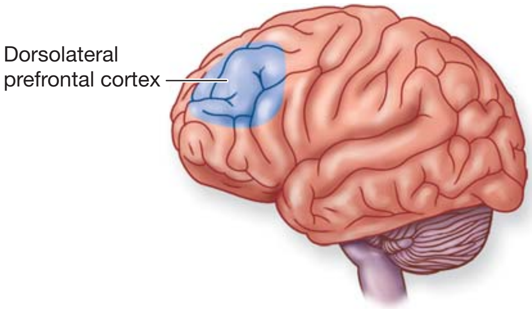


FIGURE 5.10 Inhibition of practiced actions. This view of a human brain (showing mostly the left side) shows the dorsolateral prefrontal cortex area that seems to be involved in inhibiting the tendency to produce previously practiced actions. This area is especially immature in infants relative to other brain regions and, when lesioned in adult monkeys, causes the monkeys to commit the A-not-B error.

cortex behave in precisely the same way on the A-not-B task as most 8-month-old infants and search in the wrong location, whereas adult monkeys with intact brains do not make the A-not-B error (Diamond & Goldman-Rakic, 1989).

It is quite remarkable that roughly 50 years and several hundred experimental studies after Piaget described the A-not-B error, researchers are still investigating its ultimate basis. The reflex inhibition accounts cannot fully explain why infants make the error when they merely observe the hiding and don't act; the memory-based accounts cannot explain why the infant looks at a second correct location more than at an incorrect alternative. Both motor control and memory are likely involved, and indeed we can imagine situations in which we, as adults, have acted similarly. Who hasn't lost their car keys, failed to find them where they normally are, and then after looking in several other spots, been unthinkingly "pulled" back to their usual spot to look there again? We don't do this because we cannot mentally represent hidden objects; we are merely defaulting to the most successful strategy. In short, recent research suggests that the A-not-B error has its basis in several cognitive differences between younger and older infants. No one specific difference may fully explain how infants understand the properties of hidden objects.

Infant Knowledge and Understanding

As we have seen, recent research has challenged Piaget's belief that infants have little or no awareness of objects and the broader world around them. It is now clear that infants are aware of the external world from a very early age, and they have some basic understanding of its highly regular and universal physical laws. In the rest of this chapter, we will consider what infants know about the physical world. Along the way, we will ask whether infants' impressive performance on many experimental tasks is evidence of high-level cognition or whether their seemingly sophisticated responses may be merely rigid, automatic behaviors, similar to the reflexes considered in Chapter 4. Do very young infants have intuitive belief-like theories that allow them to think flexibly about the physical world? What kinds of mental structures are minimally necessary to explain their behavior?

By way of framing the problem, consider the seemingly unlikely example of the kingfisher (Boden, 1989), which fishes for its underwater prey by diving toward it from the air. The kingfisher must strike at an angle to compensate for the distortion caused by looking down at its prey through the water, as shown in Figure 5.11. Although each dive can be described in terms of intricate geometric relations between the bird and its prey, kingfishers obviously do not "know" geometry. Instead, they automatically invoke a much more rigid and inflexible routine, outside of awareness, as they dive for fish. If a region of the kingfisher's brain computes geometric relations, it surely operates more like a "black box" module, giving the user access to its outputs but not to a conscious process of computing angles and distances (Dennett, 1991; Nagel, 1979). In considering the research that follows, it is helpful to keep the kingfisher in mind. Is the infant's performance simply an execution of automatic behaviors, or is a flexible understanding of the world truly present?

In observing infants' responses, it is difficult to tell whether we are witnessing flexible understanding or automatic

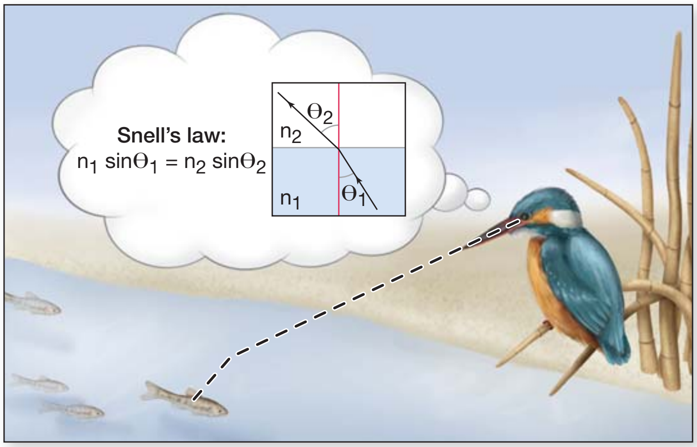

FIGURE 5.11 Inferring mental states underlying behaviors. Does the kingfisher deliberately and consciously calculate trigonometry in order to know how to dive after the fish? Clearly not, even if its behavior implies that such trigonometric calculations must be occurring. The same dilemma arises in trying to infer the mental states of a preverbal infant. Adapted from Boden (1989).

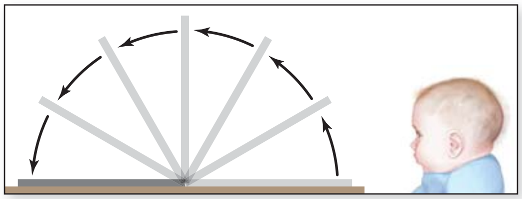
behaviors, and we often have to rely on intuitions about what sorts of behaviors seem to reflect something more than automatic routines (Bernal, 2005). We will see that some of the best evidence comes from the patterns in infants' errors as their understanding of physical objects develops. Some error patterns strongly imply a flexible, deliberative system rather than a preprogrammed "black box" response.

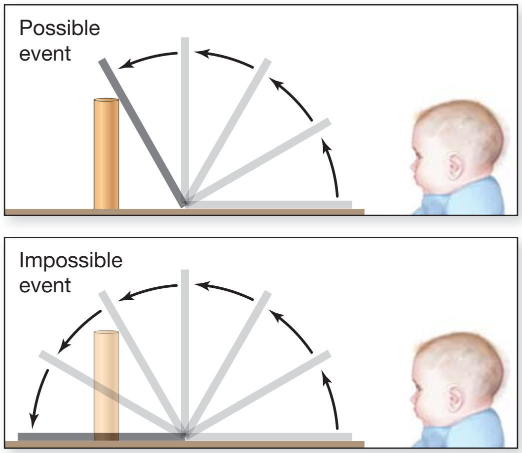
Q: How might a preverbal infant's behavior be understood either in terms of a sophisticated internal set of theory-like beliefs or in terms of interactions "below" the level of beliefs?

Thinking about the Unseen

One way that researchers have tried to determine whether infants show flexible understanding has been to observe how they react to events that occur out of view. There are now several studies illustrating that infants as young as 4 months not only know that objects continue to exist while out of sight, but also seem able to think about unseen objects interacting in ways that conform to simple physics.



A Habituation event



B Test events

FIGURE 5.12 Understanding permanence and solidity by 4-month-old infants. (A) In a habituation event, an infant sees a screen swing through 180 degrees several times. **(B)** An object is placed on the surface while the screen is down. The infant then observes the screen either moving through a smaller angle (a 112-degree arc) that would correspond to its stopping on top of the object (a possible event) or moving the full 180 degrees (an "impossible" event made possible by a hidden trap door through which the object moves while out of sight of the infant). Infants dishabituate more strongly to the 180-degree arc, even though the arc itself is much more familiar (due to the habituation event) than the movement through the smaller angle. Adapted from Baillargeon (1987).

Studies of Object Permanence and Solidity Two properties of common physical objects are extremely reliable: permanence and solidity. Object permanence simply means that objects continue to exist over time. They don't exist for a while, blink out of existence, and then reappear. **Object solidity** means that rigid or hard objects cannot pass through other rigid or hard objects because they cohere (stick together) as single entities. Billiard balls, for example, bounce off each other; they don't pass through each other. Researchers have explored infants' knowledge of these two properties as a way of understanding how infants think about physical objects in general. One pioneering study on infants' understanding of solidity was conducted by Renee Baillargeon and her colleagues and is depicted in Figure 5.12. The experimental setup involved a solid screen attached with a hinge to the surface of a table. This study is typically described as "the drawbridge study" because the authors noted a similarity between the screen rotating back and forth over the surface and the action of a drawbridge. During the experiment, infants watched the screen swing back and forth several times through a full 180-degree arc, naturally stopping as it hit the table on either side (Baillargeon, 1987; Baillargeon et al., 1985). Infants as young as 3½ months soon habituated and lost interest in the event. Researchers then introduced a new object, placing a large box on the far side of the screen from the infant in the path of the screen's arc. In one experimental condition, the infant watched the screen swing back and forth again, but only part of the way. The screen stopped where it touched the box, and at that point it also blocked the box from the infant's view. This is a perceptually novel event, but it is consistent with the law of object solidity (and so it is a possible event), and the infant showed only mild dishabituation. In a different experimental condition, the box was placed in the screen's path, but the infant then watched the screen swing through the full 180-degree arc, as in the original habituation trials. Because the screen should hit the box, this event is incompatible with object solidity. (The box dropped through a hidden opening in the table's surface to create the impossible event.)

Even at 3½ months of age, infants dishabituated much more strongly to the impossible 180-degree arc than to the partial arc that occurred when the screen was presumably blocked by the box. This response pattern seems to require the infants to understand some principles about object solidity and to apply them even to objects they cannot see (once the box is placed on the flat surface, the screen blocks it from view): (1) the infants must understand that both the screen and the box are solid objects; (2) they must know that both are rigid and do not change shape; (3) they must expect that solid objects cannot pass through one another; (4) they must assume that an object, even when it is out of sight, will stay where it was last seen unless something is seen to move it; and (5) they must assume that these properties remain consistent over time. It appears that infants as young as 3½ months are simultaneously using five or more principles to think about the objects around them and interrelating these principles to make reliable, correct predictions. As they get older, infants learn to apply these principles in more sophisticated ways. Thus, younger infants only notice significant mismatches between the screen's action and the box, whereas older infants can anticipate more subtle ways in which the size of the box should stop the screen at a certain angle (Baillargeon, 1995).

Before speculating on the details of how this knowledge might be represented and used, we need to explore in more detail the abilities of infants to make inferences about possible and impossible interactions between physical objects. In particular, can they reason about the physical interactions between multiple objects while the objects are out of sight?

After the drawbridge experiments, Baillargeon conducted a second series of studies that is perhaps the most remarkable exploration to date of infants' capacity for sophisticated reasoning about concealed objects (Baillargeon, 1986; Baillargeon & DeVos, 1991). In these studies, infants as young as 3 months watched a screen come down on a center section of a scene where there were no objects. They then watched a toy car roll down a ramp, continue on a marked roadway, go behind the screen, and emerge from behind the screen and continue rolling until it rolled "offstage" on the same path (see Figure 5.13A). After these habituation trials, the infants observed one of two new events involving a third object: a box or a small toy Mickey Mouse. In one condition, the box was placed behind the path before the screen came down (see Figure 5.13B). In the other condition, the box was placed directly in the car's path before the screen came down (see Figure 5.13C). In both conditions, the infants saw the car appear on the opposite side of the box at a time consistent with its previous speed of rolling.

Infants showed strong dishabituation only when the car seemed to have "passed through" the block placed directly in its path, an event that was physically impossible unless

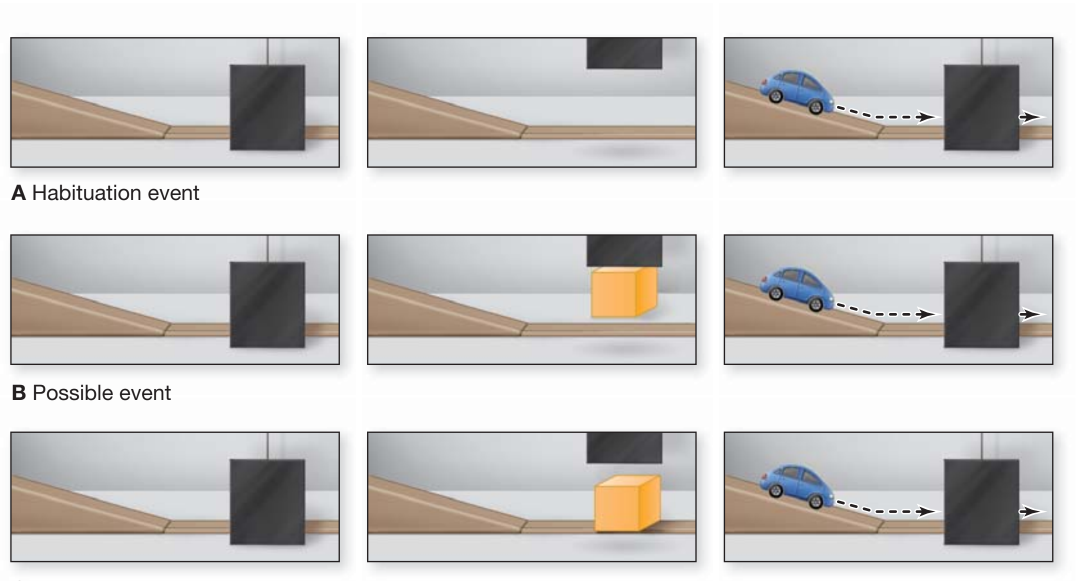


FIGURE 5.13 Thinking about interactions between objects that are out of sight. (A) In the habituation event, a screen is placed in front of a track and then is raised to show that there is nothing behind it. When a toy car is placed on the ramp, it rolls down the ramp and behind the screen until it emerges on the other side of the screen. **(B)** In a possible event, a box is placed behind the track so that when a car is rolled down the ramp, it is able to roll between the screen and the box and emerge on the other side of the screen. **(C)** In an impossible event, a box is placed on top of the track, but it appears as if the car is still able to roll to the other side of the screen. Yet even 3-month-old infants seem to understand that the car cannot pass through a box that is on the track, and thus they dishabituate if it reappears on the opposite side of the screen. They show much less dishabituation when the car reappears on the other side of the screen when the box has been placed behind the path of the car. Adapted from Baillargeon (1986).

there was external intervention to move the block. A second study showed that infants did not dishabituate longer when the block was placed in front of the path, showing that the effect was not simply caused when the block was closer. This dishabituation response may involve even more assumptions about objects' interactions than the drawbridge studies; in addition to their assumptions about object solidity and rigidity, infants appear to assume that an object traveling in a straight line will continue unless something interrupts it. Without this kind of assumption, they would not dishabituate so strongly, since the car could swerve around or hop over the box and appear on the other side without violating other assumptions about how objects interact.

Q: In what ways do infants seem to reason about the physical relations between unseen objects?

Principles That Guide How Infants Understand Studies of how infants understand object permanence and solidity suggest that it might be possible to codify the principles that they use to think about physical objects, what some have called the "intuitive physics of the young infant." Elizabeth Spelke has extensively investigated which key principles might guide infants' understanding of objects' interactions (Spelke, 1988a, 1988b, 1990, 1991). Spelke argues that young infants might use the five principles listed here to think about the physical world (see Figure 5.14):

1. *Continuity.* Objects exist continuously and move on connected paths. They cannot jump from place to place without occupying the intervening space.
2. *Solidity.* Physical objects are solid. Each object occupies a unique part of space; objects cannot interpenetrate other objects because all their parts cohere.
3. *Contact.* Objects cannot influence other objects without touching them; they must make contact; there is "no action at a distance."
4. *Gravity.* Unsupported objects will fall toward the ground.
5. *Inertia.* Objects do not change their motion abruptly unless they are acted on by another force.

Many of Spelke's studies exploring how infants become aware of these constraints involve an infant who watches as an object moves out of view behind a screen. When the screen is removed, the infant sees the object resting either in a position consistent with the constraints on physical motion or in a position that violates one or more of those constraints. Figure 5.15 shows how this technique has been used to explore infants' assumptions about continuity and solidity. As an infant watches, a ball is held above a screen and then dropped behind it. When the screen is raised, the infant sees one of several configurations. In the initial trials for habituation, the ball is resting on the lowest surface. In the other two sets of trials, a new, higher surface is added to the display. When the screen is raised, the infant sees that the ball has either landed on the higher surface (consistent with solidity and continuity) or underneath it (an impossible event that is inconsistent with solidity and continuity).

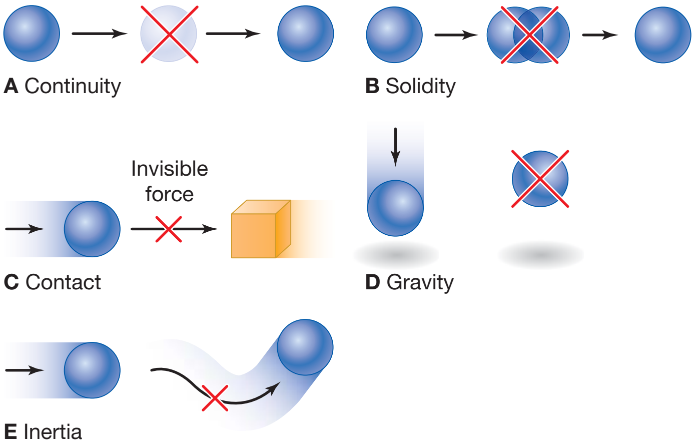

FIGURE 5.14 Intuitive physics. Depicted here are five principles that govern the behavior of most physical objects: continuity, solidity (cohesion), contact ("no action at a distance"), gravity, and inertia. The crossed-out drawing indicates a violation of the principle. Adapted from Spelke (1991).

Spelke found that 4-month-old infants dishabituate more strongly to the impossible event (measured in terms of looking at it longer), which suggests that they are surprised by violations of the principles of continuity and solidity. (To rule out the possibility that infants looked longer at the ball resting in the impossible position simply because they preferred this display, the researchers also showed the infants the ball resting in both the possible and impossible positions in the display without dropping it first—and they found no differences in looking.) In extensive follow-up studies, Spelke and her colleagues found that infants as young as 2½ months assume that objects will obey the continuity and solidity principles and that infants apply these principles broadly, across many kinds of object configurations (Baillargeon, 2004; Spelke et al., 1992).

Q: What are five principles governing the behavior of physical objects? Which ones do infants seem to grasp first, and why?

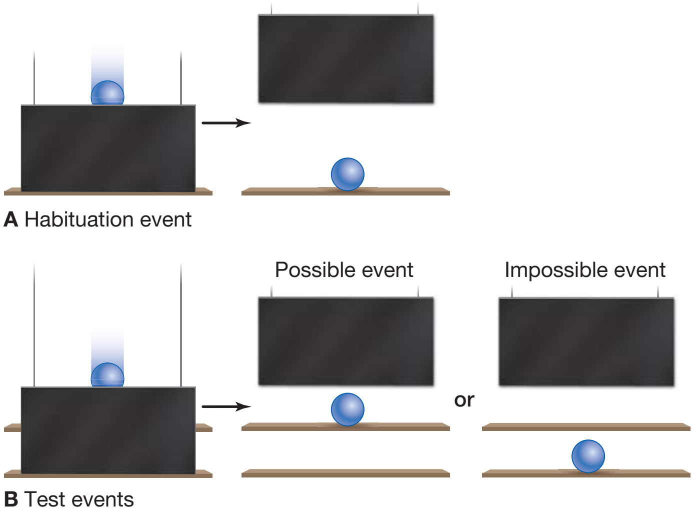

FIGURE 5.15 Testing principles pertaining to objects. (A) A habituation event shows the ball dropped behind a screen and coming to rest on a lower surface. **(B)** Test events show the ball being dropped behind the screen and either coming to rest on a higher surface that has been added to the display, which is a possible event, or coming to rest on the original lower surface, despite the addition of a higher surface above it, which is an impossible event. Spelke used this setup to explore whether infants dishabituated more to an impossible event in which the ball would have had to pass through another solid object, the higher surface. Adapted from Spelke et al. (1992).

By contrast, infants develop assumptions about the gravity and inertia principles somewhat later. For example, 4-month-olds do not seem to fully understand the gravitational relationship between a dropped object and a supporting surface that stops its fall. In some settings, 4-month-olds will not look longer at an object that stops moving in midair (an impossible event) than at an object that falls until it touches a surface (a possible event). Although other studies suggest that young infants may have some inklings of the importance of gravity—the tendency for unsupported objects to fall downward (Baillargeon & Hanko-Summers, 1990), these concepts are not sufficiently developed to make fully accurate predictions (Kim & Spelke, 1992). Concepts of inertia—the tendency of objects to continue the same motion unless acted on by another force—also take longer than the first several months to fully develop. There may be an early assumption that a moving object continues along the same path when unseen, as was found in Baillargeon's rolling car study, but if infants see a display indicating that a moving object must have abruptly changed direction while concealed behind a barrier, they will not look longer at this violation of the inertia principle until they are about 8 months old (Kim & Spelke, 1999).

Clearly, young infants are not fully aware of all the principles governing physical objects' interactions—not even principles that are extremely prevalent in the natural world, such as gravity and inertia. They do, however, seem to have a very early knowledge of the principles of continuity, cohesion (solidity), and contact ("no action at a distance"). As a mnemonic, it may be helpful to remember that young infants use the three Cs to understand objects. Indeed, infants seem to be sensitive to these principles with little or no relevant experience. Why should infants' understanding of some principles, such as the three Cs, develop before others, like gravity and inertia? One possibility is that the early-emerging principles are more important to the young infant in anticipating the behaviors of a wide range of objects. Alternatively, perhaps inertia and gravity are best understood in a conceptual framework that already includes concepts such as continuity and solidity. This pattern fits with the hypothesis that earlier-emerging "core" beliefs may be more fixed and predetermined components in the infant's conceptual repertoire.

Other researchers have also questioned whether infants might be more proficient at using certain physical principles, such as inertia, in their own actions than they are while merely observing events. For example, infants who do not dishabituate to inertia-violating displays—such as when an object goes behind a barrier at one angle and emerges at another—show patterns of reaching toward objects in motion that clearly honor the principle of inertia (von Hofsten et al., 1998). Cognition linked to action may differ from cognition linked only to observation (Goodale & Milner, 1992). We saw in Chapter 4 that perception and action are intimately linked in an infant's attempts to learn about the world. In this case of thinking about objects, cognition and action may also be linked.

Finally, this pattern of results again raises challenges for the empiricist. By most accounts, the principles of inertia and gravity are just as salient in the young infant's life as principles of solidity and continuity. If infants simply built up associations through experience that eventually led to knowledge of physical laws, we would expect their understanding of different physical principles to develop at about the same time. There are some common exceptions to the later-developing principles of gravity and inertia, such as balloons that float and papers fluttering in the wind that change direction. But there are also exceptions to the earlier-emerging beliefs: clouds and liquids appear to violate solidity, and shadows seem to violate both solidity and continuity. The patterns that the young infant encounters do not seem to support learning about principles like solidity and continuity any more strongly than learning about gravity and inertia.

Even though the evidence doesn't seem to support a strong empiricist view, neither does it strongly support a strong nativist view in which a mature knowledge of physical objects and their behaviors is present at birth. It would be misleading to suggest that the young infant thoroughly understands the principles governing the physical world. Not only do some principles take longer for infants to understand; there are also extensive developmental changes to infants' use of the earliest-emerging principles within the first year of life. For example, although quite young infants seem to understand continuity and solidity in tasks that involve an object hidden behind a barrier, they take considerably longer to understand the same principles in tasks that involve an object contained inside of another. Baillargeon proposes that while solidity and continuity may be foundational principles that develop very early, it may take many months to learn how to apply those principles to different kinds of events, such as objects containing or covering one another (Baillargeon, 2004).

One way of thinking about the developmental changes is in terms of the principle of persistence, which states that objects do not change without a cause (Wang & Baillargeon, 2008). From a very early age, infants seem to assume that objects cannot (on their own) appear or disappear, break apart or assemble, or change their size, shape, or color spontaneously. For infants to be able to detect such impossible changes, they would have to be able to mentally represent the object's properties and remember them, abilities that develop considerably during the first year of life. Figure 5.16 shows two simple events that a 2½-month-old can detect as impossible because they violate the principle of persistence (Wang & Baillargeon, 2008). As the configurations of objects' properties and their changes become more complex, however, even 12-month-olds fail to detect some violations of the principle.

In addition to thinking about the properties of solid objects, young infants also start to understand the differences between solid objects and amorphous materials such as liquids. In one study, 5-month-old infants habituated to either a tilting glass in which the solid contents tilt as well or a glass in which the liquid contents stay horizontal as the glass tilts. Researchers then tested the infants' responses to other manipulations of the materials, using their patterns of dishabituation to determine whether they thought they had been watching a solid or a liquid (Hespos et al., 2009). Those who habituated to the liquid version dishabituated when the contents were emptied out and behaved like a solid block. On the other hand, those who habituated to the solid version dishabituated when the contents were then poured out like a liquid (see Figure 5.17). Taking these findings together with the other studies of solid object perception, it is possible that infants first master the properties of solid objects by as early as 2 months, but then take somewhat longer to start to understand the distinguishing properties of nonsolids.

Comparative Considerations When we study infants, it is natural to interpret much of their behavior by attributing to them adult-like beliefs and goals. Yet, as the kingfisher example showed, sophisticated behavior does not always require complex beliefs or knowledge. The experimental tasks investigating infants' reasoning about unseen objects seem to require sophisticated cognitions that we think of as human. But before we can make such statements with any confidence, we need to consider whether other species behave similarly (Weiss & Santos, 2006). If other species

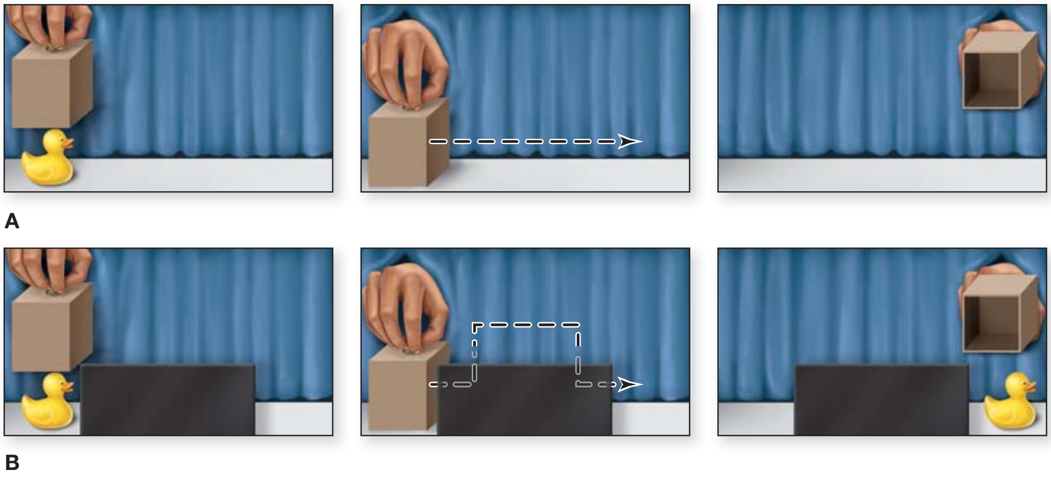

FIGURE 5.16 Early understanding of object properties. **(A)** A hand raises a cover to reveal a duck and then lowers the cover over the duck and slides it to the right. When the cover is lifted on the right, the duck has magically disappeared. **(B)** After lifting a cover to reveal a duck and then lowering the cover over the duck, a hand slides the duck behind a screen that is taller than the duck, lifts the cover when it is behind the screen (presumably leaving the duck behind), and then slides the cover out from behind the screen. When the cover is lifted, a duck has magically appeared. Infants as young as 2½ months are surprised at both event outcomes because of their assumptions about how objects interact with other objects. In particular, these event outcomes violate the principle of persistence. Adapted from Wang & Baillargeon (2008).

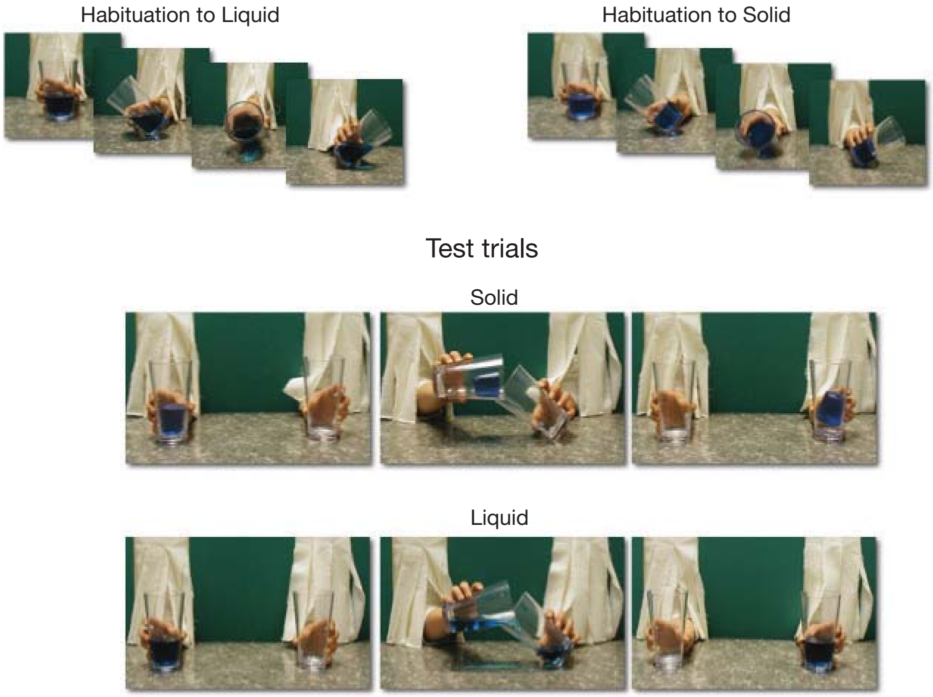

FIGURE 5.17 Properties of solids and liquids. Five-month-old infants who habituate to a substance as a liquid that stays horizontal dishabituate when it comes out of the glass as a solid. Conversely, those who habituate to a substance as a solid that tilts with its container dishabituate when it comes out as a liquid. From Hespos et al. (2009).

act in the same ways on hidden objects, then we may need to deflate the level of cognitive sophistication that we attribute to human infants. We do not yet have a thorough, systematic comparison of how primates and other mammals perform on all the tasks previously used to assess reasoning about physical objects in young human infants, but some researchers have done comparative studies of related tasks. Their results are critical to understanding what sorts of beliefs about the physical world guide infants' behaviors—and if they should even be thought of as beliefs at all.

Consider the A-not-B task, which requires an understanding of object permanence. It turns out that a wide range of species can find the hidden object in the A-not-B task, and some, such as dogs and cats, never commit the A-not-B error. Figure 5.18 shows the age at which different species first pass the A-not-B task, as well as the age at which gorillas and humans pass the invisible displacements ("shell game") task (the other species never pass it). All the primates initially fail the A-not-B task but then later pass it. In contrast, dogs and cats always pass the A-not-B task but never understand invisible displacements. Although the basis for this difference has yet to be fully explained, primates may share a particular way of encoding and remembering actions that differs from the way other species encode and remember actions and which, early on, causes the A-not-B error. Another factor that may differ across species is the influence of intentional communication (see p. 156). While many great apes, such as gorillas and chimpanzees, are able to understand when others direct their attention to an object (Pitman & Shumaker, 2009), humans may be the only species with a well-developed sense of when another person is explicitly demonstrating an action (Gergely, 2011). That is, when a person demonstrates an action to a human infant, the infant may automatically encode the action as something important that the other person wants to teach. That interpretation may cause human infants to fail the A-not-B task more often than other primates, despite being their cognitive equals or superiors in other respects.

Moreover, when we consider tasks like Baillargeon's and Spelke's for assessing knowledge of solidity, it seems that

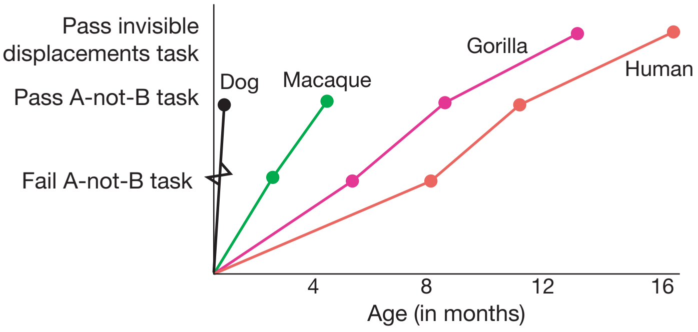

FIGURE 5.18 The object concept across species. Most primates fail the A-not-B task in early infancy and then pass it later. Members of the ape family also later come to pass the invisible displacements task. Dogs, cats, and some other animals always pass the A-not-B task and never pass the invisible displacements task. These results suggest that dogs, cats, and other nonprimate animals may be solving the A-not-B task in ways that don't create a foundation for being able to later solve the invisible displacements task. Adapted from Gomez (2005).

organisms quite distant from primates can take solidity into account. Consider, for example, a task devised for dogs that resembles Baillargeon's rolling car studies and Spelke's dropped ball studies mentioned earlier. Dogs watched a treat slide down a transparent tube and then were allowed to retrieve it from one of two doors (Kundey et al., 2010). In one condition, a highly visible wall was inserted between the two doors (see Figure 5.19). In the other condition, there was no wall. Dogs of many breeds and mixes seemed to be aware of solidity, searching for the treat in the "near door" when they could see the wall was present, but searching in the "far door" when there was no wall. This study illustrates that some aspects of the baby's understanding of physical objects, such as solidity, may have quite ancient evolutionary roots, since humans' common ancestor with dogs is evolutionarily much older than humans' common ancestor with primates. It also shows that nonprimates can solve solidity problems that are clearly different from those they would encounter in their natural environments, suggesting a quite general appreciation of solidity.

Research with nonhuman primates, as well as with some nonprimates, suggests that many species have some sense of the solidity and continuity of novel objects as well as some competence at object permanence tasks (Deppe et al., 2009; Gomez, 2005; Hall-Haro et al., 2008; Neiworth et al., 2003; Santos, 2004). They seem able to make inferences about the properties of objects that are out of sight, which take them far beyond the ways that much simpler organisms, such as insects, avoid collisions with objects or land on solid surfaces. Given that several of the species that manage to use these principles have brains of very modest size and complexity, we must be cautious about interpreting similar behavior in human infants as evidence of rich, sophisticated cognition. Further studies may demonstrate that the nuances of human infant responses are evidence of sophisticated thinking. But without that evidence, it is risky to think that infants' responses in these experiments are based on conscious, explicit, adult-like beliefs about objects.

The ability to reason about unseen events may be an important distinction between humans (and perhaps a few apes) and other animals. A monkey who passes the A-not-B task shows that it can think about an unseen object, but this task does not involve thinking about a dynamic event, such as two objects interacting. Even the invisible displacements task, which only humans and a few apes can pass, involves the simplest possible event: one object moving. By contrast, Spelke, Baillargeon, and other infant cognition researchers study events that involve reasoning about two objects' interactions while both are out of view. Very few studies have explored nonhumans' performance on such tasks, and only systematic studies comparing several species will help clarify whether human infants have a uniquely sophisticated capacity to think about the physical world. Given that only humans and the great apes (chimpanzees, bonobos, gorillas, and orangutans) can follow invisible displacements, including some intricate ones (Albiach-Serrano et al., 2010), some aspects of reasoning about objects' motions while out of sight may require certain higher-order cognitive abilities. Nonetheless, much of the object concept seems to fall within the abilities of a broader range of species.

Q: How has comparative work with other species changed our views of the human infant's developing object concept?

Understanding Causation

When infants react to "impossible" physical events with dishabituation, it is difficult not to assume that they are reason-

FIGURE 5.19 Dogs and object solidity. In a task with striking similarities to the studies assessing concepts of solidity in human infants, dogs from a wide range of breeds preferred the "near" door when the wall was inserted **(A)** and the "far" door when it was not **(B)**. Success on such tasks by nonprimates suggests that human-like cognitive abilities may not be required to solve such tasks. Adapted from Kundey et al. (2010).

ing about what they have seen in terms of cause and effect. We see them as being surprised that their causal expectations have been violated. If we, as adults, put ourselves in their shoes, we explain the problems with the impossible events in causal terms. The drawbridge should have stopped *because* the box would have prevented it from swinging all the way. The car could not have rolled all the way down the path *because* it would have had to pass through the block. Our understanding of everyday objects is saturated with causal thinking.

As we have seen, infant responses to events that seem to violate physical laws strongly suggest that infants, too, are thinking in terms of causal relations. Nonetheless, to investigate infants' understanding of cause and effect in its own right, it is helpful to examine studies that directly address this centuries-old issue. Some have argued that causal ideas are as crucial for infants as for adults and that causality is a primitive conceptual building block that the infant needs from the first moments of awareness (Fodor, 1981). Others have maintained that an understanding of causality can develop only gradually through learning from experience, either from repeated association of events that regularly occur together over time and space (Hume, 1748/1910) or through active experience initially produced by the infant's own actions (Piaget, 1955).

One line of work tried to distinguish whether infants who observed simple events actually understood the causal relationship between them or whether they were merely noticing and remembering how often the two events (such as movement of a green object and movement of a red object) co-occurred in space and time—referred to as *spatial contiguity* and *temporal contiguity* (Leslie, 1982, 1984). The researchers set up experiments to investigate whether infants actually encoded that one event caused the other, such as movement of one object launching the other's movement through a collision. For example, in one set of studies, infants watched a film of events like those in Figure 5.20A, depicting movement of a green block and a red block. In one condition, they saw the red block move across the screen until it stopped next to the green block, at which point the green block started moving. In another condition, the direction of movement was reversed: the green block moved first, and when it stopped next to the red block, the red block began to move. To adults, the first condition would convey the impression that the red block caused the green block to move, while the second condition would suggest that the green block caused the red block's movement. These events were exactly the same except for the direction of movement and the order of the two blocks' movement. To notice that the two events are different, an infant would have to notice at least one of these features. Seven-month-old infants showed clear dishabituation when the event shifted from one in which the red block "caused" the green block to move to one in which the green block "caused" the red block to move. Does this dishabituation mean that they understand that the two events are showing different causal relationships? On its own, it does not. Infants could simply be habituating to something like "red event" then "green event" and dishabituating when their order was reversed.

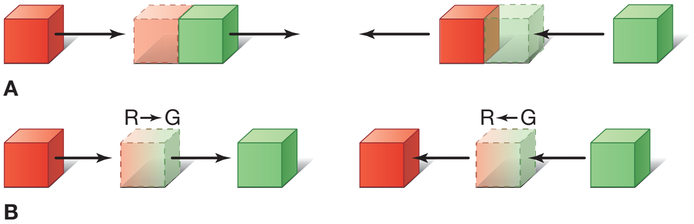

FIGURE 5.20 Perception of causality by 7-month-olds. **(A)** The red block seems to push the green block on some trials, and the green block seems to push the red block on other trials. **(B)** The same block changes color, first from red to green, then from green to red. Adapted from Leslie (1984).

Another pair of conditions examined whether the infants were making causal interpretations rather than just temporal associations. These conditions used two films, each showing only one block that traveled at the same speed as the blocks in the first films. This time the block changed its color at the same time and place where one block previously seemed to push the other (see Figure 5.20B). As before, the films then showed the same actions reversed. In one, a red block changed into a green block, and in the other, a green block became a red block. This second pair of films was used to test whether the infants would regard the mere change of color as an apparent case of physical causation. If they were merely encoding "red event" followed by "green event," they might dishabituate just as strongly when the order of these events was reversed. In fact, they showed much less dishabituation between the two single-block color change films than they did between the two films of two-block "launches," where one block seemed to collide with the other block, apparently causing it to move. They showed much more awareness when the order of cause-and-effect relations changed in the "launching" films, and found a mere shift in the order of color changes much less surprising. Several other follow-up experiments helped to rule out other interpretations and strongly indicate that 7-month-olds see causation that goes beyond mere temporal and spatial contiguity (Leslie, 1984; Leslie & Keeble, 1987).

It is difficult to tell whether younger infants think in terms of causality or whether they merely react to causal patterns without explicitly coding one event as causing another (Carey, 2009; Goodman et al., 2011; White, 2009). Some researchers argue that infants need to learn the notion of causality in their first several months of life (Cohen & Amsel, 1998; Cohen & Oakes, 1993; Haith & Benson, 1998).

According to this view, the notion of causality gradually emerges out of noticing spatial and temporal contingencies. Those contingencies might be made especially salient by the infant's own actions. Indeed, one study found that having 4½-month-old infants wear sticky Velcro mittens that enabled them to pick up balls gave them experience with causal action. These infants later dishabituated to reversed causal events (that is, events in which the agent and recipient of an action were reversed from what the infants had previously observed) 1½ months earlier than infants who were not supplied with such mittens. This result was argued to support the claim that causality is learned through actions that facilitate attention to and encoding of relevant parts of physical events (Rakison & Krogh, 2012; see also Libertus & Needham, 2010, as described in Chapter 4).

An alternative view argues that there is a primitive perceptually driven way of detecting some forms of causality that does not need to be learned or built up through experience. In this view, infants may come into the world with a mental "module" that directly responds to certain perceptual sequences with an impression of causation (Scholl & Nakayama, 2002, 2004; Scholl & Tremoulet, 2000). The idea of a *module* refers to an innate biological structure that responds automatically to specific inputs (Fodor, 1983). If this second view is correct—if impressions of simple physical causality are the output of a module—then we should be able to see awareness of causality even in very young infants. In this view, infants may come into the world with a module that responds automatically to certain perceptual configurations, such as collisions, with a sense of causation. It may still take many months, however, for infants to be able to think about cause conceptually in situations that are not like those perceptual cases.

One piece of evidence for a module that detects physical causality comes from studies showing that 7-month-old infants see physical causality under almost exactly the same perceptual conditions as adults (Newman et al., 2008a). The temporal and spatial relations that convey a sense that one object has launched another (as opposed to their movements being causally unrelated) are so similar and unrelated to actual experience observing such launchings that it is very hard to see how they could be learned. Yet, even if there is a core module for perceiving physical causality under certain simple collision conditions, it may take months or years before all the forms of perceptual and conceptual causality are easily understood by young children.

The Use of Number

The infant's ability to appreciate physical causality is impressive, and it seems to relate to specific patterns in the world. The ability to think about number, however, seems quite different. In our culture, we count ages, minutes, days, years, money, and just about everything else of importance that can be quantified. Is this tendency specific to technologically advanced cultures, or is it a universal aspect of human nature? If number concepts are universally used across all cultures, that universality raises the question of whether such concepts are present in the young infant's mind. Although universal concepts are not necessarily present in infancy—they can arise from culturally universal experiences, such as the experience of going through puberty or being elderly—a concept's universality leads us to consider whether it might have very early developmental origins.

Older accounts of number concepts claimed that children and "primitive" peoples could not think about number conceptually and could only think about differences in quantity using configurations of objects (knowing, for example, that a group of three objects usually forms a triangle). More recently, however, researchers have found that every culture that is carefully studied does use number concepts (Lave, 1977; Pica et al., 2004; Saxe & Posner, 1983; Zaslavsky, 1973). Moreover, even other species show increasingly clear evidence of numerical competence, suggesting that number concepts do not depend on humans' language skills and the ability to use number words (Gallistel, 1990). The developmental question, then, is how these universal number concepts emerge. Are young infants predisposed to understand number concepts? Several studies strongly suggest that they might be.

We have seen that developmental psychologists have a relatively limited set of ways of studying infants' mental states, most of which revolve around habituation/dishabituation paradigms. This limitation poses a challenge when it comes to exploring whether infants show numerical competency. The most successful technique involves habituating an infant to a small number of stimuli, such as three, and then seeing if he dishabituates when he is exposed to a different number of stimuli. The difficulty is to control all the other variables that could influence the infant's response. For example, a visual display of three objects normally forms a larger, more complex visual pattern than a display of two objects. As a result, many kinds of perceptual contrasts between the displays, including their different contours or configurations or the differing amounts of visual space they take up, could cause the infant to dishabituate. If an infant who has habituated to a display of three objects shows renewed interest when he sees a display of two, any of these perceptual factors, rather than a conceptual awareness of the difference in number, could be the reason. In early experiments, when researchers attempted to control for these perceptual influences, their results suggested that infants were sensing number (Antell & Keating, 1983; Starkey & Cooper, 1980). Nonetheless, concerns remained about whether the infants were truly aware of abstract numerical differences as opposed to perceptual contrasts, such as the geometric patterns formed by specific numbers of objects.

One way that researchers attempted to determine whether the infants' responses were based more on numerical concepts or perceptual contrasts was to see whether they would dishabituate to differences in number even when these differences depended on widely varying perceptual experiences, such as sights and sounds presented in a cross-modal (across two sense modalities) study (Starkey et al., 1990). In one study, infants viewed two displays side by side, one showing two objects and the other showing three objects (see Figure 5.21). At the same time, a speaker hidden between the displays repeatedly played sets of either two or three drumbeats. In this paradigm, the researcher presented the visual and auditory patterns simultaneously to determine whether infants would match the number of individual elements across the two sense modalities. Infants as young as 6 months reliably looked longer at the display showing the number of objects that matched the simultaneously presented drumbeats (Starkey et al., 1990). The effect can even be found in newborn infants, who can recognize differences between such numbers as 4 and 12, as depicted by discrete sounds and visual dots (Izard et al., 2009).

Other studies examined whether infants would show such cross-modal number concepts if the sounds and sights were not presented together. These studies therefore asked if a representation of number could emerge from a stimulus set, be held in mind when the stimulus was removed, and then be applied to a new stimulus set in a different modality. This would mean that a number concept could be held in memory apart from the actual stimuli. Researchers habituated infants to visual displays of either two or three objects; then, after turning off the visual display, they played a stream of randomly ordered two- and three-beat drum sequences. Infants as young as 6 months looked longer at the source of the sounds when the number of drumbeats matched the number of objects to which they had just been visually habituated (Starkey et al., 1983, 1990). This effect has been found repeatedly using a variety of methods (Jordan & Brannon, 2006; Kobayashi et al., 2005).

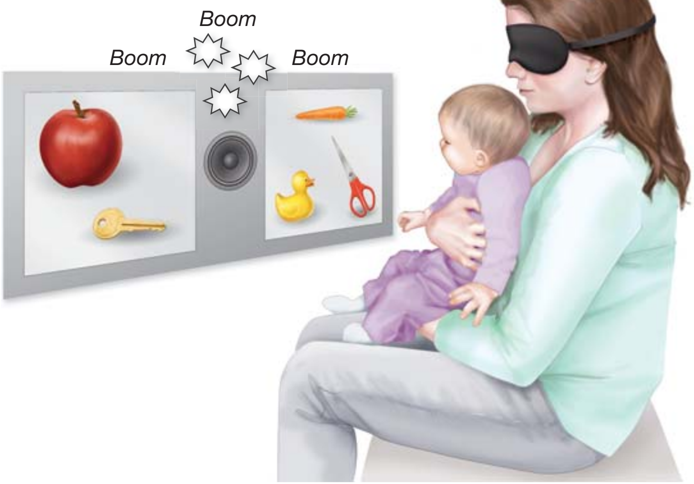

FIGURE 5.21 **Intermodal sensing of number.** When 6-month-old infants hear three bursts of sound (for example, a sequence of three drumbeats) from a speaker hidden between two photographic displays—one showing two objects and the other showing three objects—they typically look toward the display of three objects, which matches what they have heard.

It is useful to try to understand what these experiments reveal about infants' subjective experiences. It appears that even infants experience a world in which number is an important and meaningful concept and that they may do so in some cases right from birth. They appear to be aware of abstract quantities and to be able to recognize similarities in "three-ness" or "two-ness" between stimuli that differ in virtually every other respect. Moreover, the experiments that presented visual and auditory stimuli separately suggest that infants can remember these number concepts and use them across modalities. The infants seemed to know that "three-ness" was repeatedly being presented in the visual display, they habituated accordingly, and then they showed a renewed interest when they recognized that familiar number in the drumbeats. Infants have also recognized number in similar cross-modal studies involving touch and vision (Feron et al., 2002), further demonstrating that their notion of number transcends any particular modality.

These studies on infant number concepts are only the beginning of our understanding of the early roots of the number concept in infancy. Major questions remain unanswered, especially those concerning what, if anything, infants do with this ability to infer number from the physical world. Do they use it, as other animals apparently do, to guide their actions even in infancy? Other animals use number to keep track of their young or of caches of food, yet comparable behaviors in infants are not obvious. Alternatively, is it simply a necessary building block in the later-developing structure of mathematical knowledge? No matter how (or whether) it is used from the start, even very young infants appear to have some abstract concept of number.

Q: What is the evidence that infants less than 6 months of age have a concept of number?

One use of early number concepts may be to support a crude form of arithmetic. Indeed, infants can use their concept of number to understand changes in quantity, even doing simple subtraction and addition. In a seminal series of studies, 5-month-old infants were habituated to a toy mouse placed on a stage (Wynn, 1992). A screen then blocked the mouse, and the infant watched the experimenter take another, identical toy mouse and move it behind the screen. When the screen was removed, the infant saw either one or two mice on the stage (see Figure 5.22). In this "addition" test, infants looked longer when they saw only one mouse on the stage, despite the fact that they had just been habituated to a single mouse, since this violated their expectation of what the outcome should be after another mouse was added behind the screen. In another version of the experiment, the display started with two toy mice. The screen then concealed them, and the infant saw a hand emerge and remove one mouse from behind the screen. When the screen was lifted, the infants looked longer when the display showed two mice, because it violated the perceived "subtraction." These results have been replicated by other scientists in studies that rule out possible perceptual and conceptual confounds (Simon et al., 1995; Slater et al., 2010).

The meaning of these findings, which seem to show "subtraction" and "addition" by infants, has been actively debated. Do the infants' responses indicate an ability to manipulate numbers, or could infants be "solving" the task on other grounds? One proposal suggests that infants are simply remembering the individual objects they have seen. When the set of objects an infant remembers doesn't match the set of objects she perceives, she will appear surprised and look as if she had arrived at an expected result using addition or subtraction (Feigenson et al., 2002a, 2002b; Uller et al., 1999). But she may simply be comparing the set of objects she remembers with the set of objects she sees and noticing the mismatch. This process would not require any specific numerical concepts or operations such as addition and subtraction. Other studies, however, suggest that infants can add and subtract with displays of numbers that are too large for the number of objects that infants can normally represent in their minds (McCrink & Wynn, 2004). Moreover, infants can add and subtract number of events, which are not tracked by remembering specific objects (Wynn, 1996). Thus, while object representations may be used on some occasions to guide inferences about addition and subtraction, they cannot be the sole basis for such abilities.

Hence, it seems that numerical abilities, including some basic arithmetic operations, may be present very early in life, long before the infant acquires language. This preverbal ability raises questions about the use of number concepts in other species. It was traditionally assumed that other species did not understand number in the sense of different quantities of countable objects, but these assumptions have since been challenged (Gallistel, 1990). One of the most dramatic demonstrations of numerical competence in other species involved testing monkeys in replications of the studies involving adding or taking away objects. It now seems clear that not just the great apes, but a variety of monkeys not only are aware of number but also have some notion of subtraction and addition (Flombaum et al., 2005; Hauser et al., 1996; Mahajan et al., 2009). Even pigeons seem

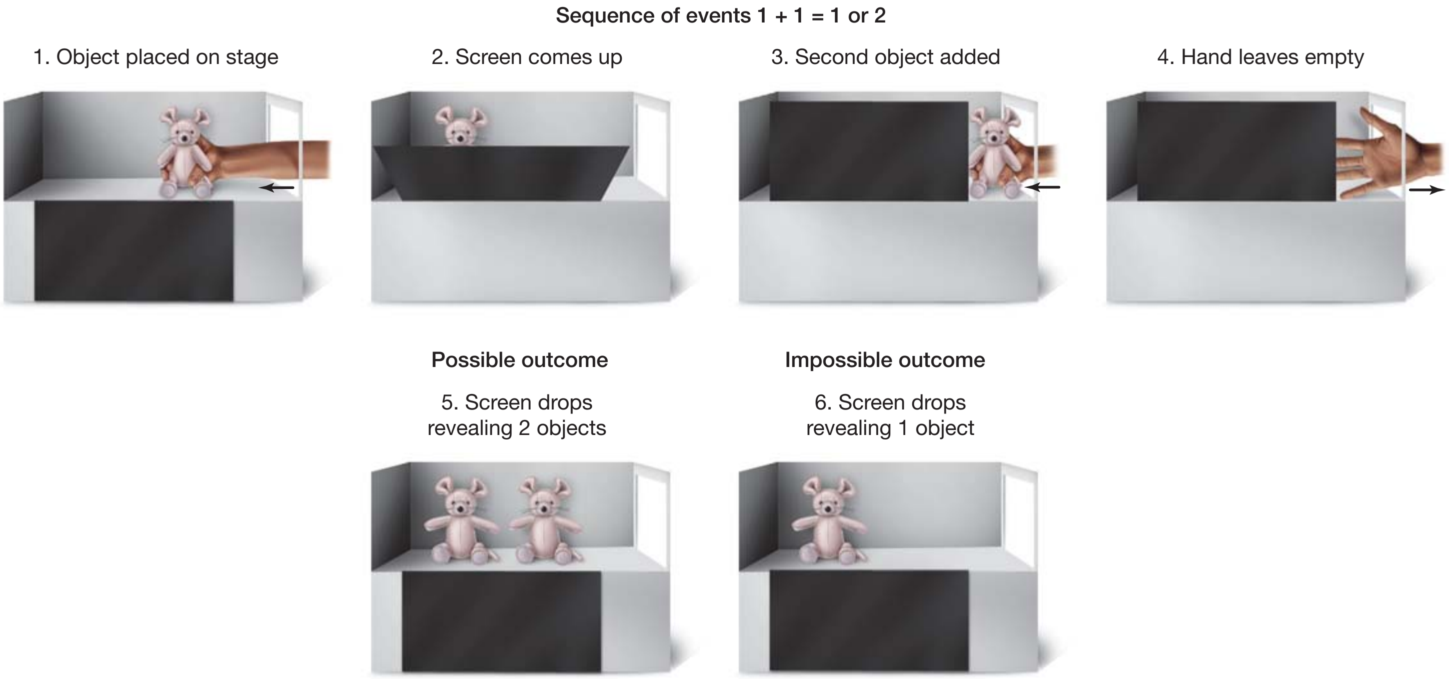

FIGURE 5.22 **Addition in infants.** A toy mouse is placed on a stage. The mouse is then blocked by a screen, and a second toy mouse is placed behind the screen. The screen drops to reveal either one or two toy mice. Five-month-old infants dishabituated when they saw just one mouse display but not when they saw two mice. Adapted from Wynn (1992).

to engage in simple forms of subtraction (Brannon et al., 2001), as do newborn chicks (Rugani et al., 2009).

Q: In what sense do infants have the ability to add and subtract?

Number awareness and mathematical skills in infants may not all arise from the same cognitive ability. There is growing evidence that numerical abilities depend on several distinct cognitive systems. One striking finding along these lines is that the ability to estimate differences in quantity involves separate areas of the brain from the areas of the brain involved in the ability to perform numerical calculations. In particular, estimation heavily involves the parietal regions of the brain, while calculations involve more frontal regions as well as areas that are also associated with language abilities (Cohen et al., 2000; Dehaene, 2009; Stanescu-Cosson et al., 2000). Different regions may be responsible for these abilities because the parietal regions emerged earlier in the course of evolution than the frontal regions, so that the abilities associated with earlier-emerging regions may be more common across species and more developmentally primitive. Thus, the estimation ability is thought to be evolutionarily very old, early to develop in the infant, and common to many species, whereas the calculation ability is possibly specific to humans, later to develop, and dependent on language (Cohen et al., 2000; Dehaene, 2009; Dehaene et al., 2004; Stanescu-Cosson et al., 2000). Considerable debate remains on just how important language is to the emergence of numerical skills (Brannon, 2005; Carey, 2001; Gelman & Butterworth, 2005; Wynn et al., 2002; Xu et al., 2005b).

In addition to an early estimation system, there is also evidence for an early-emerging system for processing discrete small numbers. When infants compare amounts such as two versus four, they may be using a distinct cognitive ability arising from a different brain region from that used for estimation. When electrical signals known as event-related potentials (ERPs) are measured on 6-month-old infants' scalps, distinct electrical patterns suggest that large-number estimations occur in different regions of the cortex from those associated with small-number operations such as addition and subtraction (Hyde & Spelke, 2011). This more primitive addition and subtraction ability, possibly one that involves mentally representing objects, does not involve language and may be shared with other species.

As one leading researcher in the field put it, "Our arithmetic intuition consists of a complex web of knowledge" (Dehaene, 2009, p. 254). Several distinct components to this intuition are present well before the first year of life and before the emergence of language, and they may function largely independently of each other. Over time, and possibly through language-based processes, these components become integrated and help create a more unified sense of number and arithmetic, although carefully designed tasks can reveal developmental vestiges of these distinct components (Dehaene, 2009).

Q: How is the preverbal infant's numerical ability different from that of a 5-year-old? How does comparative research across species shed light on this question?

Spatial Knowledge in Infants

Throughout this book, we have seen that infants are more likely to be proficient at skills that are needed early on. These skills include perceiving depth, perceiving faces, categorizing color, and tracking quantities. Another central skill involves knowing where one is. This ability requires creating mental maps of different environments, retaining them outside those environments, and being able to use those maps later to find one's way or to find an object. Spatial knowledge involves spatial representation—that is, knowing where objects are in relation to other objects or to the self and knowing where landmarks are so as to be able to find objects or to navigate from one place to another. For spatial knowledge to be used successfully, spatial representations must be abstract and flexible, going beyond simple storage of past action patterns.

The ability to use spatial knowledge might seem too complex and sophisticated for infants, and indeed a number of early researchers, including Piaget, proposed that children younger than about 1 year had no such abilities. Nevertheless, Piaget acknowledged that children younger than 2 could succeed at some spatial tasks. But recall that in his view, infants' spatial skills were based entirely on sensorimotor knowledge, which could only be used in motor schemes for performing simple actions (Piaget, 1952b, 1954; Piaget & Inhelder, 1967). One way to understand the limitations that Piaget attributed to infants revolves around how infants encode objects in relation to themselves and to other objects.

Spatial relations can be encoded egocentrically or allocentrically. An **egocentric representation** simply notes where things are relative to one's own body. A baby might remember that a chair last appeared on her right. An **allocentric representation** notes where things are relative to other landmarks in the world. You might remember that a chair was just below the right-hand corner of a window. Egocentric representations might seem simpler, but they are not reliable if the observer moves or turns her body. Perhaps young infants, who mostly sit still, can only encode spatial relations egocentrically until they have had ample experience in freely getting around on their own in the world.

Some early studies suggested that infants younger than 1 year are primarily egocentric, a finding that would be compatible with Piaget's theory that infants tend to encode the world in terms of sensorimotor representations (Acredolo, 1978, 1990; Acredolo & Evans, 1980). But other evidence indicates that even fairly young infants may have considerably more objective ways of representing spatial layout. By age 6 months, infants can keep track of changes in their own body position while making judgments about where objects are, even in featureless round environments (Tyler & McKenzie, 1990). They also seem to be able to track some geometric properties of their environment (for example, shapes and angles in the environment) and to use the angles as well as distances from landmarks to locate objects (Newcombe et al., 1998, 2005). One experimental technique involves hiding an object in a sandbox. The experimenter then retrieves it, either from the location where it disappeared or from a novel location. Infants as young as 5 months look longer when the object reappears in a new location (Newcombe et al., 1999, 2005). The infants' surprise when the object reappears in a novel location can then be used to test whether their perceptions are egocentric or allocentric.

To determine whether infants are using egocentric or allocentric representation to locate an object, experimenters habituated infants to a scene and then moved the infants to new locations or moved the object and observed where the infants expected the object to be. In one study, 4½-month-olds habituated to a pig puppet rotating in a wooden cage on one side of a table (Kaufman & Needham, 2011). The infant's view of the table was then blocked with a screen while the infant was moved, either to another side of the table or around the table and back to his original position. While the infant's view of the table was screened off, the puppet and cage were left in the same place or moved to a new position, diagonal to its original location. (In its new location, it was in the same position *relative to the infant* who had been moved to the other side of the table.) The key question was whether the infant would look longer at the puppet when it occupied its same location but stood in a new position relative to the infant himself, or whether the infant would be more surprised to find the puppet in a new location but occupying a constant position relative to his own body. In fact, the infants tended to look longer when the puppet changed its real, or allocentric, location rather than when it changed its position relative to themselves, or their egocentric location.

The finding that infants are capable of allocentric spatial representations well before age 6 months still leaves unanswered the question of why much older infants respond egocentrically in some tasks. The answer may lie in similarities between the tasks on which they respond egocentrically and the A-not-B task (Acredolo, 1990; Kaufman & Needham, 2011; Twyman & Newcombe, 2010). Remember that one explanation of the A-not-B error is that infants tend to get "stuck" repeating the same retrieval action that they have performed several times before, even when they know that the object is located elsewhere. In a similar way, some of the tasks that assess infants' representations of where objects are located train them to repeatedly turn their head to one side to look at an interesting sight. When the infants are then rotated in the same setting, they may have difficulty suppressing that earlier action, even if they don't really expect the interesting sight to be there. Of course, it is possible that infants' repeated actions are linked to their sense that the event or object really is where they are looking, but other evidence clearly indicates that they can also represent locations allocentrically. Thus, infants may have a single allocentric spatial representation that does not always correspond to their physical response bias, or they may have competing allocentric and egocentric spatial representations. Careful studies will be required to tease apart these two alternatives.

When young infants represent locations in an allocentric manner, what cues are they using? Among the distinct types of cues that infants could use, three especially prominent ones are beacons, landmarks, and the geometric shape of their environment. Using *beacons* seems to be the simplest technique, which simply involves noticing that an object is located directly under or right next to another salient and presumably permanent object (the beacon). Using *landmarks* involves somewhat more relational representations; it involves being able to use distance and direction from salient objects (the landmarks) to determine where another object is located, such as knowing that an object is located halfway between two landmarks. Thus, an infant might notice that a toy is halfway between a chair and a television. Finally, using *geometric cues* involves noticing that the environment has a particular shape—say, that it is an L-shaped room and that the object is located at the inner corner of the L.

It might seem that infants should first use beacons, then landmarks, then finally geometric cues, following our intuitions about the cues' complexity. But this conjecture should be tempered by the wealth of animal studies showing that an enormous variety of species use all three kinds of cues, sometimes without any apparent experience. Birds, rats, fish, and ants can, in some circumstances, use beacons and landmarks to find desired objects (Gray et al., 2005; Vallortigara et al., 2009), and they can also use geometric information (Brown et al., 2007; Cheng & Newcombe, 2005; Sovrano et al., 2007; Tommasi et al., 2012; Wall et al., 2004; Wystrach & Beugnon, 2009). In addition, some species reared in environments that lack unique geometric cues (for example, fish in a circular tank) will nonetheless use geometric information the first time they encounter it (for example, fish in a new rectangular tank) (Brown et al., 2007; Lee & Spelke, 2010). Thus, in at least some cases, the type of allocentric representation that seems most complex also seems to emerge without any prior experience.

Indeed, for animals and older children, geometric cues often trump landmark or beacon information when these cues are in conflict (Lee & Spelke, 2010; Spelke et al., 2010). There is no clear consensus on whether young children similarly prioritize geometric representations, let alone whether young infants do (Cheng, 2008; Twyman & Newcombe, 2010). Still, most researchers agree that infants seem to have access to all three allocentric representations by 6 months, and what may change with development is which ones serve as the default systems in specific contexts.

The simplest ways of measuring spatial knowledge, via locomotion, are difficult to use with babies, since they are so relatively immobile. But once a child can walk, the measures are easier and the evidence can be convincing. For example, although young children often get lost in strange places, they also show surprisingly impressive levels of performance. When one of our sons was barely a year old, he surprised us by very purposefully navigating a novel path through an unfamiliar shopping mall to return to a pet store that had fascinated him when we passed it a short while before. We had initially rushed our son past the pet store, and after carrying him through several turns, we had arrived at an ice cream shop in the mall. Upon being set down, he ignored the usually irresistible ice cream and immediately set off on a path for the pet store. We followed him in fascination as he wove through the crowds, taking a different path from the one on which he had been carried, until more than 100 yards later, he ended up with his face pressed against the window of the pet store. Considering that he had been walking for only a few weeks and that the mall was crowded with adults who frequently obscured his view, this navigational skill was extraordinary—and unlikely to have just emerged in his first few weeks of walking. Exactly how it developed, however, remains mostly unknown, a mystery for clever and creative future research. Infants may be endowed with an ability to use beacons, landmarks, and geometry, but with limitations on each and interference between them, as well as intrusions from egocentric responding, it may take several years after infancy to fully integrate all these cues into one coherent navigation system.

Q: Describe three different ways of knowing one's location in space. How are those different sorts of information used in development?

Categorization in Infants

In earlier chapters, we saw that infants categorically perceive color, speech, and possibly other kinds of stimuli, but such behavior is only the beginning of categorization. Going beyond perceptual categorization, infants also categorize objects, events, animals, and people—grouping them into classes based on shared features and later into classes based on shared functions or meaning. These more conceptual categories are internally processed by mental representations that are typically called "concepts" of those categories or of the objects that make up those categories. They enable an infant to both appreciate the category as a whole and to distinguish or individuate members within that category. Consider the mental representations involved in learning the categories "dog," "friend," or "truck," much less "Pokémon." How do infants come to understand categories of things that go beyond immediate perception (see Figure 5.23)?

The empiricists have a straightforward answer to this question: infants learn these categories by being exposed to many examples of objects and discovering the objects' shared properties through experience. As infants see more and more dogs, they will notice the features that these animals typically share, such as fur, barking, and particular body shapes. Over the course of many learning experiences, these common properties come to stand for the category of "dog" and enable children to recognize new dogs. In the empiricists' view, this learning process consists of strengthening the associations between certain categories and their properties through repeated experiences in which they occur together. By contrast, nativists hold that infants have predetermined

FIGURE 5.23 **Categorization in infancy.** When a 1-year-old plays with a truck, what sort of categorization is also at work? Does the infant realize that the truck is a kind of vehicle that is made by people? How is the 1-year-old's categorization different from that of a 9-month-old or a 2-year-old? Researchers hold various views of infant categorization and of the influence of language on categorization.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

Advances in Infant Eye-Tracking Methods

For many years, researchers have been measuring eye gaze as a means of making inferences about infant perception and cognition (Salapatek & Kessen, 1966). Major changes in the technology of tracking eye movements have provided important new ways of conducting such studies with infants (Aslin & McMurray, 2004). Sophisticated eye tracking has been performed on adults for quite some time, but eye tracking in infants presents special challenges. In many cases, the tracking requires adults to sit still and keep their head immobile, resting their chin on a support and holding their forehead against a brace. Other systems allow somewhat freer head movements, but larger head and body movements will compromise accuracy. In addition, calibrating most adult eye-tracking systems requires the participant to look at a number of specific objects. Because infants can't be told to sit still or to focus intently on command, measuring infant eye tracking requires a way of compensating for frequent head movements.

Technological improvements and advanced software now make it quite easy to calibrate eye-tracking systems in preverbal infants and to compensate for some degree of head movement. In addition, some eye-tracking systems simply consist of having an infant wear special glasses that contain both a camera that records what she sees and infrared sensors that constantly track where she is looking within that scene. The systems are often calibrated by showing the infant bright dots that become larger at various locations on a screen. The dots naturally attract the infant's attention, so no explicit training is needed.

Eye tracking is increasingly being used to explore how infants think about objects and their properties. For example, when an infant sees an object go behind a barrier, eye tracking provides suggestions about what he is thinking. Eye-tracking evidence suggests that when infants as young as 4 months old watch an object move for a few seconds, then disappear behind a screen, they actually visualize the unseen object moving behind the screen, as shown by their anticipatory eye movements toward where the object will reemerge (von Hofsten et al., 2007). Subtle factors may influence when infants can successfully show predictive eye movements that anticipate an object's reappearance, and here, too, eye tracking may help reveal how young infants' prior experiences—for example, repeated viewing of the object as it moves along a path before the screen is put in place to hide the moving object—facilitate this ability (Johnson & Shuwairib, 2009). By the time they are 6 months old, infants can accurately envision the object moving behind the screen and can even seem to envision one object hitting another behind a screen and this second object then moving out from behind the screen (Woods et al., 2010).

Eye tracking can go beyond exploring infants' understanding of objects' motions to probing their thinking about objects' functional properties—that is, knowing what an object can be used for. Infants usually do not show consistent, correct motor uses of simple everyday objects, such as hairbrushes, cups, and phones, until well after they are 12 months old. But do they encode objects' functional uses at an earlier age, before they are able to act them out? To measure this early ability, we can track infants' eye movements while they watch brief video clips of actors using objects either correctly or incorrectly. One study focused on infants at ages 6, 8, 12, 14, and 16 months while they watched adult actors use a brush, or a telephone, or a cup either correctly or incorrectly (Hunnius & Bekkering, 2010). For

biases to think about some categories—biases that can range from simply understanding a particular concept from the start to more abstract constraints on classes of concepts. For example, a nativist might claim that there is a bias to favor functional features (an object serves as a container) over perceptual ones (an object is a cylinder) when both are equally salient and in competition with each other. In Chapter 7, we will consider some special categories to which young infants seem to have fear responses, and in Chapter 9, we will consider in more detail how older children come to understand concepts, but we will begin here with a discussion of some work on young infants' abilities to think about categories.

We know from the research on number that infants are surprised when number changes. But what about when object properties change? Since infants base categories on their recognition of objects' shared properties, the stability of those properties is an important part of categorization. If a toy cat disappears behind a barrier and immediately thereafter a toy dog appears at the other end of the barrier, adults will assume that two objects are involved because they believe that objects' properties are stable and cannot change while moving briefly behind a barrier. Do young infants have similar ideas about what properties, such as size, shape, and color, remain stable over time (Xu, 2003; Xu & Carey, 1996)?

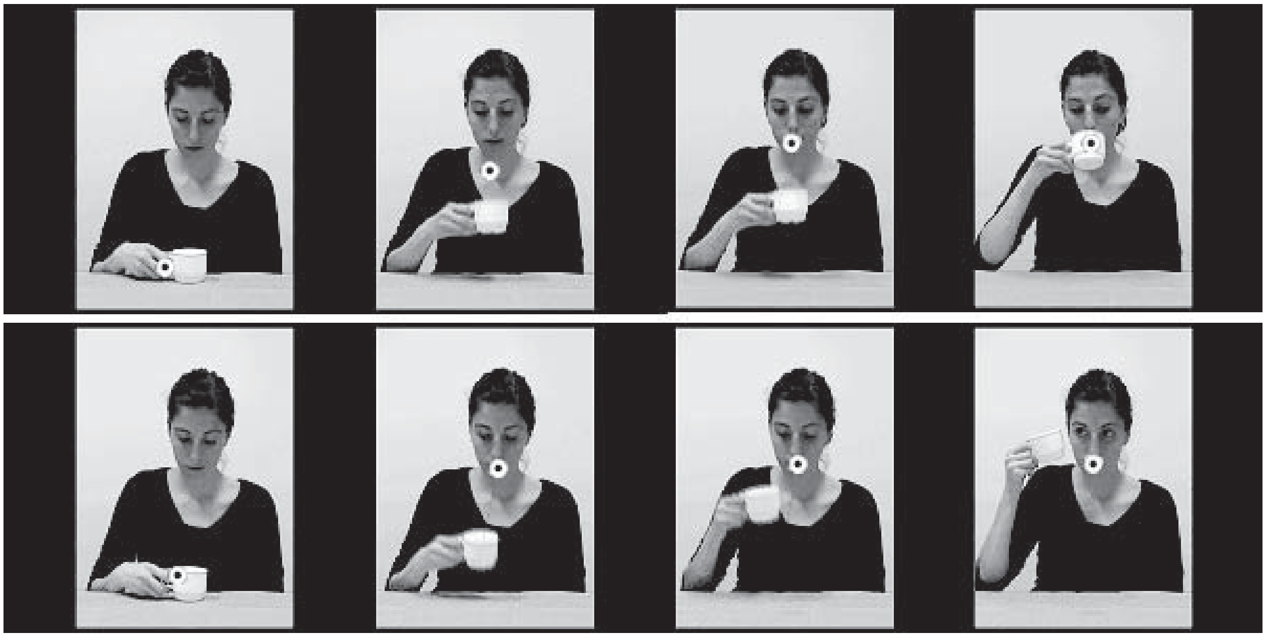

FIGURE 5.24 **Eye tracking as a window into functional understanding.** Infants as young as 6 months have strong expectations about the motor actions and targets associated with specific objects. Here infants look ahead to a person's mouth when she lifts a cup, even when the cup is moved to a location that would be more appropriate for a phone. The dot indicates where the infant is looking. From Hunnius & Bekkering (2010).

example, when the adult used the cup correctly, infants at all ages would look "ahead" from the moment the adult grasped the cup until it reached the adult's mouth, anticipating correctly that the cup would soon be at the adult's mouth. When the adult moved the cup to her ear instead, as if to use it as a phone, infants of all ages still looked expectantly at the mouth, having trouble anticipating this atypical action even as they saw the adult's hand continue to move toward her ear (see Figure 5.24). In contrast, adults quickly readjusted and tracked the object as it moved to an atypical location.

These results show that by 6 months of age, well before most infants show consistent use of such objects, infants have developed expectations about specific motor actions associated with these objects. These anticipations may not constitute a full functional understanding, but they are at least an important precursor. To be sure, eye-tracking systems, no matter how sophisticated, are only one window on infant cognition. The largest benefits of the new technology will lie in how information gathered from eye-tracking studies converges with data from other methods.

In one study that examined this question, 9-month-olds watched as a toy truck disappeared behind one side of a barrier, then saw a toy duck emerge soon after from the other side before going back behind the barrier. When the barrier was lifted to reveal only one object, the infants did not dishabituate. But when the raised barrier revealed both a truck and a duck, the infants dishabituated; they appeared surprised to see two objects. In another experimental condition, the infants saw both the truck and the duck at the same time on either side of the barrier before both disappeared behind it. In this condition, the infants seemed to expect to see both objects when the screen was raised (Xu & Carey, 1996).

These results suggest that 9-month-olds do not realize that objects, like the truck and the duck, keep most of their properties over time. Some researchers have suggested that as children's early language skills emerge (at about 1 year), their way of representing category knowledge changes, resulting in properties being more stably attached to objects (Xu, 2002; Xu et al., 2005a). The labels provided by words may help infants direct their attention to an object's properties so as to know how a category contrasts with other categories. An alternative interpretation is that younger children's memories of properties may fade more quickly in certain kinds of tasks, but that with categories that have more memorable properties or tasks that reduce the demands on memory (such as briefer disappearances behind the barrier), children might view the properties as being preserved over time (Baillargeon & Wang, 2002; Wilcox & Baillargeon, 1998; Wilcox & Chapa, 2004).

One piece of evidence supporting this second view is the finding that when researchers demonstrate a different function for each of two objects in advance (for example, pulling a handle on one object makes a light flash, while turning a knob on the other object makes a short melody occur), the 10-month-olds pass the task as easily as 12-month-olds, expecting that there are two objects (Futo et al., 2010). Further support has come from studies in which infants observe a self-moving, seemingly animate object (a moving toy caterpillar) go behind one side of the screen and an inanimate, inert object (a red cup) go behind the other side. When they are presented with such a large distinction between animate and inanimate categories, 10-month-olds again pass the task (Surian & Caldi, 2010; see also Bonatti et al., 2002). But younger infants may need more powerful indicators of distinctive object properties to remember them across different parts of the screening event (Baillargeon et al., 2012). Taken together, these studies illustrate that infants have some early sense of object types, but the studies also illustrate the great challenge of knowing how infants categorize the world before they can speak and whether their early categories are anything like the ones we associate with names like "dog," "cat," and "truck."

Q: How do 9-month-olds and 12-month-olds differ in their abilities to track objects and their properties when the objects are out of sight? How have these developmental differences been explained?

In addition to exploring infants' use of categories by studying their understanding of objects' stable, physical properties, developmental researchers have also investigated the level of abstraction (that is, the generality) at which categories are first represented in the infant's mind. Some studies strongly suggest that infants as young as 10 months old tend to categorize at surprisingly abstract levels, using "vehicle" rather than "car," or "animal" rather than "dog" (Mandler 2004a, 2004b, 2012; Mandler & McDonough, 1993, 1998; see Figure 5.25). This may be because certain general properties (for example, being a self-moving entity) are easier to recognize than more specific properties (for example, number of legs or kind of tail). One method of studying the categories that infants use involves looking at the order in which infants touch a group of objects arrayed in front of them (Mareschal & Tan, 2007; Ricciuti, 1965). Researchers infer that objects touched one right after the other, such as all vehicles, are seen by the infant as belonging to the same category. The same high-level categories have been found with other techniques involving imitations of taught properties about categories. Thus, if an infant sees an experimenter say "vroom vroom" while moving a truck, she will then make the same motion and sound not just with other trucks but also with other vehicles, such as cars and planes (Mandler & McDonough, 1996). Infants may not always categorize at the higher level, and researchers can prime them to categorize at lower levels by showing them multiple lower-level examples earlier (Mareschal & Tan, 2007), but the key point is that infants do not need to begin categorizing at a lower, "more concrete" level. Other studies suggest that infants as young as 6 months can form abstract categories such as "vehicle" and "animal." In those studies, after infants habituate to many members of a broad category, such as vehicles, they then dishabituate more to novel items that are not vehicles than to novel members of the habituated category (Bornstein et al., 2010).

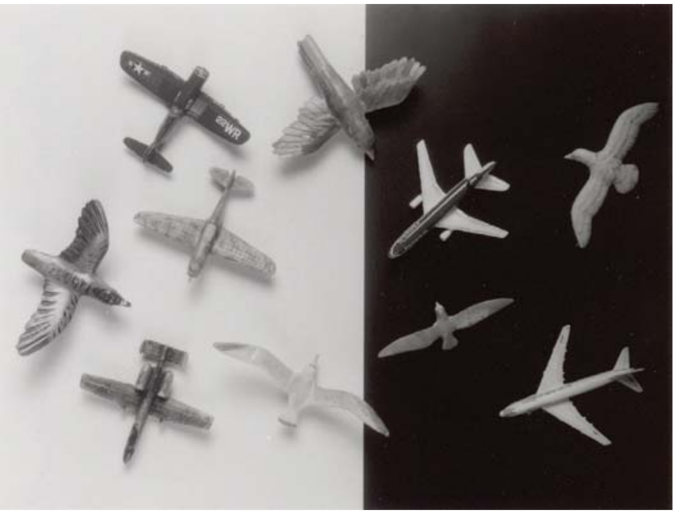

FIGURE 5.25 Levels of categorization. Despite very high perceptual similarity between the birds and the airplanes, infants as young as 9 months recognize the two categories as distinct in sorting and imitation tasks. These results have been taken to show that preverbal infants form categories on conceptual bases as well as on perceptual ones. From Mandler (2004a).

Infants expect members of the same categories to have the same kinds of hidden features. Thus, when 9-month-olds are taught that a novel feature exists inside a kind of box, they expect all boxes of that type to have the same feature inside, but they do not expect that other types of boxes will have that feature inside (Dewar & Xu, 2010). Even more dramatically, infants develop hunches about which properties are essential to a category and which are more incidental. For example, we tend to think that inside properties of animals are more likely to indicate their category than surface, outside properties like a collar. Some have argued that this psychological bias toward inside, usually unobservable features is a human universal and is found in all children of early preschool age (Gelman, 2003; Keil, 1989). In fact, the bias may emerge even earlier. In one study, 14-month-old-infants watched two animated cats that each moved in their own way: one swayed side to side and the other jumped up and down. Each cat had either a red hat and a red stomach (indicated by a translucent image beneath the skin) or a blue hat and a blue stomach. Then, a new cat with a mismatched hat and stomach (either a red hat and a blue stomach or a blue hat and a red stomach) appeared and began to move like one of the original cats. The infants did not dishabituate when the new cat moved like the cat that shared its stomach color (since this is what they expected). But they did dishabituate, and look longer, when the cat moved like the cat that shared only its hat color (Newman et al., 2008b; see Figure 5.26). The infants seemed to find the inner property of stomach color more important for categorizing and forming expectations than the surface feature of hat color. Thus, not all features are treated equally in categorization, and infants favor some of the same ones that adults consider essential.

B Test events

FIGURE 5.26 Categorization and essential features. One study sought to determine whether infants use internal or external information to categorize animated objects. **(A)** In a habituation event, animated cats with a blue hat and blue stomach moved side to side, while animated cats with a red hat and red stomach moved up and down. **(B)** In test events, the stomach color and hat color were mismatched, and the cat's movement either matched the motion of the cat with the same stomach color or with the same hat color. Infants expected the motion to be the same as that of the cat with the same stomach color (internal feature), and they dishabituated when it was the same as that of the cat with the same hat color (external feature). Adapted from Newman et al. (2008b).

Q: What is the evidence that children under 1 year of age sometimes more easily grasp higher-level categories than lower-level ones?

Distinguishing the Physical World from the Social World

Much of the infant's understanding of the physical world involves having a clear sense that social agents behave in radically different ways from inanimate things. We have already seen that the difference between social and nonsocial categories may be one of the most fundamental conceptual distinctions that infants make. They do far more than make the distinction, however; they reason about social agents and nonsocial things in very different ways. For the most part, social agents are other people, but they can also be animals. Social agents have many observable properties that distinguish them from inanimate things (see Table 5.3). Social agents typically can move on their own, whereas inanimate objects need external agents to set them on their way. Social agents can change their own trajectories, whereas

Social Agents (People and Animals)	Inanimate Things
Can move on their own.	Require an external force to move.
Can change the direction of their own movement midpath without external influence.	Only an external force can change their direction of movement midpath.
Causal reactions can be immediate or delayed.	Causal reactions tend to be immediate.
Influence from afar ("action at distance") is common.	Influence almost always requires direct contact.

TABLE 5.3 Some easily perceivable properties that distinguish animates and inanimates. There are several properties relating to the behaviors of social agents that are markedly different from those relating to the behaviors of inanimate things and that appear to be known to young infants.

inanimate objects will continue on the same path of motion unless an external object or obstruction intervenes. Inanimate things and social agents also respond differently to causal influences. For inanimate objects, consequences tend to be immediate. Hit one ball with another, and it instantly responds to the collision. By contrast, a social agent might take some time to respond. A child who is pushed may not react at all, but after several pushes may erupt in a rage. In addition, inanimate objects cannot be influenced from a distance; they require direct contact. By contrast, social agents can be influenced from afar, a concept that can be described as "action at a distance." For example, a person can react to something she hears or sees from far away (Gelman & Spelke, 1981). Moreover, social beings are believed to have goals and intentions for their actions, whereas the movements of inanimate objects are not believed to be intentional. Many organisms pick up on these cues to divide the world into social and nonsocial categories. Even when newborn chicks are presented with two kinds of objects, one that moves on its own and one that moves only when it comes into contact with another object, the chicks prefer to associate with self-propelled objects, presumably because self-propulsion is a reliable cue indicating animate mothers and not inanimate objects (Mascalzoni et al., 2010).

Action at a Distance and Social Contingency

Infants can be quite sensitive to the ways that social agents, and not inanimate objects, can influence each other from a distance. In a study that investigated infants' expectations about "action-at-a-distance" causality, the infants watched animated videos of two 6-foot-high cylinders "interacting" in different ways (see Figure 5.27). In the first interaction, which showed action at a distance, cylinder A moved toward cylinder B and stopped near it, without touching it. After a moment, cylinder B then moved away. In the second video, which showed a "launching" event, cylinder A moved toward cylinder B, but the cylinders made direct contact before cylinder B immediately moved away. Infants as young as 7 months showed different reactions when watching similar events that involved either social or nonsocial pairs of objects (Spelke et al., 1995). When the moving objects were simple cylinders, infants dishabituated more strongly to the action-at-a-distance event than they did to the launching event, since they did not expect that one cylinder could cause another to move without touching it. Even at age 7 months, however, infants reacted quite differently when, instead of cylinders, the videos showed two people interacting in these same ways. Infants no longer dishabituated more strongly to the action at a distance than to the launching. It is as if they knew that social beings don't require direct contact to influence each other (Schlottmann & Surian, 1999; Schlottmann et al., 2009; see also Luo et al., 2009, for related findings with 5-month-olds).

In somewhat older infants, various cues that there is a social agent present will trigger inferences that the agent is perceiving and attending to information. One study asked if cues that there is contingent responding (where responses from one person or object are dependent on the responses from another) were sufficient to elicit expectations of a perceiving and attending agent. In that study, 12-month-old infants saw a featureless furry object in front of them on a table (see Figure 5.28). The object seemed to make beeping sounds contingent on the infant's own sounds (Johnson et al., 1998). (In fact, an experimenter was covertly pressing a button to make a sound each time the infant made one.) Even though the beeps did not sound human, the way the furry object's "responses" seemed to depend on the infant's sounds gave

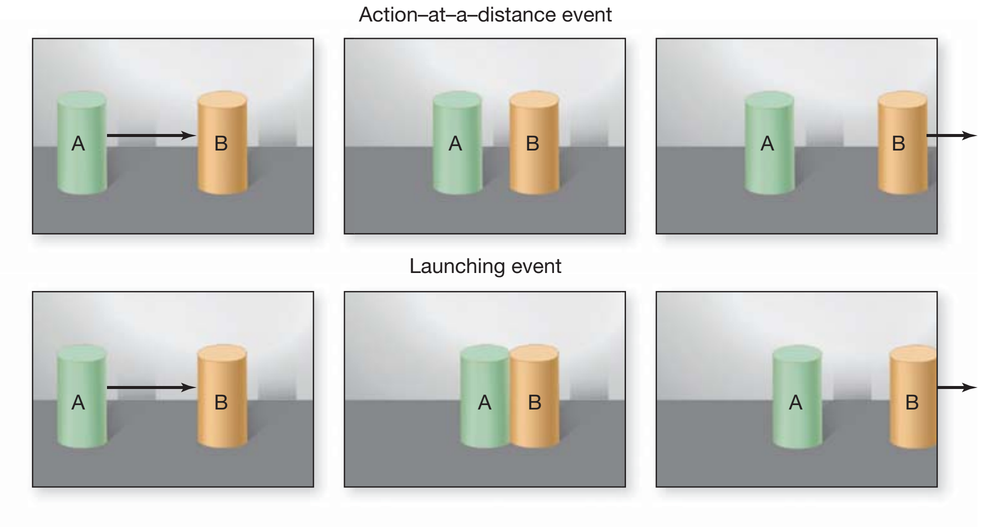

FIGURE 5.27 Action at a distance. When infants saw cylinder A stop without touching cylinder B and then saw B move off on its own, they dishabituated more strongly than when they observed cylinder A make contact with cylinder B. When cylinders A and B were replaced with people, infants did not show stronger dishabituation to the action-at-a-distance event. They seemed to expect inanimate objects to act on each other through direct collisions but allowed for animate beings to act on each other at a distance. Adapted from Spelke et al. (1995).

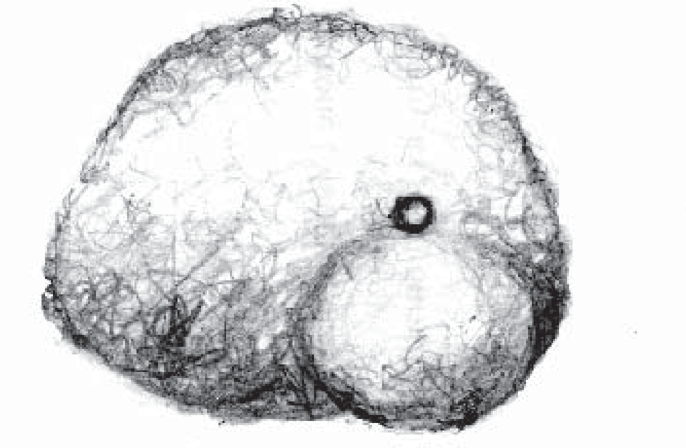

FIGURE 5.28 Perceiving social contingency. When confronted with a featureless furry object that made sounds contingent on their own sounds, 12-month-old infants seemed to regard the object as a social being. They even turned when the furry object turned in order to look where the object seemed to be "looking." From Johnson et al. (1998).

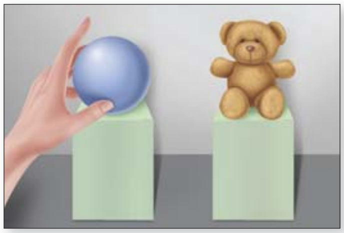
the infant a strong sense that he was interacting with a social agent rather than with something inanimate. This sense was powerful enough that when the furry object then turned 90 degrees, the infant also turned to look where the object appeared to be "looking" (Johnson et al., 1998, 2007, 2008; Shimizu & Johnson, 2004). Moreover, infants appeared to infer that if an object interacts contingently with a person, seemingly responding to his actions, then the object's attention-gathering side faces the person during the interaction (Movellan & Watson, 2002). Knowing that an entity is social leads to this kind of inference about the motives for its actions. In fact, adults respond similarly; in interactions with a robot that clearly looks mechanical but is programmed to respond contingently to them, adults also tend to overestimate its mental capacities (Scassellati, 2002).

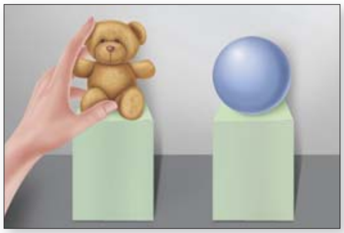
Goal and Belief Attribution

We have seen that quite young infants can distinguish social agents from inanimate objects based on the social agents' capacity to respond to action at a distance and contingency information and that infants use this information to make inferences about what other social beings are perceiving and where they are directing their attention. Beyond the directly observable differences between social agents and inanimate objects, some of the most profound differences concern social agents' intentions, goals, and beliefs. Although these distinctions are not measurable the way a change in trajectory is, adults and older children can infer them immediately—and we often make inferences automatically about another person's goals and intentions. We seem to understand immediately that a person reaching for a door handle intends to grasp it or that a person or animal that chases another may have negative intentions. Infants, like adults, seem driven to interpret the behaviors of social agents in terms of goals.

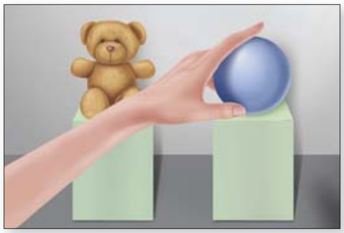
One line of research asked if infants tend to encode events in terms of goals as opposed to simpler physical attributes. In one study, 5-month-olds and 9-month-olds saw a small stage-like setup with one object—say, a ball—on the left and another object—say, a teddy bear—on the right (Woodward, 1998; see Figure 5.29). They then saw something move in from "backstage"—a hand in one experimental condition or a stick in the other condition—and remove the ball. Next, a screen came down to block their view of the stage, and when it was raised, the infants saw that the teddy bear and the ball had switched locations—the teddy bear was now on the left and the ball was on the right. Once again, they saw either a hand or a stick "enter" from backstage and remove one of the objects. The question was whether infants would



A Habituation event



B Same reach



C Same goal

FIGURE 5.29 Interpreting actions in terms of goals. After watching a hand reach for an object **(A)**, infants as young as 5 months are more surprised to see the hand move to the same location to retrieve a different object **(B)** than they are when the hand moves to a different location to retrieve the same object as before **(C)**. Apparently, they interpret the hand as having the goal of obtaining a specific object. By contrast, after seeing a stick "reach" for an object, the infant appears surprised to see the stick go to a new location to retrieve the same object. They appear to view the stick as simply moving to a set location without having a particular goal. Adapted from Woodward (1998).

assume that a person (represented by the hand) would have a goal related to a particular object, but a stick would not. Researchers would answer this based on how the infants reacted to where the hand or the stick moved after the objects changed location. If for all events the infants simply encoded the physical actions in front of them, they should be more likely to dishabituate when the action changed and the hand or stick went to a new location. If, however, they selectively encoded the hand in terms of the goal of its inferred actor, they might be more likely to notice when the hand reached for a new kind of object, even if it was in the same location. By contrast, even if infants did encode goals for hands, they should not encode any goals for the stick and should show stronger dishabituation when it went to a new location.

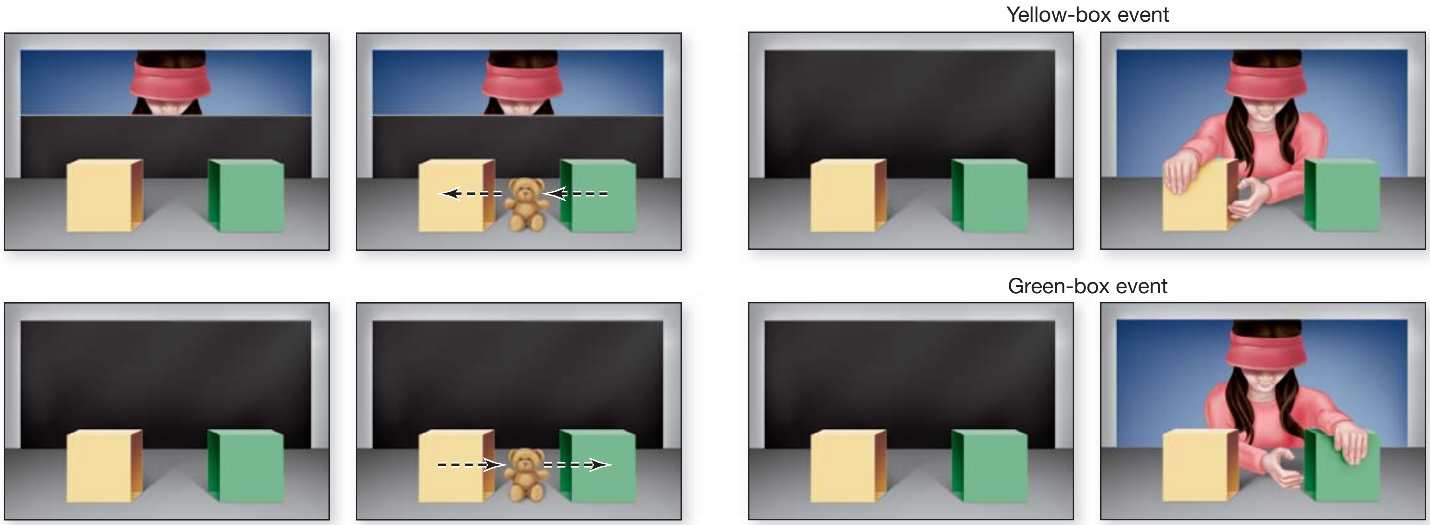
The results were clear. When infants had originally seen a hand remove the ball, both the 5-month-olds and the 9-month-olds dishabituated more strongly if the hand went to the ball's old location (on the left) and removed the teddy bear than if the hand once again found the ball, even though it was in a new place (on the right). By contrast, if they had originally seen a stick remove the ball, they dishabituated more strongly if the stick went to the ball in its new location (on the right) than if it went to the ball's old location (on the left) and ended up with the teddy bear instead (Woodward, 1998). The opposite patterns of results in the two conditions neatly demonstrate that the infants interpreted the actions of the hand as intentional but did not attribute intentions to the stick. The infants in these studies certainly seemed to think about social agents as being embedded in different patterns of causation than inanimate objects, and in some cases these results were even found in infants as young as 3 months (Luo, 2011; Luo & Baillargeon, 2005). Nonetheless, we must be careful in attributing adult-like beliefs to infants. More conservatively, we can say that the infants' responses make good sense to our adult intuitions.

For many years, it was assumed that infants, as well as young toddlers, might be able to think about others' goals and desires but not about their beliefs. This assumption arose from the ways in which children younger than about 3½ years old fail at certain kinds of laboratory tasks that require understanding that a person may have false beliefs—for example, a person's false belief that an object that was moved when she was not present is still in its original location (Wimmer & Perner, 1983). We will look at these false-belief tasks in more detail in Chapter 13, but the key point here is that these tasks that are failed by young children require the children to answer an explicit question about an individual's false belief—for example, they are asked where the person will look for the object that was moved in the person's absence (Baillargeon et al., 2010). But if a child's understanding of false beliefs is instead measured in terms of the child's spontaneous responses, such as the child's reaction to a violation of expectations, then quite remarkably, infants as young as 13 months seem able to take false beliefs into account in interpreting others' actions.

In these studies, an infant might observe an actor watching a toy being moved from one container to another. Then a screen comes up, blocking only the actor's view of the containers. The infant watches as the toy is moved to the other container while the actor's view is still blocked. When the screen comes down, the infant observes the actor either reaching for the container where the toy was originally hidden or reaching for the container into which it was moved while out of sight (see Figure 5.30). Infants look longer when the actor reaches toward the toy's new location, even though it is where the toy really is (Onishi & Baillargeon, 2005; Surian et al., 2007). They seem to expect the actor to look for the toy at the original location, based on the assumption that the actor has a false belief that it is still there. If the same experiment is performed without a screen, the infants look longer when the actor reaches for the toy at its original location, because they assume that the actor watched as the toy was moved and formed new beliefs about where it is.

Infants appear to be surprisingly sensitive to the cues that indicate the particular goals of a social agent. If infants watch an animation in which a triangle moves around a screen in a way that suggests it is "chasing" a square, they will dishabituate when the shapes reverse their roles and the chaser switches from chasing to fleeing, indicating that the infants recognize that each now has a different goal (Rochat et al., 2004). These studies shed new light on decades-old research showing that adults also attribute goals to simple geometric figures. The infant studies clarified that these attributions were not a gradually acquired cultural convention but a foundational way of seeing social agents (Heider & Simmel, 1944).

Young infants even appear to understand social agents' goals in ways that lead to inferences about the agents' dispositions and future behaviors. In one study, 12-month-old infants watched an animation in which one shape (a triangle) "helped" another (a ball) to move up a hill while a different shape (a square) "hindered" the ball. Researchers then asked if the infants would make inferences about how the shapes would interact in a new task. Specifically, would the infants assume that the ball would more likely approach the shape that previously had helped it move up the hill rather than the shape that had hindered it (Kuhlmeier et al., 2003; see Chapter 7)? The results indicated that in a new context (one without a hill to climb), the infants looked longer when the ball approached the helping shape. They may have looked longer because they saw approaching the helper as the more coherent ongoing event and therefore wanted to keep monitoring it. (Although infants sometimes look longer at unexpected events, in other cases,



A Belief–induction trial

B Test trial

FIGURE 5.30 Understanding false beliefs. (A) In the belief-induction trial, infants observe the actor watching the toy being moved from the green box to the yellow box, and then the infants observe the toy being moved from the yellow box to the green box while the actor is out of sight and her view is blocked. **(B)** In the test trial, the infants watch the actor reach for the toy either in the yellow box or in the green box, and researchers measure the infants' reaction (based on looking time) to where the actor searches for the toy. Infants as young as 13 months look longer when an actor reaches for the object in the green box if it was surreptitiously moved from the yellow box while a screen blocked the actor's view. Adapted from Onishi and Baillargeon (2005).

such as this one, they look longer at expected events. The key finding is that they showed a clear difference in looking time between events in which the ball approached helpers versus when it approached hinderers.) Remarkable as this finding is with 12-month-olds, it was then replicated in an even more striking way with 6-month-olds (Hamlin et al., 2007). In this version of the task, infants watched as a display of real three-dimensional objects either helped or hindered another object's path up a ramp. The infants were then allowed to choose (indicated by reaching) which object they wanted to hold, the helper or the hinderer. They consistently preferred the object that helped. Attributing goals to social agents therefore leads infants to make further inferences about how those same agents will behave in the future and whether it is desirable to be in close proximity to them.

By 18 months, infants understand human actions in very different terms from those of objects, and they become increasingly able to differentiate between a true social agent with intentions and goals and an object that is merely behaving like one. For example, if infants watch someone repeatedly attempting an action, such as putting a ring on a hook or pulling the cap off one side of a bar, and failing, they will not imitate the failed action they repeatedly observed but instead will imitate the action they assume was intended (Meltzoff, 1995; see Figure 5.31; see also Johnson, 2000). By contrast, after watching an inanimate object produce the same "failed action," the infants do not infer a goal—they simply reproduce the action they saw.

Q: How do studies on infant imitation reveal differences in how infants see social and nonsocial agents and their actions?

What is it about watching social agents' actions that triggers infants to attribute goals to them? Are human-like features, such as a face or a hand, essential? That view, although long popular, seems unlikely, given that infants will attribute goals to simple geometric shapes after watching them chasing and fleeing. In fact, just the appearance of self-propelled motion in any sort of object can trigger infants to attribute goals to the object.

In a study similar to one discussed earlier, in which a hand or a stick retrieved a teddy bear or a ball (Woodward, 1998), when 5-month-olds saw a small block seemingly move on its own toward an object, they assumed that it had a goal. Much as infants in the earlier study assumed that a hand moving an object was a social agent and that it had a goal, the infants in the second study assumed that the self-propelled block was also a social agent and that it would have the goal of "seeking out" and approaching the same object, even when that object was moved to a new location. In contrast, if the block had a long handle that seemed to be manipulated by something out of view, the infants inferred that it was an inanimate object and that it

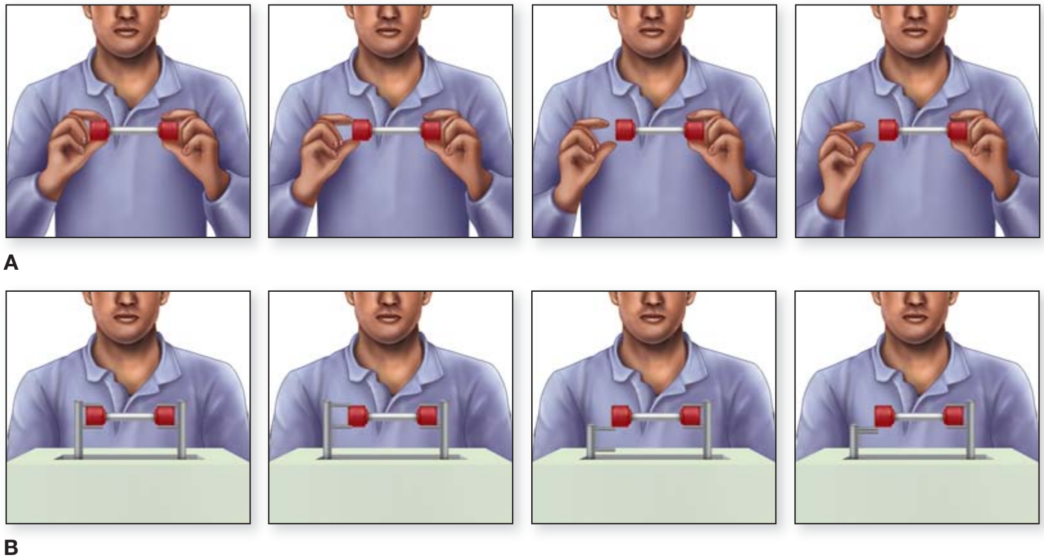


FIGURE 5.31 Imitation of intended goal. (A) When a social agent is viewed as engaging in an action, 18-month-old infants imitate the intended action (even if the agent is not able to achieve the goal) rather than the real action, inferring a goal to act on. In this case, the human actor is repeatedly trying to pull the cap off a small bar. The infant imitates actually taking the cap off instead of the failure to take it off. **(B)** When the same action is performed by a machine (which also is not able to pull the cap off the end of the bar), the infant does not imitate the goal. Adapted from Meltzoff (1995).

would return repeatedly to the same location, even when a different object was located there, since they assumed that an inanimate object would not have a goal (Luo & Baillargeon, 2005; see Figure 5.32). Thus, even before their first 6 months of life, infants attribute goals based on simple perceptual cues of apparent self-directed movement (see also Luo, 2011). The more cues there are indicating that something is a social agent, such as action at a distance, contingent responding, and self-propelled movement, the easier it is for younger infants to infer that a social agent,

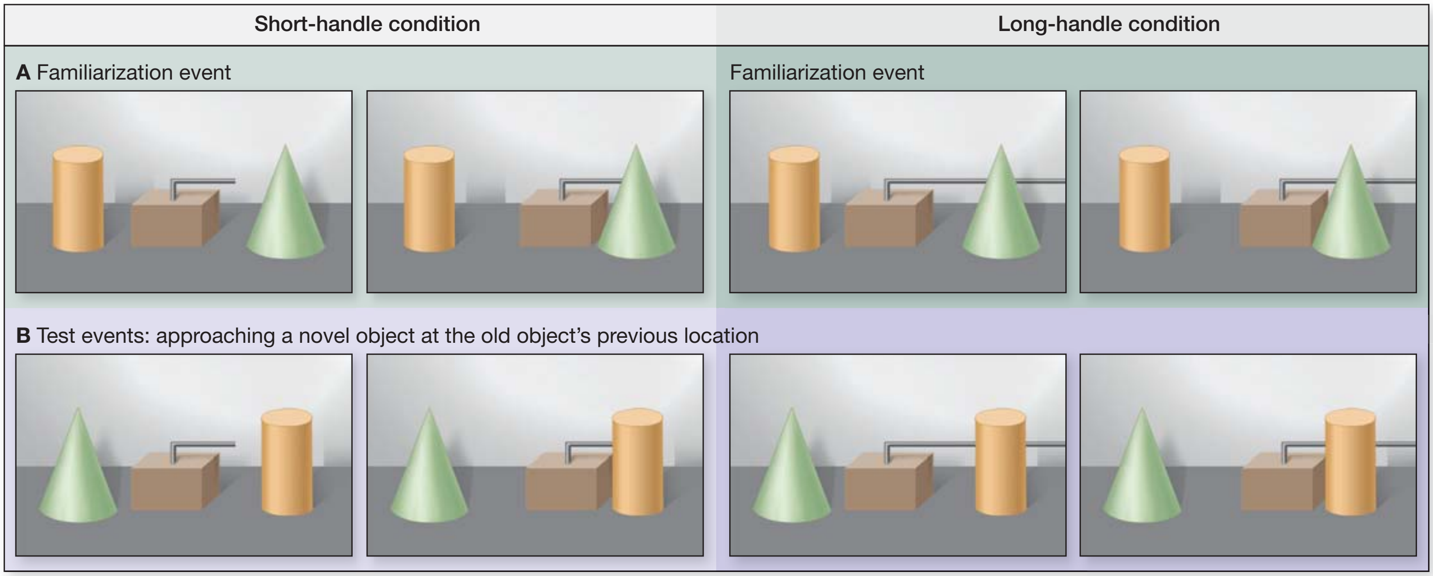

FIGURE 5.32 Context and goal attribution. When infants saw a block with a small handle as moving by itself, they attributed goals to it. During the familiarization event, the infants observed the block with the short handle contact the cone (and since it seemed to be self-propelled, they perceived the cone as its goal). When the location of the cone and cylinder were switched, the infants expected the block to contact the cone at its new location, and they dishabituated when the block seemed to have a new goal (approaching a new object—the cylinder—at the previous location of the cone). When they saw the block being moved by an off-screen agent holding a longer handle, they no longer attributed goals to the box and did not dishabituate when the box approached the cylinder at the previous location of the cone. Adapted from Luo & Baillargeon (2005).

DEVELOPMENT AND SOCIAL POLICY

The Myth of the First 3 Years

Do children's experiences in the first 3 years of life have an especially powerful impact on the development of brain structures and functions that then has long-term consequences for psychological abilities long after that period is over? Both proponents of early education and intervention programs and purveyors of products like "educational toys" that are said to maximize early learning experiences in infants frequently refer to neuroscientific evidence, such as the formation of an especially large number of synaptic connections in the first few years of life, to suggest that children must develop cognitive skills when these new neural circuits are forming or risk having insufficient neural growth later on to support rapid learning. These changes are described as evidence for developmental "windows," or critical periods, during which essential learning must take place if it is to happen at all. Other discussions refer to the pruning of synaptic connections, which starts to occur in toddlers, arguing that this process shapes the brain's architecture in particular ways. Certain forms of pruning are said to occur only in early development, so that if a young child misses out on certain early experiences, optimal pruning will not occur.

These neurodevelopmental patterns are used to argue that early intervention programs for disadvantaged children are especially important because early childhood is a time when environmental inputs sculpt the brain. Others outside of psychology, such as economists, have used these claims to support arguments for targeting most funding for disadvantaged children to the first few years because they believe it will have the greatest impact at that time (Doyle et al., 2009; Heckman, 2006).

Accepting such claims is tempting, given the many significant brain changes that occur during the first few years. But even though the patterns of brain change in early childhood are remarkable and widespread, anatomical development doesn't provide supporting evidence for benefits from a specific kind of early intervention program.

John Bruer, a philosopher of science with expertise in neuroscience, has examined how well the neuroscience data on development support the popular claims that there are critical learning periods in early development. It is especially important to put these claims to the test, as they are used to justify social policies that allocate vast resources for enriched experiences in the first 3 years of life (Bruer, 1999, 2006, 2008). In short, the strong neuroscientific claims about critical learning periods before age 3 do not hold up (with the important exception of cases in which children are severely neglected). As Bruer puts it, "neuroscience cannot currently tell us much about whether we can, let alone how to, influence brain development" during the first few years (Bruer, 1999). Bruer has also pointed out several reasons to be cautious about neuroscience-based claims about critical learning periods: (1) Bruer says that most critical-period effects that have been clearly demonstrated pertain to quite focused abilities, such as binocular fusion of the eyes' separate images or the ability to see with high acuity. He states that there is no evidence for broad, general critical-period effects on perception and cognition. Even the critical periods for visual development can happen at different times, depending on the visual task involved. (2) Bruer points out that most of the patterns of synaptic overexuberance and pruning in the brains of infants and young children may be largely determined by genes in a way that is not influenced very much by the normal range of environmental experiences, even if there may be effects in cases of more extreme deprivation. (3) He argues that the detailed timing of major early brain developments, even in the areas of neural tissue that would be most relevant for such abilities as executive processes in memory and reasoning, doesn't closely coincide with the time frames or critical periods considered most important for psychological change (Bruer, 1999, 2002).

Clearly, popular claims about development can have a huge effect on public policy. To evaluate these kinds of claims, we need to have a detailed understanding of early cognitive development and how its patterns relate to what is known about early brain development, including experimental studies showing how experience might be related to changes in cognition and the brain. The kind of interesting, stimulating environments that Early Head Start and similar programs promote surely do provide experiences that are valuable for children's cognitive development. The problem lies in the policy choices that parents and politicians make when they are convinced that the first few years are all that really matters (Heckman, 2006). If all of cognitive development was constrained by such a powerful, fixed critical period, then communities would devote all of their resources and energies to infants and toddlers, leaving little or no resources for the later years. When bad science causes even modest changes in spending along these lines, older children may suffer. Advances in cognitive neuroscience are shaping how we understand cognitive development in infancy and early childhood. It is important to keep these exciting findings from being distorted in ways that might hurt rather than help most children (Goswami, 2006; Munakata et al., 2004).

rather than an inanimate object, is present (Biro & Leslie, 2007). Older infants and children will easily make such inferences with just one cue (see Scientific Method box).

The behavior of somewhat older, but still preverbal, infants shows that their inferences about social agents can be complex: they assume not only that agents have goals and beliefs, but that they will act reasonably. For example, if infants as young as 9 months old have been habituated to an animation of a shape hopping over a barrier to move next to another object, they will dishabituate if they see the shape perform the same hop when the barrier is gone. They will not dishabituate, however, when, in the absence of the barrier, the shape simply moves along the ground straight toward the object. Even though the shape takes a different path from the one they saw during habituation, the infants apparently recognize that this is the only reasonable way to behave, in light of the shape's apparent goal (Gergely et al., 1995).

Given that young chimpanzees have similar reactions to these kinds of animated scenes (Uller, 2004), any interpretations we can make about human infants' social understanding based on these findings may also apply to some of the great apes as well. Thus, chimpanzees are believed to understand that social agents have goals and intentions. They may differ from human infants, however, when it comes to understanding false beliefs. Despite many attempts, it has not been possible to show that apes, such as chimpanzees, can consistently take into account false beliefs, even when using the spontaneous response methods that have revealed such abilities in human infants as young as 13 months old (Call & Tomasello, 2008; Krachun et al., 2010).

SCIENTIFIC METHOD: Agents and Order

Hypothesis:

Before they have language, infants will understand that only intentional agents are likely to create order out of disorder.

Method:

1. Twenty-four 12-month-old infants watched either a video of a disordering event, in which the blocks went from order to disorder, or a video of an ordering event, in which a randomly arranged group of blocks became neatly ordered.
2. For both kinds of events, infants saw (a) the blocks in the initial state, (b) a screen in front of the blocks, and (c) the blocks in the end state after the screen had been removed.
3. After the screen was in place, either an animated, self-moving object or an inanimate object went behind the screen and stayed there after the screen was removed.
4. Researchers recorded infants' looking times at the end state.

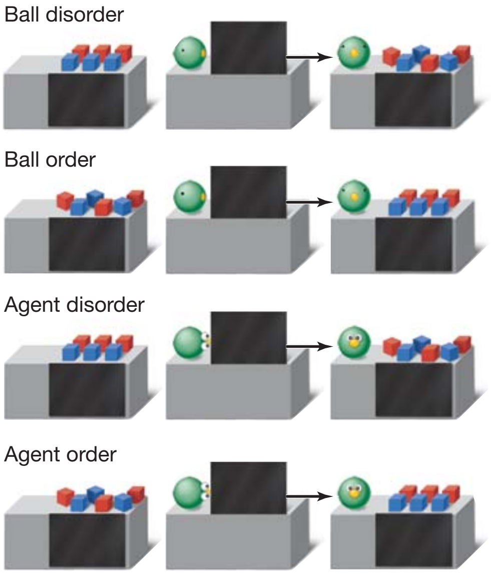
Results:

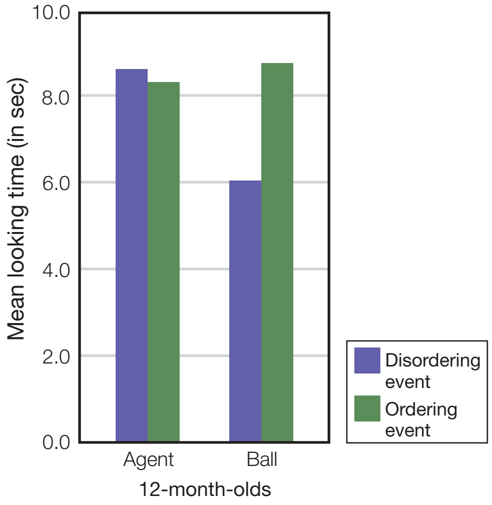
Infants looked longer at an ordering event that was accompanied by an inanimate agent than they did at a disordering event that was accompanied by an inanimate agent. They did not show a looking time difference between disordering and ordering events for animate objects.

Conclusion:

By 1 year of age, infants expect only animate agents to be capable of producing order from disorder. They expect that both animate and inanimate entities can produce disorder from order.

Source study: Newman et al. (2010).





Finally, older infants start to infer that only social agents acting intentionally can cause certain kinds of changes, such as imposing order on a disordered scene. One study set up different conditions to observe infants' reactions to changes in the orderliness of a display. In one condition, a set of blocks formed a neat array (an ordered grouping of the blocks), which was briefly obscured by a screen. When the screen was lifted, the blocks were seen to have been scattered. In this condition, it is easy to imagine that either an intentional agent or an inanimate object, such as a rolling ball, could have caused the change. In a second condition, a disordered set of blocks was momentarily concealed by a screen. When the screen was removed, the blocks were seen to have been neatly ordered. In this condition, only an intentional agent could have caused the change. When 12-month-olds are shown similar events, they look longer when an inanimate object seems to have created order from disorder, as this violates their expectations about what inanimate objects can do (Newman et al., 2010; see Scientific Method box). In contrast, once infants determine that something is a social agent, they understand that it can cause specific kinds of changes that follow from having goals, such as imposing order. Similarly, infants as young as 9 months expect a hand, but not a claw, to be able to select two colors of balls out of a transparent container in a nonrandom manner and to put them in a display where the colors show a precisely repeating pattern (Ma & Xu, 2013). In short, well before the end of the first year of life, infants view inanimate objects as dramatically different from animate creatures. We will see in Chapter 6 that these expectations about the social world and the capabilities of social agents form a critical foundation for developing the earliest social relationships: attachments to caregivers.

Conclusions

Infants are clearly able to think about the world in ways that go far beyond merely having perceptions and engaging in actions. It seems likely that even at birth, infants have certain expectations about the properties and behaviors of physical objects and are surprised when their expectations are violated. We have seen that these expectations seem to be linked together as a coherent set of principles. These expectations also seem to involve a clear understanding of causation, although perhaps only the causes reflected in simple physical interactions. As a result, it is tempting to attribute to infants an intuitive grasp of basic physical mechanics even though this is primarily known through their reactions to possible and impossible events. Based on fairly recent advances in developmental research, we have also come to see that infants in the first few weeks of life can use abstract principles—for example, that solid objects cannot interpenetrate—to reason about unseen events. And we have seen that years before they learn to count, infants can distinguish various quantities on the basis of number. In addition, we have seen that infants can recognize that there is a profound difference between animate and inanimate entities, a contrast that will be an important building block for the development of social relations. More broadly, infants may come into the world with evolutionarily quite old foundations of "core knowledge" that they can use early on to make rudimentary sense of areas such as physical mechanics, social agency, number, and spatial layout (Carey, 2009; Carey & Spelke, 1996; Keil, 1981; Spelke & Kinzler, 2007). The challenge lies in trying to better understand how this early knowledge is mentally represented and how it changes in the years that follow.

Because research on infant cognition is one of the fastest growing areas of psychology, it is especially important to take a step back and consider how the exciting advances in this area fit into the larger picture of our understanding of development. In recent years, researchers have repeatedly shown that infants previously considered essentially precognitive were capable of remarkably precocious performance on tasks that seemed to require impressive cognitive abilities. There were numerous strengths in this approach, especially to counter the many years of mistaken views that infants could only understand the physical world in terms of basic perceptions and actions. But the intense focus on infants' surprisingly sophisticated capacities has come with a cost as well, for we may sometimes forget that infancy is a time of enormous developmental changes that also affect cognitive capacities. A full story of infant cognitive development will have to explain how infants come to understand new concepts and how simple understandings can become more complex and richly connected. Answers to these questions, along with careful characterizations of infant capacities throughout the first year of life, are needed for a full account of how infants' understanding of the physical world emerges. We also see an important message in this chapter that will reappear in later chapters. Development doesn't just consist of perceptual skills feeding into cognitive ones. Advances in cognitive development, such as learning about categories, can also feed back on performance of more perceptual tasks, such as recognizing distinct objects. These two domains of development are intricately linked and often interdependent.

STUDY AND REVIEW

SUMMARY

Piaget's Approach

- Jean Piaget, the undisputed giant of developmental psychology, characterized a child's knowledge and behavior in terms of schemes, or patterns of perceiving, thinking, and interacting with the world. He described how these schemes were constantly adapting to the environment through the processes of accommodation and assimilation.
- Piaget argued that there is a distinct stage of development in infancy known as the sensorimotor period, which in turn consists of six substages. The main focus of this period is the developing object concept.
- Piaget did not view infants as really capable of seeing a world out there that is independent of their actions until after the first year of life.
- Piaget believed that for younger infants, out of sight is truly out of mind; he was convinced that they can only think about objects when they are acting on them and that their concepts of the objects are subordinated to those patterns of action.
- Piaget examined infants' developing object concept by testing how they respond to manipulations of objects. One task, known as the A-not-B task, which involves hiding an object and seeing where the infant will search for it, was thought to be a litmus test for whether infants can really represent objects in their own right and as enduring while out of sight. Infants fail this task until roughly 1 year of age.

Infant Knowledge and Understanding

- The last three decades have seen a revolution in the study of infancy, based in large part on studies using dishabituation or other violation-of-expectation paradigms. This research suggests very different developmental patterns and much earlier forms of understanding than Piaget had proposed.
- Even the youngest infants seem to know there is a world "out there" that is independent of their actions.
- Young infants also appear to have several interlinked expectations about the nature of physical objects and how they behave. These expectations suggest that infants may have an intuitive theory of the mechanics of bounded physical objects, but there is a great deal of uncertainty as to what it means for an infant to have such a theory.
- Studies seem to suggest that young infants understand that there is object permanence or continuity, that objects are solid and cannot interpenetrate other objects, and that objects must make contact to influence other objects.
- Quite young infants also have notions of causation that are not simply the result of associations of elements over time and space. They seem to be able to perceive physical causality in simple collision situations and show surprise when their causal expectations about such physical events are violated.
- Infants are not only able to differentiate different quantities of objects in terms of their number, but are also able to interpret events representing addition and subtraction. They do all of this without any spoken language, raising provocative questions about how their numerical knowledge might differ from that of older verbal children.
- Infants also have spatial knowledge of the world. They are able to construct representations of the layout of the world around them and then can use those representations to remember the locations of objects. From an early age, they may be able to use several distinct cues to spatial layout, including beacons, landmarks, and geometric properties of the environment, relying on different cues, depending on the context to locate objects.
- Perhaps the highest level of cognition is the use of abstract concepts that stand for classes and relations that go far beyond perception. Infants are often able to use quite broad categories, and the category-related knowledge does not invariably proceed developmentally from the most specific categories on upward to the most abstract, general categories.

Distinguishing the Physical World from the Social World

- Infants develop sharply contrasting expectations about the behaviors of animate creatures and inanimate objects. They recognize that social agents can move on their own and can be influenced from afar (action at a distance), whereas inanimate objects need an external force to move them or change their direction through direct contact.
- They see different patterns of contingent responding, different principles governing interactions, and are heavily influenced by inferences about goals when they believe that an entity is animate.
- There is increasing evidence that infants can also attribute false beliefs to social agents and use those attributions to anticipate different kinds of behaviors.

THOUGHT QUESTIONS

1. While chimpanzees and other great apes often appear quite close to human infants in how they reason about physical mechanical relations, there appears to be a major contrast

concerning their ability to think about false beliefs. Human infants as young as 13 months are able to take false beliefs into account, but adult great apes are unable to do so. What, specifically, is likely to be the cognitive difference between these two groups that can explain this difference?

2. What kinds of experiences might be most valuable to emphasize for a young infant's cognitive development, and what kinds of experiences might be least valuable? What are the social policy implications?
3. Preverbal infants seem to have very distinct expectations about the properties and behaviors of social agents and inanimate physical objects. Consider whether preverbal infants also have systematic distinct expectations about other contrasting categories, such as between naturally occurring and human-made objects, between living and nonliving objects, and between edible and inedible things. How might we test for whether preverbal infants do have different expectations about such objects?
4. Preverbal infants seem to appreciate physical causality in a collision and social causality in a situation in which one agent seems to frighten another. Is there a common concept of "cause" being evoked in both cases, or is each completely distinct in the mind of the infant, with no awareness that both instances can be described as one thing causing another? What experiments might distinguish these possibilities?
5. Dogs seem to pass the A-not-B task very early, but they never pass the invisible displacements task. What sort of cognitive or perceptual process might enable them to be more precocious than human infants in the A-not-B task but much worse at invisible displacements?

Conclusions

Summary

Anna Mae He was born in Memphis, Tennessee, in 1999. Her parents were Chinese immigrants who had recently fallen on hard times and had very limited income. Because of complications during the pregnancy, the hospital bill was quite large, and Anna's parents began looking for a way out of their financial crisis. When Anna was 27 days old, her biological parents put her into what they thought would be temporary foster care with another couple.

Anna's parents visited her once a week until her second birthday, when they had an altercation with Anna's foster parents. This incident resulted in a court order preventing Anna's biological parents from seeing her and terminating their parental rights. After a long series of subsequent court battles over custody, the original court ruling was finally overturned in 2007, and Anna was returned to her biological parents 8 years after she had been placed with her foster parents. Anna's foster parents adored her, and Anna's feelings toward them seemed equally positive. But the judge who overturned the case ruled that any harm that might come to Anna by being removed from her foster parents was outweighed by the rights of her biological parents (see Figure 6.1).

The custody battle over Anna Mae He drew intense interest in the national press because it seemed to pit two very powerful human impulses against each other. On the one hand, the rights of the biological parents should not be permanently terminated unless the parents pose a risk to the child. On the other hand, a child who has been raised, practically from birth, by loving foster parents should not be removed from the only family she knows and loves. Moving beyond the complexities of this particular case, it is easy to see how the broader issues it raises relate to all children and their families. How and why are bonds formed between children and their parents, and what are the costs of breaking those bonds? Do newborns bond with specific caregivers in the first few weeks of life, or do those bonds form later, when the infant is more psychologically sophisticated? Is the period of infancy and early toddlerhood especially important for establishing these relationships? How do early bonds with caregivers differ among children, and how do these differences arise? Do those social patterns established in infancy have irreversible effects on interpersonal relations later in life?

FIGURE 6.1 **Anna Mae He case.** For 8 years, Anna Mae He grew up in the United States with foster parents. But after a lengthy court battle, she was returned to her biological parents, who took her back to China. The case highlighted a tension between two competing principles: the rights of biological parents and the rights of those who bring up a child from early infancy. In addition, the rights of the child must also be taken into account.

Building on Chapter 5's discussion of how infants seem to think differently about social beings than they do about inanimate objects, this chapter focuses on the earliest social bonds in infancy, especially those between parents and their children. We will first consider how these bonds typically develop and how they were explained by early theorists, providing a context for the more detailed examinations that follow. We will consider some early perspectives on parent-child bonds, starting with the work of Sigmund Freud, whose ideas continue to have reverberations today. We will then discuss learning theory approaches, which dominated the American psychological landscape for much of the twentieth century, yet were ultimately undermined by both theoretical and empirical considerations. We will then turn to the ethological approach, pioneered by the British researcher John Bowlby and one of his North American colleagues, Mary Ainsworth. This approach underlies most current theories of bonding and is the dominant framework for the study of **attachment**—the strong and enduring emotional bond between a child and a significant other and the processes that create and maintain this long-lasting social relationship.

We will look at the underpinnings of attachment, focusing on the behaviors that facilitate and maintain attachments for a species. In humans, we will see that smiling, cuddling, clinging, following, and "cuteness" may play particularly important roles. We will also look at analogous behaviors in other species to better understand the implications of these attachment behaviors that fit with the ethological approach. We will then examine two social and cognitive skills that help give human attachment its unique nature: social referencing and joint attention.

Not all attachments happen in the same way, however. There are pronounced individual differences in the ways that infants and young children relate to their parents. We will consider how researchers measure these differences and ask why they occur, examining the roles of parenting, children's temperaments, environmental stressors, and genetic factors. We will also ask whether particular attachment styles are associated with certain ways of relating to others later in life. For example, if a young toddler seems to show great insecurity in his attachments, does that behavior predict anything about how he will form intimate relations in college? We will also consider the important contributions of cross-cultural studies and ask if particular attachment styles and behaviors found in other cultures mean the same thing in terms of underlying attachments as they do when they are found in North American cultures.

Finally, we will focus on the ways that extreme social deprivation affects attachment. Its devastating consequences raise questions about how these effects develop and how long they persist after the children's circumstances improve. The ethological perspective, which underlies a variety of comparative studies of attachment in other species, has proved particularly useful for understanding the impact of deprivation. At the end of the chapter, we will return to the familiar theme of critical-period effects to ask whether there is a critical period for the formation of normal attachments.

Age	Behaviors That Set Up and Maintain Bonds between Caregivers and Infants
Newborn	Infants show a preference for looking at faces over other stimuli and attend to human voices, but they do not show clear bonds to specific people.
3 months	Infants smile at people more, but they still do not show specific bonds to particular individuals.
6 months	Infants have now formed bonds to specific individuals and smile most in their presence.
8 months	Most infants show separation distress when the individuals with whom they have formed specific bonds leave.

TABLE 6.1 Development of early bonds. Four behaviors related to forming and maintaining specific bonds between caregivers and offspring and the approximate ages at which they first appear in infancy. This is the most typical developmental sequence in humans from birth to approximately 8 months.

Developing Bonds between Infants and Caregivers

Virtually all human infants, like the young of many other species, form bonds to those who take care of them. These bonds are difficult to measure in their own right, but they can be inferred through certain sets of behaviors that serve to set up and maintain proximity between human caregivers and their children (see Figure 6.2). Disrupting these bonds or preventing them from forming can lead to devastating and often lasting effects. The first such bond is generally between parent and infant, but infants also develop strong bonds with others, including siblings and other family members and caregivers. Nonetheless, much of the theory and research we will explore in this chapter involves the infant-parent bond and especially the infant-mother bond. The most typical sequence for developing bonds is summarized in Table 6.1.

FIGURE 6.2 The origins of attachment. Both parent and child display behaviors that any observer would recognize as the beginnings of an attachment. Here, for example, a Mongolian mother coos to her very young baby. But can a newborn infant have a specific attachment to her mother?

A newborn does not seem to have **specific bonds**—that is, bonds to particular individuals. As we have seen in earlier chapters, this does not mean that newborns aren't sensitive to social stimuli as being somehow different, but they show no evidence of a strong desire to be around particular people. Even though very young infants may be able to recognize their parents through sound, smell, and sight and may find that recognition pleasing, they do not show distress if a parent is not there. Infants' lack of specific bonds early on has been a cornerstone assumption of adoption agencies for centuries. Those agencies typically would like an adoption to occur as early in the infant's life as possible to avoid separation pains in both the infant and the biological parents.

Infants first show specific bonds at around 6 or 7 months. Prior to that age, they may well prefer to interact with their parents over others, but this is largely because the parents know best what makes the baby happy. A socially adroit stranger can usually be just as effective. At 6 months, infants become more skilled at being social partners and seem to shift from being junior partners to full partners in the social interaction. As such, they are more sensitive to others' social and emotional states and are more adept at influencing and responding to those states.

Q: When do specific bonds first seem to form, and why do they form at this age?

Developing social skills may well be involved in building a foundation for bonds between children and caregivers. Such social skills include recognition of and interactions with specific individuals and communication of distress when a caregiver leaves (see Figure 6.3). An infant younger than approximately 7 months might show distress when someone she is interacting with leaves, but this distress doesn't indicate a specific bond to that person because another person can reengage the infant and stop the distress. By contrast, true **separation distress**, which typically emerges at about 8 months and is also known as **separation anxiety**, does indicate a specific bond. In this case, the infant cannot be consoled by a stranger, no matter how skillful; the infant wants a particular person to come back, not just any social partner. This general sequence of developing specific bonds is seen in all cultures throughout the world and has been noted since the beginning of written history.

As infants develop over the first 2 years, a wider range of behaviors reflects the bonds between infants and others. These include crawling to maintain proximity to the caregiver and increasingly rich communication skills. The infant also gets better at coping with brief separations and at inferring exactly when a separation is likely to be brief or long lasting. In short, even though infants may recognize their parents very early in development, that recognition does not directly translate into specific bonds. Only after several months of life do infants seem to have strong bonds to particular people and show distress when those individuals are not near. We now turn to theories of how those bonds emerge over the course of development.

FIGURE 6.3 **Separation distress.** At 6 months of age, babies begin to form specific attachments to their primary caregivers and within a month or two typically show distress at separation, often clinging to an attachment figure who is about to depart.

Q: How is separation distress related to the emergence of behaviors to maintain proximity?

Early Perspectives on Infants' Bonds with Others

Many theories have been proposed to explain the bonds that infants form with others, but most research has occurred in the context of three major approaches: psychoanalytic theory, learning theory, and the ethological perspective. Today, the ethological perspective is the dominant view in the field, but it is important to understand that perspective in terms of other approaches that preceded it.

Psychoanalytic Approaches to Infant-Parent Bonds

Early in the twentieth century, Sigmund Freud changed how we view our mental lives. Freud is best known for his theories of mental illness and the unconscious and for launching the discipline of psychoanalysis, but some of his most important contributions concern the emergence of social relationships and personality (Freud, 1905/1976, 1925/1976).

Freud's theory of bonds between infants and parents emerged out of a broader account of **psychosexual development**, a proposed series of stages of development related to drives, instincts, and sources of pleasure, with a particular focus on sexual desire. According to Freud, all boys and girls progress through these stages in ways that are intimately related to the kinds of bonds they form to others. Freud placed an extraordinary emphasis on the unique nature of the early mother-infant bond, which he believed stems from breastfeeding, a source of oral gratification that becomes associated with the mother. Although Freud's focus on breastfeeding has been criticized by later writers, it is important to remember that in Freud's time, breastfeeding was so widespread in all social groups that any other form of infant feeding would have seemed abnormal. Freud considered nursing to be the earliest and most basic pleasurable act for the infant. He believed that in performing that act, the infant forms a profound attachment to the mother (and to her breast). Freud maintained that the mother-infant relation is the prototype around which all later close relationships revolve.

Yet, Freud overemphasized the pivotal role of the mother-infant bond. Many studies have shown that given the right opportunities, father-infant bonds can be equally intense and important to the infant (Lamb, 2004, 2010; Parke, 1996). Thus, the amount of time spent with the infant is a much better predictor of the strength and quality of attachment than the sex of the caregiver (Clarke-Stewart, 1989). Similarly, the special place of breastfeeding comes under question, given that no differences in later attachment behaviors have been found between bottle-fed and breastfed babies. Although there may be some behavioral differences in breastfeeding versus bottle-feeding mothers, with the breastfeeding mothers sometimes reporting closer feelings to the infant, those differences do not seem to translate into differences in how infants bond to their mothers (Lawrence, 1994). Some of these errors in Freud's approach may have arisen because he never really engaged in any direct observations of children; his accounts relied much too much on adults' reports of their childhoods.

Q: Why, in Freudian theory, might bottle-feeding and breastfeeding have different consequences for the infant?

Freud's views were followed by several other psychoanalytic approaches that collectively contributed to recurring themes that have survived to this day. One issue that Freud considered was how children develop relationships to their parents that are linked both to their own sexuality and to the sex of the parent. Today, the question is whether fathers and mothers behave differently with children of different sexes, even when they are carefully trying to be evenhanded, and whether such differences affect gender roles and influence the nature of attachment itself. A second major issue concerns whether early relations between parents and the young child become powerful touchstones for all later relationships and whether anything like a critical period effect occurs. Finally, there is the question of how much the human infant's cognitions and beliefs come to shape attachments, as opposed to the more basic drives for affiliation seen in other animals. All of these issues were examined by Freud and his psychoanalytic successors and, as you will see shortly, are still actively researched today.

Learning Theory Approaches

Learning theory approaches to infant-parent bonds were defined by an attempt to focus exclusively on the infant's behaviors and the ways in which the environment reinforces them. Learning theorists believed that the drives of oral gratification and pleasure seeking are not well defined and therefore not easy to study and measure. They attempted to restate drives in terms of more clear-cut physiological constructs, such as thirst, hunger, and physical discomfort (Sears et al., 1957), which can be responded to by any caregiver. Learning theorists believed that bonds emerge by being associated with positively reinforcing stimuli. Initially, the stimulus might be the breast or bottle, but soon it would become the mother herself (or any other caregiver) because of her close association with breastfeeding or bottle-feeding. Learning theory tried to avoid all talk of an infant's internal mental states and tried to posit the simplest biological drives as motivating forces. The focus on behavior and positive and negative reinforcements led to assumptions that feeding schedules, the form of feeding (bottle versus breast), and the age of weaning might all heavily influence the nature of attachment (Gewirtz, 1961). After all, if bonds are forged by caregivers being associated with reinforcing stimuli, the schedule of reinforcement and its delivery system should matter greatly. Learning theory views of attachment enjoyed a period of great popularity, especially in the 1950s and early 1960s, when learning theory dominated many areas of psychology. These views promised a simple and perhaps even quantifiable set of rules for understanding how and when attachments occur.

The stark simplicity of learning theories, however, made it easy to see where the theories fell short in their ability to explain the formation and maintenance of infants' and children's bonds as they exist in the real world. One problem with learning theory approaches was that they neglected any cognitive components in the development of bonds. For example, if it is important to the development of bonds that infants understand that their mothers are unique beings who continue to exist when they are out of sight, learning theory has no way of taking into account an infant's or child's thoughts and how they relate to the formation of bonds. Similarly, if an infant's thoughts about a caregiver's intentions and goals are relevant to the nature of the bonds that are formed, learning theory is of no help in understanding how bonds might vary with differences in those thoughts.

Another major flaw of learning theories was their difficulty in explaining how an infant's bond could endure in the face of repeated and consistently negative interactions with a parent or caregiver. Normal learning theory would predict that abuse would lead to the "extinction" of a bond, but this is often not the case. In many cases, an abused child still desperately wants to be close to the abusive parent, even though the closer the child is, the more likely it is that painful interactions will occur. It is in these situations, where an infant is being repeatedly abused both verbally and physically, that the bonds can be most surprising.

Q: What are some limitations of learning theory approaches to attachment?

Bowlby's Ethological Approach

The study of bonds between offspring and their parents underwent a dramatic shift largely because of the pioneering work of John Bowlby and Mary Ainsworth (see Figure 6.4). Bowlby described the bond between children and their caregivers as an attachment, and that term has come to dominate contemporary research on how infants and young children (and even adults) form bonds to others. Although the term *attachment* had long been used in literature to describe close social bonds (White, 1916), it was not commonly used for the processes of forming and sustaining these social bonds until Bowlby made it central to his theory. In developmental psychology, the term has now come to have a specific set of meanings arising from Bowlby's body of work. Bowlby emphasized the behaviors that created and maintained attachment, leading some to describe his view of attachment as "the infant's ability to seek proximity to a specific caregiver" (Pipp & Harmon, 1987).

A B

FIGURE 6.4 John Bowlby and Mary Ainsworth. (A) John Bowlby's studies on attachment and separation transformed how the psychological community thought about the bonds formed between child and parent. **(B)** Mary Ainsworth began working with Bowlby in the early 1950s, making many important advances in the study of attachment from an ethological perspective.

In discussions of human attachment, affection and emotion are often mentioned. For example, Ainsworth defined attachment as "an affectional tie that one person or animal forms between himself and another specific one—a tie that binds them together in space and endures over time" (Ainsworth & Bell, 1970, p. 50). But if we take a comparative approach and consider attachment across a wide range of species, a more conservative definition focuses on the *behaviors* that set up and maintain bonds between offspring and parents (see Figure 6.5). It is difficult to know what emotions to attribute to other animals when they show attachment to their mothers by acting to keep the mother close, such as chicks peeping and following. In these cases, it is much easier to infer the attachment bond based on the behaviors that maintain contact between parents and offspring.

Along these lines, the ethological approach to attachment has become the dominant perspective in the field. It approaches the bond between offspring and parents from an evolutionary and comparative perspective, asking about its functional role in the development of organisms and groups of organisms. Ethology largely developed in Europe in the 1930s, when such major figures as Konrad Lorenz and Niko Tinbergen studied animals' social behavior in naturalistic contexts (Lorenz, 1965; Tinbergen, 1951). These studies gave rise to the notion that animals have repertoires of actions that are assembled into larger-scale behaviors. Ethologists paid special attention to animals' signaling systems and the species-specific "conventions" used to communicate threats, sexual availability, and the like. And they studied how these systems are then assembled into the more complex behaviors that govern mating, territoriality, and caring for offspring.

In this ethological context, Bowlby began studying attachment in human infants (Bowlby, 1969). Bowlby's major contribution was to describe attachment in evolutionary and comparative terms, focusing on the similarities and differences in the ways that various species' offspring

FIGURE 6.5 Attachment in different species. Many organisms form attachments to their parents, as seen in these examples across several species. The ethological approach stresses the functional role not only of attachment itself but also of the component attachment behaviors that set up and maintain attachments.

attach to caregivers. He saw complex attachment behaviors as being built up out of specific behavioral elements, such as smiling, crying, and clinging. Across species, the particular combinations of these elements varies considerably; what species have in common is the way they integrate these elements into coordinated behaviors that set up and maintain attachments. One of Bowlby's most important contributions was to focus attention on these attachment behaviors as an essential means of binding the caregiver to the infant—thereby creating attachment itself. For any species whose young are relatively helpless early on, attachment is a crucial way to make sure that parents take care of their infants. For Bowlby, attachment has the evolutionary function of protecting infants from threats to their survival, ranging from predators to physical hazards to starvation. Across a wide variety of organisms, it is adaptive for vulnerable offspring to engage in behaviors that increase the odds of staying in proximity to parents, and it is adaptive for parents (in terms of passing on their genes) to be responsive to those behaviors in ways that maintain proximity to the offspring. As such, caregivers become safe havens in situations that are threatening or frightening, thereby offering a **secure base** from which the young offspring can explore.

As noted earlier, the young infant does not appear to have a unique bond to a specific caregiver. Bowlby built on the observations of many others by noting four phases in the development of attachment (Bowlby, 1969; see also Ainsworth et al., 1978):

- *Preattachment phase* (birth to 6 weeks). Infants in this phase display attachment-related behaviors but do not seem to target them to particular individuals.
- *Attachment-in-the-making phase* (6 weeks to 6–8 months). During this phase, infants start to use signals such as smiling and crying to focus on specific people.
- *Clear-cut attachment phase* (6–8 months to 18 months–2 years). During this phase, infants more actively stay near a particular person by using more effective signals (such as protesting if a particular person leaves) and by behaviors to maintain contact with that person (such as crawling toward her and clinging to her). Infants use the caregiver as a secure base for exploration.
- *Reciprocal relationships phase* (18 months–2 years and older). During this final phase, children are better able to take into account the parent's needs and adjust their behavior accordingly, such as being able to wait for the parent to return without protesting. Thus, the child and the parent become more like partners solving a problem to help them get to a common goal.

But Bowlby may have underestimated how even newborns can quickly recognize their mother based on her smell and can use that information to have specific kinds of interactions with her. Newborns may not really be attached, but they may begin tailoring interactions with specific people right from the start (Winberg, 2005).

Bowlby stressed that although attachment behaviors are crucial for creating and maintaining attachment, they should not be equated with attachment itself. He believed that careful analysis of attachment behaviors could yield insights into the nature of the underlying attachment but that assuming a simple linkage between attachment and attachment behaviors could be misleading. For example, he insisted that the strength of an attachment behavior does not necessarily indicate the strength of the attachment itself. Some of the strongest and healthiest attachments provide infants with such trust in their caregiver that they have no need to cling to the person constantly to guarantee that they will not be separated. If a child is anxious about whether the mother will always be there, however, he might show extremely strong attachment behaviors, such as clinging, crying, and following, in an attempt to stay near the mother at all times. The strength of attachment behaviors can also depend on the particular situation, whereas the nature of the underlying attachment does not. A child who shows very strong attachment behaviors in frightening or alarming situations may show very low levels of the same behaviors in safe situations, such as being at home among well-known people, even though the strength of the attachment itself remains constant across both situations.

Q: Why is it important to distinguish attachment from attachment behaviors?

Bowlby also wanted to distinguish attachment from **dependency**, which is reliance on another person for basic physiological needs, such as food and shelter, and for protection from perceived or real threats. Although most early attachment relationships between infants and parents involve the infant's high level of dependency on the parents, it is misleading to equate dependency with attachment. Dependency is not necessary for strong attachment, nor do all dependencies lead to attachment. Dependency also implies a passivity on the part of the infant that Bowlby felt underestimates the infant's capacities, as he instead saw the infant as actively engaging in behaviors that help create attachment.

Sometimes strong attachment develops between an infant and those who play relatively minor roles in satisfying the infant's most immediate needs for nutrition and comfort. Some infants whose parents have intense work demands may spend 50 hours a week in day care and have a caregiver at night who helps feed them and put them to bed. Those children may interact playfully with their parents only a few hours a day, yet they still seem to form strong attachments to them, often the strongest of all their attachments (Clarke-Stewart, 1989; Harvey, 1999).

Although Bowlby was influenced by psychoanalytic approaches, he disagreed with psychoanalytic views that linked attachment to the infant's feelings of gratification while breastfeeding or to some form of sexual drive. In the end, he rejected many details of the psychoanalytic perspectives on attachment, even though, in a broader sense, he was influenced by their emphasis on the importance of early bonds and the ways that disrupting those bonds could cause long-term problems in relationships (Bretherton, 1992). He also advanced the idea that infants develop cognitive models of their early attachments, which guide their interpretations of future interactions with caregivers (Bowlby, 1958). Although this notion has not been explored until quite recently (Johnson et al., 2010) it is, in many ways, a natural outgrowth of earlier psychoanalytic approaches.

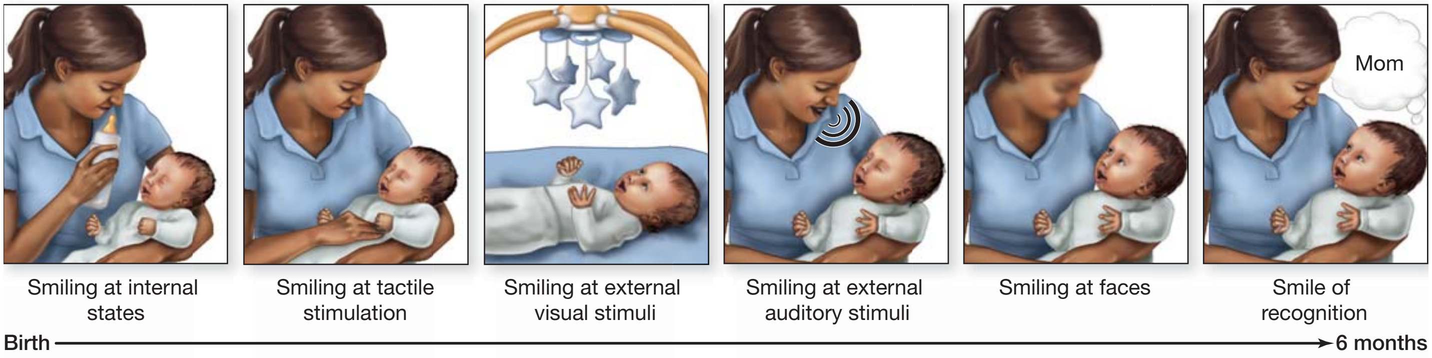
The ethological approach has become the dominant perspective for understanding attachment because of its clear continuity across species and because it allows for integration of many other psychological processes, such as those involving emotions, social interactions, cognitions, and motivations. It is best understood as an approach or perspective rather than a precise theory, since its large reach allows for many different interpretations of the details. Because comparative studies of behavior have shown a resurgence in recent years, its relevance remains strong.

The Underpinnings of Attachment

Infants as young as 1 month are social beings and participate in one-on-one social interactions much of the time that they are awake. Soon after birth, infants engage in behaviors that initiate and maintain social interactions (Stern, 1985). Bowlby focused on these behaviors and how they contribute to the formation and maintenance of social bonds. Both in human infants and in infants of other species, components of attachment, such as smiling, clinging, and touch, as well as baby-like features, help form and maintain attachment so that parents will care for their helpless offspring. The ability to form human attachments builds on other abilities as well, including particular kinds of social skills and understanding. The more recent cognitive approach says that for infants to develop bonds with others, they must also have some grasp of the special tempo of interactions with others and the kinds of information that such interactions can convey. Without these underpinnings, the special nature of human attachments would not be possible. These underpinnings help support a large array of activities beyond attachment, including communication, feelings of empathy, and threat detection. But here we focus on the ways they contribute to the formation and maintenance of attachment.

Components of Attachment

We have seen that attachment behaviors bind caregivers and infants together, and for many developmental psychologists, these behaviors are the basis for inferring attachment itself. Nonetheless, the role of the particular components of the **attachment complex**, the set of behaviors and mental states that, when taken together, are responsible for setting up and maintaining attachment, can vary considerably across different species. These commonalities and differences are nicely illustrated by smiling and clinging and by their different roles in humans and monkeys. They also are seen in the juvenile features that make up "cuteness," which serves to trigger caregiving responses by adults toward infants.



Mom

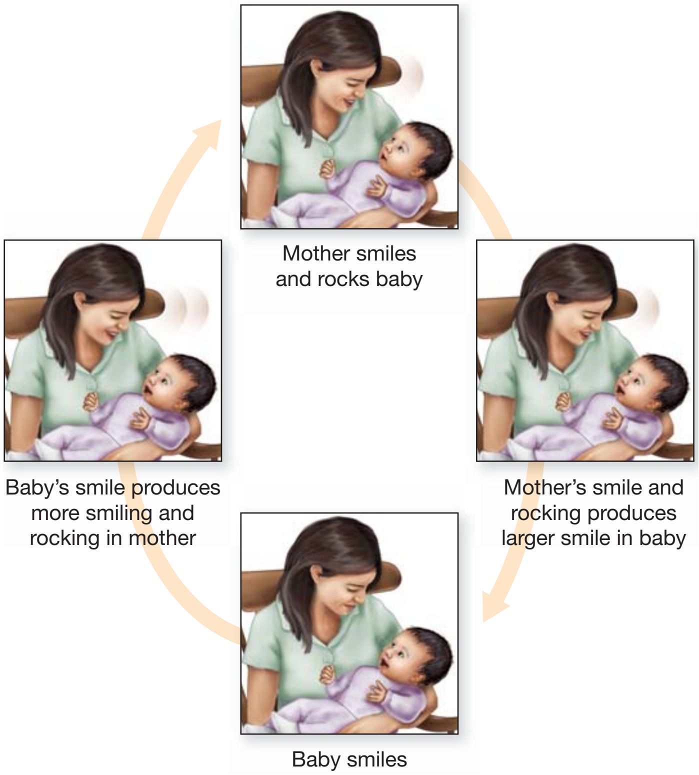
FIGURE 6.6 **Stimuli that elicit smiles.** In Wolff's classic account, stimuli that elicit an infant's smile progress from internal states to external stimulation to social stimulation and finally to unique individuals. Today we regard the young infant as having greater sensitivity to social entities, but Wolff's general pattern does capture changes in smiling in the first months of life.

Smiling Infants' smiles are among their most endearing behaviors. The first smile clearly meant for a specific parent brings great pleasure. But smiling does not emerge as a mature behavior in the newborn (see Figure 6.6). Indeed, most parents quickly realize that they are very ineffective at making their newborn smile, no matter how many silly faces and sounds they make. It is not that newborns are incapable of smiling, but what makes them smile may be quite different than at later ages. The first researcher to study these developmental changes systematically was Peter Wolff, who investigated which stimuli elicit smiles most effectively at different ages in infancy (Wolff, 1963). He found that as infants get older, they increasingly prefer auditory and visual social stimuli.

The infant initially appears to smile in response to her own internal state, such as just after a feeding or after a particularly good burp. A little later, the best stimuli to elicit a smile are likely to be external, primarily those involving touch and motion, such as hugging and rocking—which give way to other kinds of external stimuli, such as interesting sights and sounds. Then, the most pleasing stimuli become specifically social, as the infant smiles at the sound of a person's voice or on seeing her face. Finally, at about 6 months of age, the best elicitor of a smile is the face of a particular known individual, producing the "smile of recognition." Countless parents would agree that at around 5 or 6 months, something changes: the infant starts to clearly look into your eyes and smile at you because she knows and likes you and not simply because some other stimulus has made her feel good. Those endearing first smiles of recognition often seem to appear just in the nick of time for parents who have been lurching through months of sleepless nights. In fact, this smile of recognition might serve an important adaptive function for the human infant. Just when caregivers feel completely overwhelmed and exhausted, the smile of recognition appears, and the invigorated parents suddenly feel that they can withstand anything their adorable bundle throws at them.

The smile is a classic example of an attachment behavior that serves a signaling function in a feedback loop between parent and infant (see Figure 6.7). The mother rocks the baby gently, causing the infant to give a small smile. This



Mother smiles and rocks baby
Mother's smile and rocking produces larger smile in baby
Baby smiles
Baby's smile produces more smiling and rocking in mother

FIGURE 6.7 **Contingent responding.** The infant and the mother often become partners in a positive-feedback loop in which smiling and rocking on the mother's part produces more smiling in the baby, which in turn produces more smiling in the mother. Through such a loop, close bonds are developed and maintained between the two.

smile pleases the mother, causing her to smile back at the infant and continue rocking, which in turn causes the infant to smile more, and so on, until each partner is fully engaged with the other. This is an example of a positive-feedback loop, a system in which the actions of each component serve to escalate the actions of the other, so that the system quickly reaches a maximum level and remains there for as long as the system components can work without fatigue. In this case, the behaviors of the infant and the mother continue to escalate as each responds to the other until, eventually, either the infant or the mother gets tired and breaks off the encounter. Just watching a mother attending to her smiling infant can reveal the intensity of these interactions. The mother is often leaning forward and actively engaging the infant, while both mother and baby appear to completely ignore the rest of the world. And if the mother breaks out of this feedback loop too abruptly, the infant becomes distressed. These feedback loops become more and more effective in the first year of life as infant and caregiver become more sophisticated and perceive and produce effects in the other through their smiles and other signals of positive emotions (Mendes et al., 2009).

In short, an infant's smile prolongs the interaction with the target of the smile (Csibra, 2010), increasing the amount of time spent in close proximity to the caregiver. The infant's smile actively produces positive emotions in the caregiver (Fogel et al., 2000; Symons & Moran, 1994), motivating the caregiver to keep interacting with the infant. These effects can be demonstrated at a physiological level as well. For example, when most mothers view their infant's smile, the smile elicits high levels of neural activity in the reward regions of the mother's brain, such as in the ventral striatum, as well as in an area of the hypothalamus associated with the production of **oxytocin**, a hormone found in higher concentrations in the mother's saliva as a consequence of seeing her infant's smile (Strathearn et al., 2008). This effect is especially strong in mothers who are more sensitive to the moods and emotions of their infants (Strathearn et al., 2012). Oxytocin, in turn, is known to produce increased feelings of trust and affection toward others (Kosfeld et al., 2005), especially when they are part of one's "in-group" (De Dreu et al., 2010).

Q: How does the smile function as an attachment behavior?

Clinging and Touching Infants often cling to their caregivers while being held, and clinging may play a role somewhat comparable to that of the smile in the formation of human attachments, namely, to maintain proximity. For monkeys, clinging may be considerably more important than smiles or other facial expressions to keep close to their mothers. Infant monkeys do show expressions similar to smiles that may reflect roughly similar internal states, but these expressions do not appear to be as closely linked to the mother's behavior as human infant expressions are. In contrast, clinging is essential to the welfare of infant monkeys. They will often hang on to their mothers for hours (see Figure 6.8). Clinging not only helps keep them near the mother and moving with her, it also seems to serve a signaling function, building a bond of attachment between the two. In humans, clinging may be less essential in its own right, because it is just one of several ways to help form attachments. Thus, human infants born with tiny or nonexistent limbs form perfectly normal attachments to their parents (Decarie, 1969); monkeys with similar afflictions may not fare nearly as well. For humans, touching between the caregiver and the infant is still important in the development of attachment, but this contact seems less crucial as a signaling behavior on the human infant's part, compared with its function in other species.

One way to understand the species differences in clinging and related behaviors comes from a model of how clinging emerged and changed over the course of evolution (Matsuzawa, 2006). Clinging first emerged in primates about 50 million years ago, as primates had a unique ability to grab fur with their hands. In its initial form, still seen in primates such as lemurs, the baby clung to the mother but she did not respond. Around 40 million years ago, however, higher-level primates started to embrace their offspring back, and a form of mutual clinging, or embracing, emerged. The next major leap occurred about 5 million years ago, with the emergence of great apes. In contrast to other monkeys, who find direct gaze threatening, the great apes started to hold each other stomach to stomach in ways that enabled mutual gazes. Those gazes were reinforcing, especially when accompanied by smiles, which reflect positive relations in both humans and chimpanzees. Finally, in humans a unique ability emerged to disengage more easily from direct clinging while maintaining contact through facial expressions, vocalizations, and more intermittent touches. Humans, therefore, have an especially powerful set of behaviors for forming and maintaining attachments without direct contact. Nonetheless, the decline in the necessity for direct physical contact does not indicate that clinging and other forms of touch are irrelevant to the formation of human attachments.

Humans share with many other mammals a long common history of the positive effects of contact. For example, there is an extensive literature on the effects of contact on rat pups, which shows that gentle stroking can calm stress responses and help develop positive bonds (Jutapakdeegul et al., 2003; Weller & Feldman, 2003). Touch can also

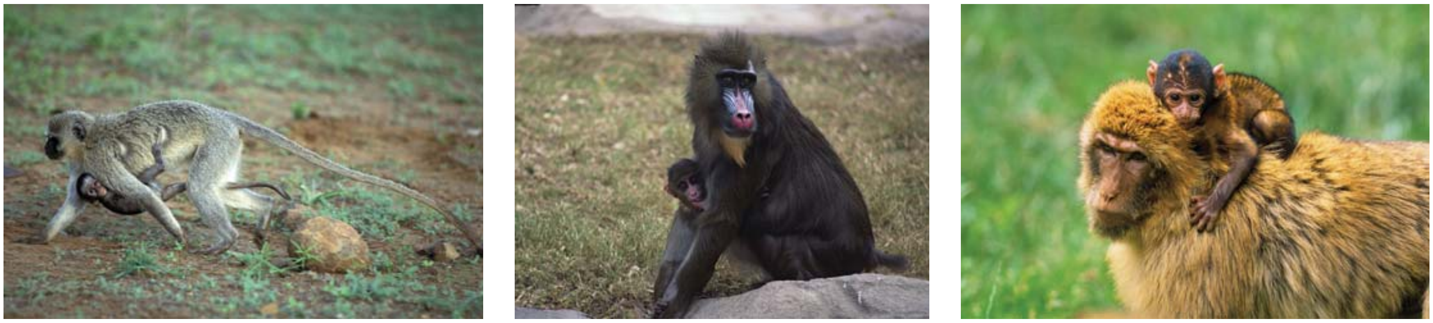


FIGURE 6.8 Clinging in primates. Normal infant monkeys of many species cling to their mothers. This not only helps the infant monkey hang on, but also seems to help the infant forge bonds with its mother and promote a feeling of security.

help pups learn whom to attach to. Touch of the sort normally received from a pup's mother can set up a positive bond with a smell that is experienced at the same time, presumably a mechanism through which infant rats learn to form bonds to their mother (Kojima & Alberts, 2011). In human infants, too, gentle touching seems to reduce stress. Thus, when infants are put in a situation in which their mothers do not respond to them, touching can reduce the infants' typical physiological stress response to the situation (Feldman et al., 2010; Jean & Stack, 2009; Jean et al., 2009; Moszkowski et al., 2009). Even in newborns, skin-to-skin contact has been shown to have an analgesic, or pain-reducing, effect (Gray et al., 2000). There are also indications that human infants who sleep in physical contact with their mothers breastfeed more often through the night and may have lower rates of sudden infant death syndrome as well as lower stress levels (McKenna et al., 2007). While this is not to suggest that this should be the only sleep pattern for an infant, it is yet another indication of the value of physical contact between mother and infant (Waynforth, 2007).

An infant's touch also helps to create responses in parents that strengthen the infant-parent bond. Much as infants' smiles lead to increases in oxytocin in their mothers, their touching and stroking of the mother's breast also increases the mother's oxytocin levels (Matthiesen et al., 2001). Moreover, it appears that affectionate contact between fathers and infants can also cause the father's oxytocin levels to rise (Gordon et al., 2010). These findings suggest that there are some common physiological pathways in both mothers and fathers for forming and maintaining attachments.

Comparing the ways that humans and other primates use touch and facial expressions to develop early bonds illustrates both common themes and species-specific adaptations. As we have seen, various forms of tactile contact play an important role in many species, and clinging is often especially significant among primates. Nonetheless, while touch remains very important for human infants, they often come to interact most richly with their caregivers through visual and auditory means, often several feet away from the target of affection. By contrast, most primates other than the great apes (who engage in direct eye contact as do humans) appear to need more immediate physical contact to build and maintain attachments. Thus, both of these systems help to develop and maintain social interactions, working through different routes in humans and most other primates.

Q: Compare and contrast smiling and clinging in terms of their functions in setting up and maintaining attachments.

Cuteness Even "cuteness" seems to be a critical component of attachment across several species. The so-called "kewpie doll" configuration of more rounded faces, larger eyes relative to the face, and smaller noses, chins, and limbs is found in the infants of an enormous range of species and is thought to evoke affection from mature members of the species. Biological models of growth help to explain the developmental patterns that give rise to these features, which have been shown to be extremely appealing to humans (Alley, 1988). Even 5-month-old infants prefer looking at infantilized faces rather than looking at more mature faces (Van Duuren et al., 2003). Konrad Lorenz was one of the first ethologists to propose such a pattern, as shown in Figure 6.9. He suggested that certain juvenile features automatically activate a kind of "baby schema" in much the same way that other stimuli trigger responses.

It is intriguing how often toy developers, cartoonists, and other kinds of artists greatly exaggerate baby-like features in portraying older children to make the images more appealing. Although the effects of cuteness have not been studied systematically in many species, it appears that at least some species may share the human predisposition to respond positively toward members of their species with

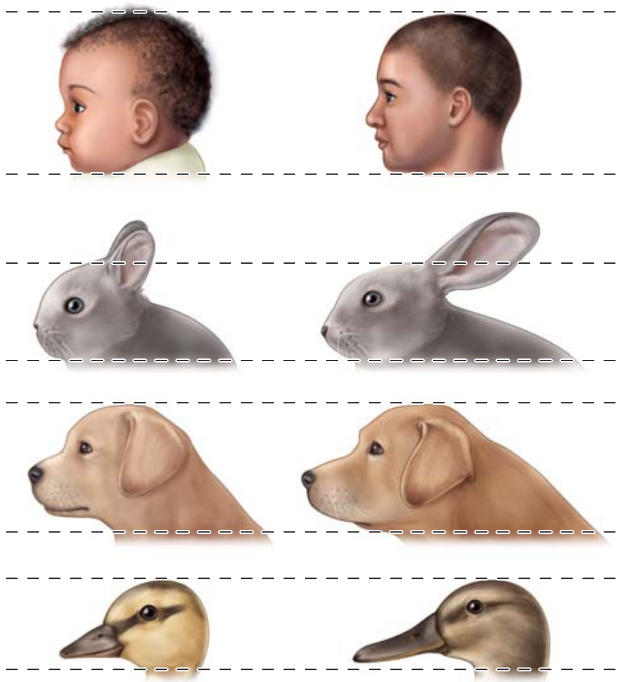

FIGURE 6.9 Baby features that lead to the perception of cuteness. The ethologist Konrad Lorenz suggested that there might be features shared by the young of many species that elicit a "cuteness" response in adult members of those species, a response that inhibits aggression and encourages nurturance. Commercial artists frequently attempt to enhance the cuteness of a child or an animal in greeting cards by exaggerating the head and eye size. While the artistic merit of such a style may be debatable, the ethological manipulation of instilling "cuteness" tends to work on even the most jaded viewers. Adapted from Lorenz (1971).

infant-like anatomical features. For example, adult female rhesus monkeys are more likely to interact positively with monkeys whose facial fur and skin have been dyed to match the hues common in rhesus infants (Higley et al., 1987).

Human infant cuteness appears to arouse specific neurophysiological patterns of responses in adults, often based on quite subtle differences in perceived cuteness. One study involved digitally altering photographs of babies' faces to make them appear either more or less cute, using algorithms that subtly changed key facial features (Glocker et al., 2009; see Figure 6.10). Adult participants viewed three versions of each face: the unaltered face; the face that was artificially made cuter by showing such high baby schema features as a round face, high forehead, big eyes, and small nose and mouth; and the face that was made less cute by showing such low baby schema features as a narrow face, low forehead, small eyes, and big nose and mouth. In response to the images, the areas of the adults' brains typically associated with anticipating a reward showed activation levels corresponding to the degree of cuteness of the infant. The cuter the face (as validated by independent ratings), the more active the reward-anticipating system was. The authors suggested that this bias might be an evolutionarily selected mechanism for eliciting mothers' caregiving responses toward their young. Other evidence suggests that women of reproductive age may be able to detect more subtle differences in baby cuteness than older women or men of any age, possibly because it is especially adaptive for women in that group to have a strong response to cuteness (Sprengelmeyer et al., 2009).

Although not yet studied systematically, it seems likely that infants don't just appear cute. They likely also behave in ways that increase their cuteness to relevant adults. These behaviors could range from vocalizations and facial expressions to body postures or motions that seem to elicit strong positive responses from adults. The proposal that infants play a more active role in displaying cuteness so as to maintain proximity to adults would be very compatible with Bowlby's perspective.

Q: How does cuteness play a role in ethological views of attachment?

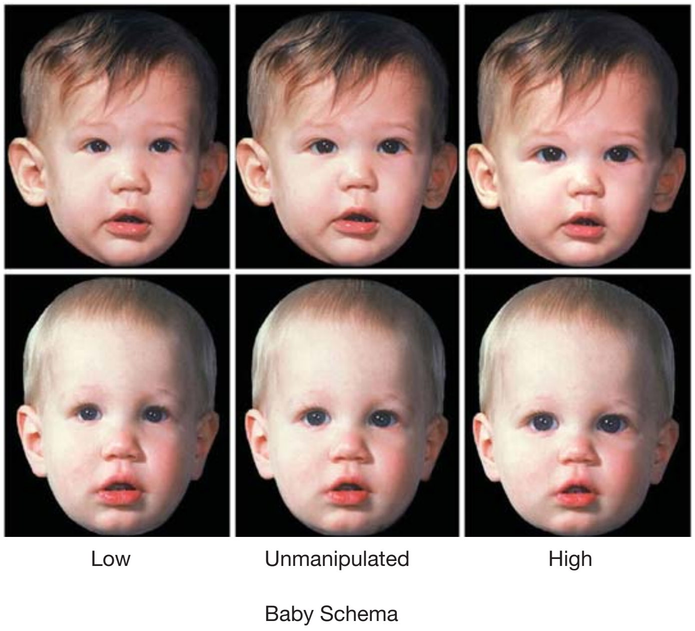

FIGURE 6.10 Variations in cuteness. Subtle variations in baby schema features, as shown here, lead not only to different adult ratings of cuteness but also to different levels of activation of brain regions associated with anticipation of reward. The photos were altered to change the baby schema features to low baby schema features (narrow face, low forehead, small eyes, big nose and mouth) or high baby schema features (round face, high forehead, big eyes, small mouth and nose) or were unaltered, and then these photos of the same infant with low, unaltered, or high baby schema features were rated for cuteness. From Glocker et al. (2009).

Bases of Social Interactions

For an infant to form attachments to people and not to stray items of furniture, there must be something different about social beings that the infant perceives as special. As discussed in previous chapters, certain social stimuli, such as the face, have a special status in the infant's perceptual development. We have also seen that young infants can distinguish social beings from inanimate objects and that they think about social and nonsocial entities in very different ways, understanding, for example, the causes and consequences of behaviors. With respect to attachment, we will see that these abilities to distinguish social agents from nonsocial objects also affect an infant's social interactions.

Contingent Responding Infants anticipate the behaviors of social beings and may experience quite powerful emotional reactions when those expectations are violated. For example, infants expect their parents to attend to them and respond in the rhythmic pattern of give-and-take that characterizes social interactions—that is, they expect contingent responding. If a parent looks at an infant with an impassive, straight face, known as a **still face**, infants as young as 1½ months of age become distressed at the lack of response and reciprocity in the social interaction (Adamson & Frick, 2003; Bertin & Striano, 2006; Cohn & Tronick, 1988; Field, 1977; Tronick, 1989; see Figure 6.11). It is easy to empathize with the infants' reactions; it is very rare and always uncomfortable to attempt a face-to-face interaction with someone who does not seem to react. Infants seem to share the expectation that social overtures will cause a response in the other person, and they show discomfort when there is no response. Reactions to a still-face task may also be indicative of the quality of an infant's future attachment to the caregiver. One meta-analysis of many still-face studies concluded that infants who showed fewer negative reactions to their mother's face during the task were more likely to show higher-quality attachments several months later (Mesman et al., 2009).

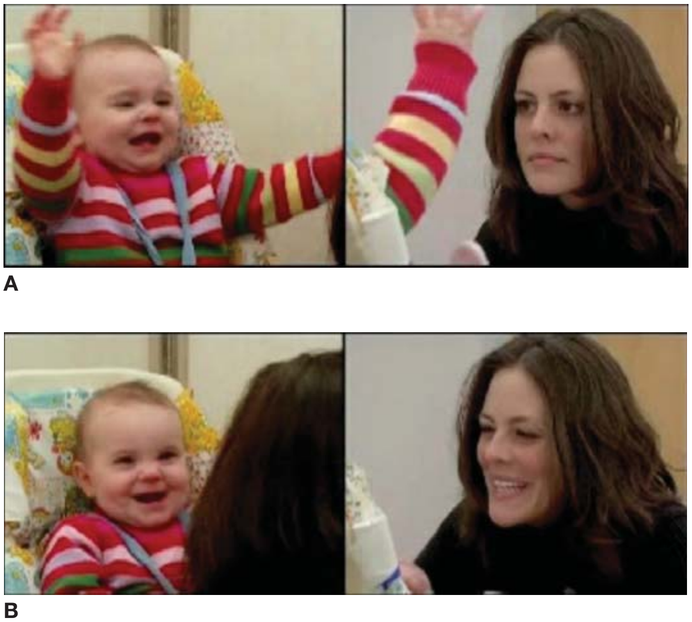

FIGURE 6.11 Infant's reaction to the still face. (A) If an infant's mother stops interacting with her and freezes her face into a "still face" that she maintains for several seconds, the infant will start to disengage socially and will often show distress as well. **(B)** When the mother smiles and interacts with the infant, this will encourage the infant to reengage in social interaction with the mother.

Local cultures can influence patterns of contingent responding between caregivers and infants early in the infant's life. For example, mothers' responses to infant vocalizations start to vary across cultures within the first few months after birth. In one study, infants from northern Germany and from small villages near Kumbo, Cameroon, in West Africa, were observed several times between the first and third month of life (Kärtner et al., 2010). At first, mothers in both cultures tended to respond to their infants' vocalizations in roughly the same manner. By 3 months, however, the German mothers and the Kumbo mothers were responding quite differently, reflecting differences in the way that older infants and mothers interact in each culture. The German mothers showed more visually oriented responses, such as gazing, using facial expressions (for example, smiles, raised eyebrows, or wide open mouths), or pointing to an object roughly 2½ times more frequently than the Kumbo mothers, while the Kumbo mothers showed 50 percent more touch-oriented responses (for example, stroking, patting the infant's body, or kissing his face) than did the German mothers. Apparently, in just a couple of months, the parent-infant pairs start to pick up these cultural norms. This key contrast in attachment behaviors—namely, behaviors that can occur at a distance versus those that require close contact—seems to be quite modifiable across cultures.

Social Referencing Another fundamental social behavior that emerges very early in development involves relying on the expressions and behavior of others for important information about how to interpret various situations. For example, in an unfamiliar and potentially dangerous circumstance, it makes sense to watch the facial expressions and actions of those who know more about the situation. If they are panicking, your anxiety will likely increase as well. This phenomenon is known as **social referencing**, and its development has been extensively studied (Campos & Stenberg, 1981; Feinman et al., 1992; Hornik & Gunnar, 1988). These studies suggest that infants as young as 7 months use the facial expressions of others as an important source of information about how to react to ambiguous situations.

Studies of infants' reactions to the visual cliff situation, which we explored in Chapter 3, have shown that infants use social referencing as one source of information about whether to cross the transparent surface over the visual cliff. If the mother appears alarmed, the infant will be much more likely to avoid the deep side of the cliff, while an encouraging mother can often coax the infant to cross the transparent surface (Sorce et al., 1985). Similarly, older infants have been shown to use social referencing of their mothers' reactions to guide their walking on unfamiliar surfaces (Adolph et al., 2010). Moreover, a mother's emotional reaction to a new toy can influence whether her infant will choose to play with it; for example, an infant will carefully avoid playing with a toy for which the mother shows marked distaste (Hornik et al., 1987; Mumme et al., 1996). Regardless of whether a mother shows her anxiety or some other reaction in her voice or in her face, the emotion she expresses can strongly influence her infant's behavior (Vaish & Striano, 2004).

Social referencing can play a key role in the development of specific attachments. If infants observe someone showing fear or anxiety while interacting with a stranger, they are less likely to want to interact with that stranger. This increased wariness toward certain strangers will slow the process of forming an attachment to those individuals, which can have negative practical effects. For example, if an infant's parents are quite anxious about leaving their child with a new caregiver, the infant may pick up on that anxiety and thereby take longer to bond with the new caregiver. Conversely, if the parents show low anxiety and a welcoming attitude toward a new caregiver, the infant is more likely to be receptive to the caregiver as well.

Joint Attention and Gaze Following In addition to social referencing, infants show another crucial social behavior known as **joint attention**, in which the infant and another person simultaneously attend to the same object or event. When there is joint attention, both partners understand that pointing or some other indication is meant to focus the two of them on the same thing (Bruner, 1983, 1990; Scaife & Bruner, 1975; see Figure 6.12). Joint attention is not only a social behavior; it is also intrinsically communicative, and many have suggested that mastery of joint attention may be critical for the foundation of language skills (Bruner, 1976; Carpenter et al., 1998; Tomasello et al., 2005).

Some critical components of joint attention may be present as early as moments after birth, as newborns have been shown to follow the gazes of others at above-chance levels (Farroni et al., 2004). Gaze-following skill improves considerably in the following months, when infants become better able to follow gazes to increasingly distant objects. After 3 months or so, infants increasingly use their observations of others' hands and eye gazes as indicators of where to look (Amano et al., 2004; Csibra & Gergely, 2005). Well before age 1, they can interpret another person's gaze as indicating

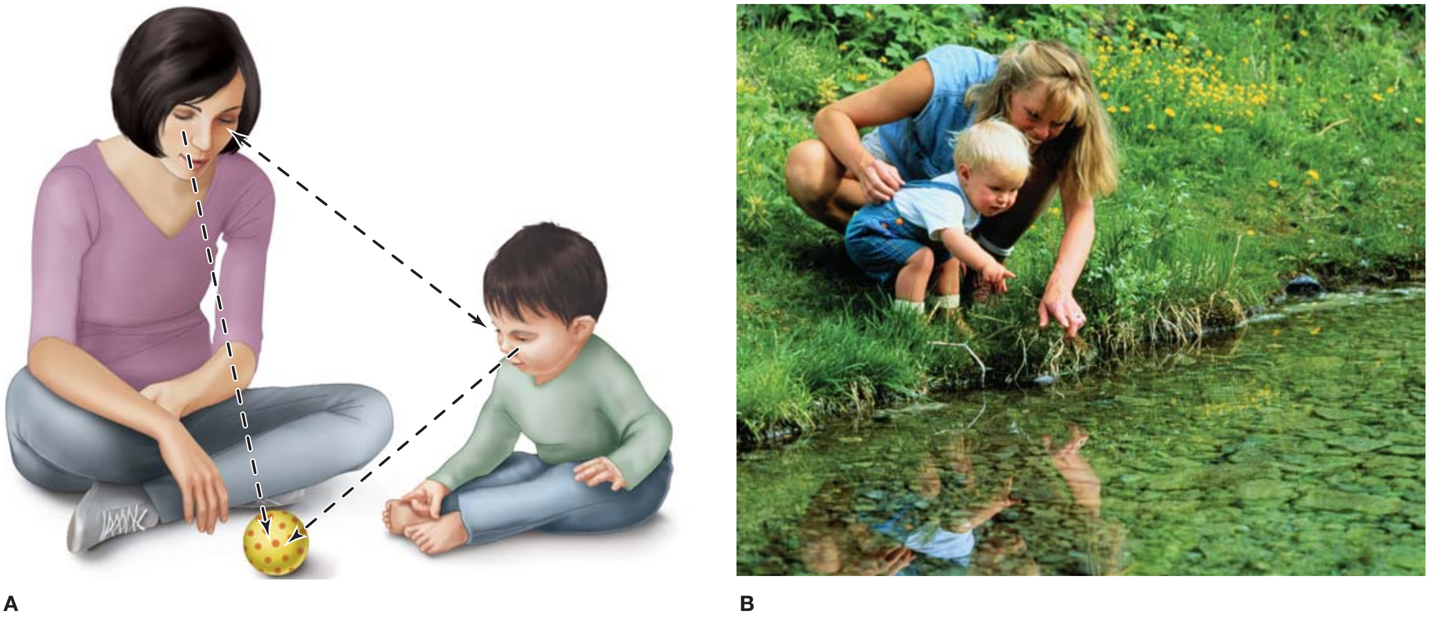

FIGURE 6.12 Joint attention. (A) In joint attention, a triangle is set up between two individuals and a referent in the world. The two individuals look at each other and at the object in a reciprocal fashion that suggests that each wants to make sure that the other knows they are referring to the same object. **(B)** Pointing often accompanies these interactive looking behaviors, as it focuses attention on an object in a way that is both a social act and a communicative one. Joint attention emerges at around 9 months of age and reflects a more sophisticated way for the infant to link to the social world.

that an object is behind a barrier (Csibra & Volein, 2008). In general, gaze following is a fragile skill before 2 months and then develops strongly between 2 and 8 months, at which time infants reliably follow the gazes of others (Gredebäck et al., 2010).

Q: How might gaze following help support the growth of human attachments?

At about 9 months, gaze following seems to develop into more full-fledged joint attention. Around this time, infants begin looking at things that an adult is looking at, seemingly in an attempt to gather information about what interests the adult (Bakeman & Adamson, 1984). In doing so, they may be more explicitly thinking of the other person as a being with goals and desires that are indicated by direction of gaze. These joint-attentional behaviors appear roughly at the same time as pointing and are used to include both the other person and the pointed-at object. Although younger infants may point to things, it seems to simply reflect the infant's own attention to an object, usually as a result of recently touching it, rather than an understanding of a shared focus with another person (Carpendale & Carpendale, 2010). At around 9 months, though, the infant starts to point to an object and then alternate her gaze between the object and the person, as if trying to track whether the person is "following" her (Bates, 1976). Similarly, when someone else points at an object, the infant is now much more prone to alternate her gaze between the indicated object and the person. These tasks require the infant to attend to both the object and the other person simultaneously, with the clear intention that the other person should likewise attend to both the object and the infant. This process seems to require the ability to understand that others have minds with their own goals and desires (Trevarthen, 1979).

Q: What is joint attention, and how is it relevant to the young child's understanding of social entities?

Joint attention typically becomes fully functional within 2 to 3 months after infants form their first specific attachments, and it may be critical for elaborating those attachments into richer and more meaningful bonds. Those bonds may be based, in part, on the interests and experiences the infant shares with others. This dimension of shared interests and experiences may well be uniquely human. Although a great many other species show gaze following (often based on head direction but sometimes also on eye direction), it is possible that only humans use gaze following as a window into others' minds and a way of building a sense of shared experiences (Rosati & Hare, 2009).

This discussion demonstrates that infants are sensitive to the special ways in which social beings can interact and the important information that those interactions provide (Dykas et al., 2011). Their attachments to social beings start quite early in development. Later in infancy, they develop even richer expectations about social creatures, especially those to whom they have formed attachments. The development of attachments to parents, caregivers, and peers occurs in a great variety of animals, but the nature of these attachments often differs from species to species. The differences may largely arise from variations in the way different species perceive and understand social beings.

Individual Differences in Attachment Style

Our discussion of attachment so far has focused primarily on developmental patterns that most children share. In particular, we have considered how an ethological perspective can illustrate the various component behaviors involved in forming and maintaining attachments. We have also noted how different cultures may rely on different kinds of behaviors and have mentioned that some attachments seem to be of higher quality than others. We now turn to the issue of individual differences in attachment style, which is the focus of most attachment studies.

Individuals show significant differences in **attachment style**—the pattern of relating to significant others that is based on expectations about how they will respond and that affects perceptions, emotions, thoughts, and behaviors in close relationships. In this section, we will explore some of the profound questions about what these differences mean for infants' relationships with others. We will examine some ways of measuring these variations in attachment and consider the challenge of determining what factors are responsible for them. Finally, we will consider some implications of different attachment styles: How should we understand cultural differences in attachment patterns? And do early attachment styles have any implications for intimate relationships later in life? First, however, we need to discuss ways of characterizing different attachment styles and measuring them.

Studying Attachment Styles in the Strange Situation

Some infants and children tend to show high levels of trust and confidence that a parent will be reliably available for comfort, support, and protection, while others are more anxious and insecure about whether this kind of support will be available. In developmental psychology, these kinds of expectations about close relationships, as well as the associated emotions and behaviors, are the basis of attachment styles. Comparing attachment styles requires a standardized method that can objectively pick up indications of different styles across a wide range of individuals. The oldest method, which is still the most prevalent one, was developed by Mary Ainsworth (Ainsworth, 1979). Inspired by the ethological approach, Ainsworth became interested in developing a method of measuring behaviors that reflect different attachment styles. Ainsworth's method is commonly known as the **Strange Situation** because it examines an infant's reactions in certain unusual and mildly threatening situations, both in the mother's presence and when the mother has left the room, as well as how the child responds when the mother returns (see Figure 6.13). In the Strange Situation, different children respond to the experience in different ways, but a particular child continues to show the same response pattern across repetitions of the same measure. This measure is most often used with infants between 1 and 2 years old.

Q: How is the Strange Situation used to measure different attachment styles?

The Strange Situation involves a sequence of eight episodes that vary in terms of the apparent level of "threat" to the infant, ranging from the mild unease of being in a strange room with the mother to the potentially greater discomfort of being left alone with a stranger (Ainsworth et al., 1978; Ainsworth & Wittig, 1969). Typically, the infant's behavior in each episode is filmed, and judges who are unaware of the infant's responses in other episodes are asked to rate the behavior in a given episode according to a scale developed by Ainsworth and her colleagues. On the basis of the infants' behavior in the Strange Situation, infants' attachments were initially classified into three categories:

- Type A infants showed an **insecure/avoidant attachment**, typical of approximately 20 percent of middle-class American children.
- Type B infants showed a **secure attachment**, typical of approximately 70 percent of middle-class American children.
- Type C infants showed an **insecure/resistant attachment**, also known as an **anxious attachment**, typical of approximately 10 percent of middle-class American children.

Type A infants, characterized as having insecure/avoidant attachments, tend to spontaneously explore more than the other types do when they are in a room alone with the mother. More important, they do not appear upset when the mother leaves, and they show much less concern toward strangers than other infants do. Most infants are at least cautious and watchful around unfamiliar people, and many become strongly agitated. In contrast, Type A babies tend to react less to strangers, sometimes even completely ignoring or avoiding them. One of the most distinctive behaviors of Type A babies occurs when the mother returns after a separation. At her return, Type A infants usually actively avoid contact with the mother by turning away or by appearing to ignore her. In some cases, it seems as if they blame the mother for the stressful separation and try to reduce the pain by withdrawing from her. Some Type A infants may simply be too preoccupied with play and unconcerned with whether the mother is there to notice when the mother returns after a separation. Several behaviors of Type A infants tend to cluster tightly together for members of that category. Thus,

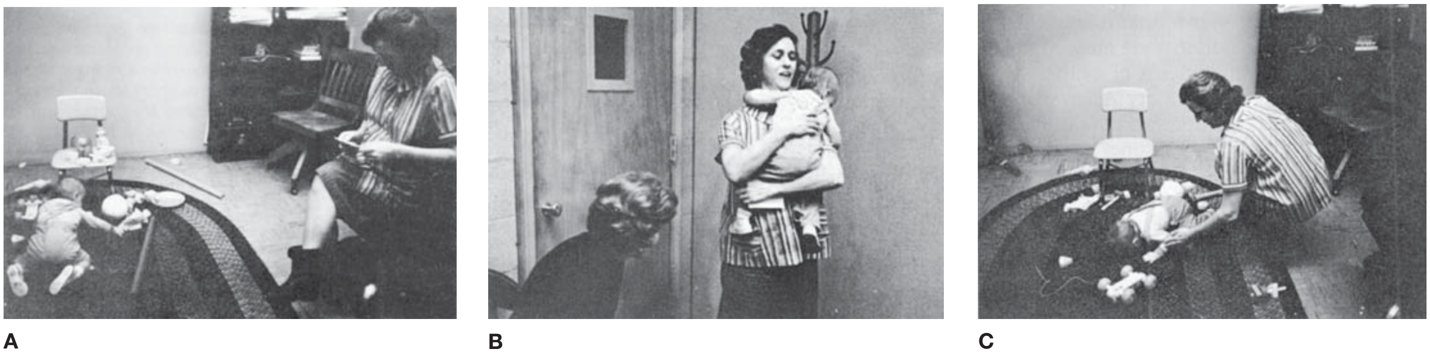

FIGURE 6.13 The Strange Situation. In the Strange Situation, researchers assess the infant's attachment to the mother by watching **(A)** whether the infant plays with toys when the mother is in the room, **(B)** how the infant reacts to a stranger in the room, and **(C)** how the infant reacts when the mother returns to the room after having left it for awhile.

Type A babies are not only avoidant, but they also show less visible anxiety in the absence of the mother.

Type B infants show secure attachments and actively explore novel environments when the mother is present, presumably because they know they can trust and rely on the mother's help if the situation becomes frightening. These babies clearly show distress when the mother leaves and will be quite apprehensive toward strangers when alone with them. When the mother returns after a separation, Type B babies are delighted to see her. They clearly enjoy close physical proximity with the mother and interact with her in positive ways, such as hugging and smiling. These children also tend to be much friendlier to strangers when the mother is present, perhaps greeting a new person with a wave or smile or even approaching the stranger. They appear to be so confident in the mother that while she is present, they don't seem to worry about getting into a difficult social situation. Looking more closely at the Type B group reveals several clear subtypes, ranging from babies who reunite happily with the mother at a distance through smiles and gestures to those who need prolonged, close physical contact to reunite.

Type C infants, who show insecure/resistant, or anxious, attachments, somewhat resemble Type A infants in that both types of infants have insecure attachments. A key difference in these types is that Type C infants are much more likely to show their distress. They are less prone to explore than the other types, even when the mother is present; when the mother leaves, they show great distress, often more than Type B babies. They can initially be more clingy to the mother in unfamiliar situations. Yet, after a separation episode, they may appear angry with the mother, despite maintaining close proximity to her, unlike the Type A (avoidant) babies. Type C infants are uncomfortable around strangers, not only when left alone with them, but even when the mother is present. In short, they seem anxious about whether they can rely on the mother, but rather than dealing with the problem by avoiding her, Type C babies show greater distress than normal when she leaves and continue to indicate their unhappiness even after she returns.

Researchers have disagreed about whether the three types of attachment are the most appropriate categories and whether they are robust outside of middle-class America (Lamb et al., 1984). Later researchers developed a fourth category, Type D infants, who show another form of insecure attachment called **disorganized attachment**. Their behaviors seem far less consistent than those of the other types, and these infants appear to be insecure and unusually controlling with their parents at the same time (Barnett et al., 1999; Cicchetti & Toth, 1995; Main & Solomon, 1990; Solomon & George, 1999). Type D babies usually represent fewer than 10 percent of infants, and they are more likely to come from homes in which they have been maltreated. They are also more likely to show aggressive behavior as preschoolers (Lyons-Ruth et al., 1993). Developmental psychologists have been especially interested in Type D babies because increasing evidence suggests that disorganized attachment in infancy predicts psychopathology in adolescence (Atkinson & Zucker, 1997; Cicchetti & Toth, 2005).

As you will see later in this chapter, there may also be another attachment style that is strongly associated with the severe deprivation that often occurs in institutions. Infants with this **indiscriminate attachment** style can be as affectionate and receptive to complete strangers as they are to their primary caregivers (O'Connor et al., 2000; Tizard & Ross, 1975; Zeanah et al., 2002). In many cases, they will rush up and hug and cling to virtually any adult in the same manner. Researchers have suggested that an indiscriminate attachment style can be quite unrelated to the security of attachment (Zeanah et al., 2005) and is therefore a different dimension on which attachment can vary. Indiscriminate attachment may also be measured in the Strange Situation (Lyons-Ruth et al., 2009), which enables researchers to more easily explore its occurrence in noninstitutionalized populations as well.

Q: What are the four attachment styles associated with Type A, B, C, and D babies?

Causes of Different Attachment Styles

How do different attachment styles arise? To what extent are they influenced by an infant's initial disposition? To what extent are they influenced by the way the parents and other caregivers interact with the infant? Later in this chapter, we will see that severe social deprivation can have dramatic, albeit often not irreversible, impacts on later attachments. Here the central question is whether the differences between less extreme social environments can contribute to subtle differences in attachment style. We will also consider how infants' dispositions might foster certain kinds of social interactions and hence certain kinds of attachments, creating another example of how feedback loops can be so critical to understanding attachment. Researchers have been especially interested in disentangling the causes of insecure attachments because of concerns about how insecure attachment in infancy might affect children's later relationships (see, however, Ein-Dor et al., 2010). For that reason, we will focus primarily on the causes of insecure attachments.

Parent Effects on Insecure Attachment Even without realizing it, parents can sometimes behave in ways that might increase the chances of an insecure attachment.

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

New Insights into the Role of the Father

Until fairly recently, almost all attachment studies focused on mothers and infants, relegating fathers to a marginal or nonexistent role. Although the majority of attachment studies still focus on mother-infant bonds, research on father-infant relations is providing a more comprehensive account of attachment and a better understanding of how maternal and paternal roles often differ.

Historically, fathers have been less involved in child rearing than mothers (Barry & Paxson, 1971; Hewlett & Macfarlan, 2010; Munroe & Munroe, 1992). The question of why this is so has been considered extensively from an evolutionary perspective (Gettler, 2010; Munroe & Munroe, 1992). One evolutionary argument revolves around uncertainty about the paternity of a child—the notion that, unlike mothers, fathers can rarely be 100 percent sure that they are the child's biological parent. This argument suggests that fathers are less invested in child care because there is some doubt about whether their efforts would be promoting the survival of their own genes (Dawkins, 1976). Along these lines, some have suggested that even when fathers do devote time and care to their offspring, they could be doing so to curry favor with the mother and thereby increase the odds of future mating and more offspring (Geary, 2000; Gettler, 2010). Nonetheless, it is critical to remember that human fathers tend to spend far more time taking care of infants than the fathers in virtually any other primate species (Geary, 2000).

Research suggests that the differences in how human fathers and mothers bond with their children are primarily a consequence of dominant cultural practices rather than a result of intrinsic differences between fathers and mothers (Lamb, 2004; Russell & Saebel, 1997). In some cultural contexts, the differences can be very large. For example, while mothers and infants sleep in the same bed across many cultures, father-infant co-sleeping has never been a strong cultural tradition (Ball et al., 2000; Weisner, 2009). Yet, the more dramatic cross-cultural finding is the enormous variation in the level of father involvement with their children (Lamb, 2004). For example, Aka fathers, who are part of a nomadic hunter-gatherer culture in central Africa, stay within an arm's reach of their children roughly 50 percent of the time. In contrast, Kipsigis fathers, who are part of a pastoral culture in Kenya, spend very little direct time with their children until around the child's fifth year (Hewlett, 1991; Hewlett & Macfarlan, 2010). More broadly, fathers tend to be more involved in child rearing in hunter-gatherer cultures than in pastoral-agrarian cultures, although specific cultures deviate from this pattern (Gettler, 2010). This wide variation has led some researchers to argue that it is misleading to focus on differences between mothers and fathers as intrinsic and unchangeable (Lamb, 2004). Culture seems to have an enormous influence on how much time fathers spend with their children and the kinds of activities that they engage in with their children.

Fathering may be associated with certain biological changes in fathers, especially in those who spend more time with their infants and children. When they become fathers, males in many species show a drop in testosterone. Testosterone is thought to foster both mate seeking and competition between males for the best mate, while a reduction of testosterone may facilitate parenting, in that the males with lower testosterone levels may spend less time seeking mates and more time with their offspring (Muller et al., 2009; Wingfield et al., 1990, 2000). Just being a father does not necessarily lead to sustained low levels of testosterone; the kind of fathering matters as well. This was convincingly demonstrated in two groups living next to each other in Tanzania who came from nearly identical biological backgrounds (Muller et al., 2009). One group, the Datoga, was pastoral and mostly made up of herders, whereas the other group, the Hazda, consisted of foragers in the hunter-gatherer tradition. Following the general correlation that we noted earlier, the Hazda fathers were much more involved parents who spent more time than the Datoga fathers in close proximity to their infants. When researchers measured testosterone levels in the fathers' saliva, they found that the Hazda fathers had consistently lower levels of testosterone than did the Datoga fathers. In contrast, men in both groups who were not fathers showed higher testosterone levels and no group difference. Thus, dif-

What causes those behaviors? Early on, Ainsworth and her colleagues proposed that some parents may have difficulty understanding the infant's needs (Ainsworth et al., 1978). More recent research has supported the notion that parents' problems in perceiving and responding to social cues can lead to more insecure attachments (Belsky, 2005; Braungart-Rieker et al., 2001).

One set of studies in this area examined mothers' ability to accurately perceive negative emotional states, not only in their own 4-month-old infants, but also in their ferent cultural roles for fathers can influence hormonal levels, which in turn feed back to support more intense fathering roles. Similar feedback loops also seem to occur with prolactin and oxytocin, two hormones associated with nurturance and trust, both of which have been measured at higher levels in fathers who are more in tune with their infant's social and emotional states (Gordon et al., 2010). It seems very likely that cultural differences will be found here as well.

One difference between mothers and fathers in some Western cultures concerns their role with respect to who is more playful and who is more authoritarian. Studies conducted in Mexico, the United States, and Australia have shown that fathers tend to spend more time playing with their children, while mothers more often act as the disciplinarian (Bronstein, 1999; Lamb, 2010; Parke, 1996; Russell & Russell, 1987). This finding runs counter to some stereotypes about parental roles, but it is important to remember that when the father spends less time with the child, it may be easier for him to ignore the child's transgressions. Fathers also tend to play in more physically active ways with both boys and girls. Finally, while fathers tend to spend more than twice as much of their time with children in play (see Figure 6.14), mothers have to divide their time between play and many other activities in which fathers tend to be less involved, such as feeding, bathing, and dressing.

Often, the differences in mothers' and fathers' relations with the child seem more related to the amount of time each parent spends with the child. Thus, fathers and mothers who are primary caregivers interact with their infants in similar ways, and secondary caregivers of different sexes also show similar interaction patterns (Field, 1978). In the past, most Western infants developed an attachment to the mother earlier than their attachment to the father, but as fathers have become increasingly involved in child rearing, differences as to when attachments are formed are diminishing (Sayer et al., 2004). Moreover, as more fathers become stay-at-home parents, it is likely that a considerably more detailed account of attachment in general will emerge, as well as a better understanding of how maternal and paternal roles may differ.

In contrast to popular stereotypes, when cultural practices and time spent with infants are factored out, mothers and fathers do not appear to be biologically different in their sensitivity to infants. Despite the common belief that mothers are biologically better tuned to be sensitive to their infant's cries or facial expressions, empirical studies have not provided evidence for these differences (Field, 1978; Frodi et al., 1978). Mothers respond physiologically to crying in ways that fathers cannot (such as increased lactation in nursing mothers), but these physiological differences do not necessarily correspond to psychological differences. When men and women behave comparably with their infants, the outcomes appear to be much the same as well. Having parents of either sex who are sensitive and responsive to their infant's needs, desires, thoughts, and feelings is associated with more positive psychological outcomes in the children (Lamb & Lewis, 2010).

FIGURE 6.14 Fathers and attachment. Although traditional studies of parent-child bonds have focused on the mother, a more recent line of work has examined fathers. Some behavioral differences do seem to exist in how mothers and fathers interact with their children, such as fathers being more playful and mothers more authoritarian, but the largest difference is still a much greater amount of time that mothers typically spend interacting with their children compared to fathers.

partners and their own parents before the babies were born. The less accurate a mother-to-be was at perceiving distress-related emotions, the more likely her infant was to show insecure attachments at age 12 months or older (Braungart-Rieker et al., 2001; De Wolff & Van IJzendoorn, 1997). Thus, a mother's ability to understand when another person is truly distressed, without being insensitive or oversensitive, is related to developing an appropriate interactive relationship with her infant. Although the precise mechanisms of the parent's influence may be complex and indirect

(Atkinson et al., 2005), the correlation between parental social perceptions and the quality of the child's later relationships is not surprising—especially in light of the essential reciprocal give-and-take that characterizes even the earliest infant-mother relations.

Q: What is an example of how interaction patterns between parents might predict parent-child attachment relations?

As a second example of parental influence on attachment, high levels of maternal anxiety during the prenatal period can predict insecure attachments. Mothers who showed higher levels of general anxiety during their pregnancy with their first child had a higher incidence of insecurely attached infants at 12 months of age (Del Carmen et al., 1993; O'Connor et al., 2003). Other studies have shown that maternal depression before or during pregnancy is also related to difficulties in parent-child attachment (Atkinson et al., 2005; Bagner et al., 2010; Carter et al., 2001; Field, 2000; Toth et al., 2009).

The fathers' attitude toward the infant and his appropriate role as parent may also affect whether the infant has secure or insecure attachments. Fathers' views of infants and paternal roles, as measured when their infants were 3 months old, partially predicted the qualities of interaction in the Strange Situation at 12 months, as did patterns of interaction with the infant at 3 months. Thus, fathers who described their infants in more positive terms, who saw themselves as important in their infant's development, and who felt that time spent with their infant was an important life priority were more likely to have securely attached infants. Similarly, fathers who were more sensitive to their infant's states at 3 months, who were more animated in play, and who showed more reciprocal play were more likely to have securely attached infants. But fathers who had negative attitudes toward their infants and were not sensitive to their infants' needs when interacting with them at 3 months were more likely to have insecurely attached infants. On the other hand, mothers' attitudes and views of maternal roles did not predict attachment quality, although interaction patterns at 3 months did. Part of the effect may stem from the fact that maternal attitudes tend to be more similar across mothers, but the difference may also suggest that fathers' roles are more influenced by their attitudes (Cox et al., 1992).

In general, parents' social skills and other attributes—measured before their child is born—seem to correlate with the nature of infant-parent attachments. These correlations seem to suggest that parents' attributes can cause different attachment outcomes, but these causal inferences require a great deal of caution. A number of other factors may also explain the correlation, such as parents' and children's shared genotypes for social skills. That is, biological parents and their children may share genes that contribute to difficulties in perceiving or understanding social and emotional information. For example, Asperger's syndrome, an autism spectrum disorder in which individuals have difficulty understanding emotional and mental states of others, co-occurs more often in people who are genetically related (Campbell, 2010). If a parent has Asperger's, a child is more likely to have it as well and may have greater difficulties understanding social nuances in interactions, leading to insecure attachment styles. Similarly, there have been several arguments that genes may substantially affect individual differences in emotional regulation (Hariri & Holmes, 2006; Posner et al., 2010; see Chapter 7). A mother who has trouble regulating her emotions might be more likely to have a child with similar problems (because of the genes they share), and those difficulties might lead both mother and child to overreact to stressful situations, potentially increasing the likelihood of insecure attachment. Direct comparisons between parents and children are challenging, however, because the behavioral and physical manifestations of the same genotype can vary with age and often look quite different in a child and an adult. For example, the phenotype for an Asperger's genotype will look different in a 1-year-old than in an adult.

Q: What are some ways in which father-child and mother-child interaction patterns differ?

Child Effects on Insecure Attachment Children themselves might contribute to the formation of insecure attachments. They may have traits that make them insecure, or they may behave in ways that cause their parents to respond in ways that then influence the child's attachment style, leading to a feedback loop between the behavior of the child and that of the parents. These child effects on attachment are of great interest to parents who wonder if they, as parents, are primarily responsible for their child's attachment style or whether the child is more responsible.

Some researchers have investigated child effects on attachment by examining whether infant temperament plays a role. As discussed more fully in Chapter 7, infant temperament describes how each infant tends to emotionally respond to specific situations; for example, some babies are highly reactive and fussy to loud noises, while others are hardly perturbed. At this point, there is not a clear consensus on precisely how much infant temperament affects attachment style. Among the researchers who suggest that it does not have an influence, some have pointed out that because the same child can show different attachment styles with different caregivers, a child's temperament does not *invariably* cause a particular style of interaction (Sroufe, 1985; Sroufe & Waters, 1982; Sroufe et al., 2010). Moreover, in twin studies comparing monozygotic and dizygotic twins' attachment styles, it has been difficult to consistently demonstrate a higher level of concordance in monozygotic twins, even though temperaments are more similar in monozygotic twins (Bokhorst et al., 2003; O'Connor & Croft, 2001; Roisman & Fraley, 2006, 2008). It can therefore be difficult to find a consistent association between a particular infant temperament and later attachment style.

Other research groups, however, have found some relationship between early behaviors associated with temperament and later attachment styles. For example, newborn infants who react more negatively to the interruption of sucking are more likely to be classified later as Type C babies (Miyake et al., 1985), as are infants who cry longer, more frequently, and more intensely than others (Calkins & Fox, 1992, 2002; Crockenberg & Leerkes, 2003). Some researchers suggest that both infant temperament and parents' behaviors contribute to attachment style but because those components strongly interact with each other, it can be difficult to consistently find simple temperament effects (Mangelsdorf et al., 2000).

Infants may have traits like extreme arousability or irritability or impulsivity that affect their reactions to people and situations (see Figure 6.15). These reactions, which are based on their ability to self-regulate, may in turn affect how their parents react to them. Thus, irritable infants can cause some mothers to be less responsive, which in turn may influence the quality of attachments (Crockenberg, 1981; Gervai, 2009).

For example, consider a "colicky" infant whose distressed crying wakes his parents every few hours, leaving them constantly sleep deprived. The exhausted parents, confronted with an infant who always seems upset, might be less sensitive to changes in the infant's emotional states than the parents of a child who shows distress only rarely, sleeps through the night, and regularly naps during the day. Children with respiratory illness or Down syndrome also more frequently show insecure attachments, presumably reflecting ways in which the baby's illness and communication problems might decrease the parents' ability to be sensitive to the infant's emotional states and needs (Cassibba et al., 2004; Sroufe, 1985).

While infants sometimes do have different attachment styles with different parents, in studies of families with two children and two parents, each child's attachment style typically stays constant across both parents instead of each parent's style staying constant across both children. Thus, in those families, the children's attachment styles are more consistent than those of the parents, suggesting that the children themselves may be shaping the styles they use more than their parents are (Schneider-Rosen & Burke, 1999). Furthermore, any parent of more than one child will attest that even young infants show distinct characteristics that inevitably color the parent's interactions with the baby. As we will see in greater detail in Chapter 7, these individual differences in how babies interact with caregivers may predispose them to different attachment styles.

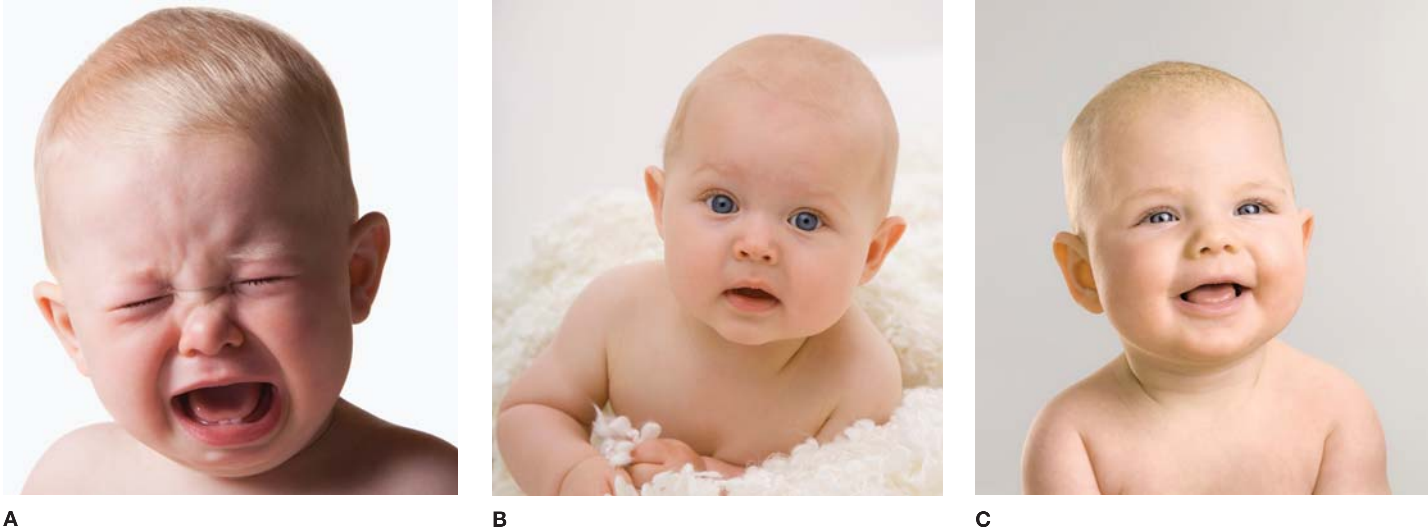

FIGURE 6.15 Child effects on attachment. Some infants seem to be intrinsically less happy and more sensitive to adverse events than others. These differences in temperaments may well lead to different social interaction patterns with parents and caregivers that in turn help create different attachment styles. Parents are likely to react differently to **(A)** an irritated baby, **(B)** a neutral baby, and **(C)** a happy baby.

Interactions of Parent Effects and Child Effects The development of more sophisticated ways of assessing child effects has also helped clarify how interactions between child effects and parent effects shape attachments. Although there is an increasing belief that infant temperament does influence attachment, we must still look for feedback loops, wherein parental behavior affects the child's behavior, which in turn affects parental behavior. Temperamental differences may often interact with particular social dispositions of the child's caregivers (Kagan, 1998). These views are supported by more recent work looking at links between particular gene variants associated with infant temperament and particular kinds of parenting. For example, if caregivers communicate poorly with their infant, that difficulty can increase the infant's risk of showing a disorganized attachment style—but only among infants who have a particular allele of the dopamine-related gene known as *DRD4*. That particular allele of *DRD4* may help create a temperament that is particularly susceptible to the effects of parental communication problems (Gervai et al., 2007). In short, the effects of a certain temperament on attachment style may depend on whether it co-occurs with a particular form of parenting.

Interactional patterns may be greatly amplified by the infant's own beliefs about how caregivers are likely to behave. Bowlby clearly sensed this possibility when he proposed that infants have an **internal working model**—namely, a mental representation of the self and others and how they might interact in different circumstances (Bowlby, 1969, 1979). These models seemed plausible as ways of explaining how infants with different attachment styles might have different expectations about and responses to caregivers. Yet, the models were difficult to verify in their own right until studies directly looked for their presence using techniques that have successfully explored social cognition in infants. As described more completely in the Scientific Methods box, securely attached infants expected other infants to seek comfort from caregivers and for the caregivers to respond accordingly. In contrast, insecure/resistant infants also expected infants to seek comfort but thought that caregivers would not provide it; and insecure/avoidant infants thought not only that infants would avoid seeking comfort but also that caregivers would not provide it if requested (Johnson et al., 2010). The infants' expectations based on these models amplified the role of feedback, as the models might help to strengthen a particular kind of attachment style, which in turn would reinforce a particular class of models.

Q: To what extent do infants' temperament styles influence later attachment styles?

Consequences of Different Attachment Styles

Does an infant's attachment style early in life have long-term consequences? And if it does, how stable are those effects? To address these questions, we turn to behaviors and other psychological variables that correlate with attachment styles in infancy. For example, researchers have studied whether infants' attachment styles affect such broad abilities as negotiating the environment by finding one's way successfully through toys and furniture, reaching for toys, and positioning oneself in a convenient position for interacting with those toys. Securely attached 18-month-olds show more skills in all these abilities than do insecurely attached infants (Cassidy, 1986, 2001). Securely attached infants therefore seem to have a more refined situational awareness and a better ability to orient themselves to those situations, even when they are not social. In the rest of this section, we will concentrate on the effects of attachment styles on later social interactions. As always, we will also ask about possible causal relationships and the presence of possible feedback loops. A final issue concerns the extent to which our later attachments are predetermined by what happens to us as infants—in particular, whether there is a sensitive period in infancy that results in infant attachment styles that exert effects on later attachments (Sroufe, 1978).

Correlations between Infant Attachment Styles and Children's Social Interactions In the past two decades, many studies have asked how different attachment styles influence an infant's ability to negotiate the social world. In general, secure attachments of Type B infants seem to lead to more successful social abilities. In contrast to insecurely attached infants, securely attached infants engaged in more reciprocal interactions in peer play, had more positive emotions, and were less withdrawn. Securely attached infants had smoother interactions with strangers when they were 3 years old, and they were rated more highly by teachers for competence in peer play (Lieberman, 1977; Lutkenhaus et al., 1985; Waters et al., 1979). Similarly, toddlers who were securely attached as infants were judged to be more sociable with peers and more attentive and interested in their playmates (Pastor, 1981). Many other studies also suggest relations between infant attachment styles and later social skills in toddlerhood and preschool years (Granot & Mayseless, 2001). For example, infant attachment styles seem to predict a 3-year-old's attractiveness as a potential playmate with peers. Children who were securely attached as infants were seen as more attractive to interact with than those who had been anxiously attached, suggesting that lower interaction skills may be partly caused by

SCIENTIFIC METHOD: Internal Working Models and Attachment Styles

Hypothesis:

Infants with different attachment styles have different mental representations about how infants and caregivers will interact in situations involving seeking and providing comfort.

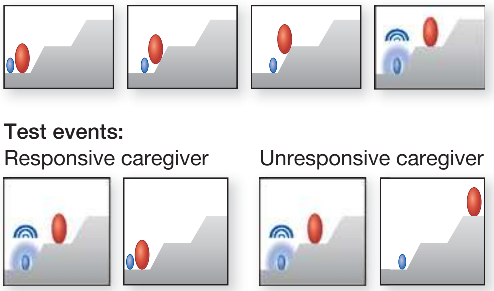
Method:

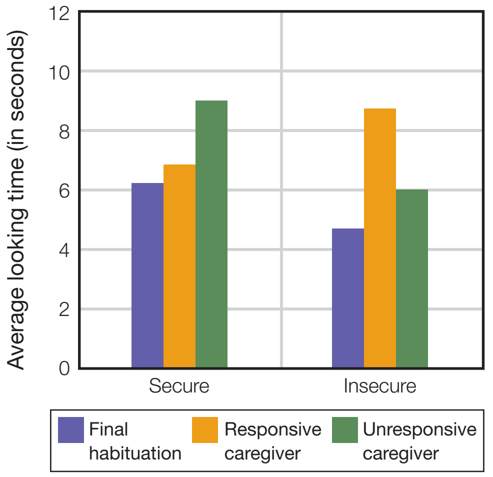
1. Thirty-three 13-month-old infants watched animations in which a “baby” encountered difficulties and a “mother” responded.
2. Infants were habituated to a “separation” video in which the “mother” left the “baby” and the “baby” pulsed slightly and emitted human infant crying sounds (as indicated by the sound waves).
3. Infants then observed two test events in which the “mother” either responded by moving next to the “baby” or responded by moving farther away.
4. Researchers recorded infants’ looking times and related these to infants’ classifications in the Strange Situation.

Habituation event: Separation

Test events:

Responsive caregiver Unresponsive caregiver





Results:

Secure infants looked longer when the “mother” moved away from the distressed “baby,” while insecure infants looked longer when the “mother” moved closer.

Conclusion:

Infants’ cognitive models of how caregivers and infants interact vary with their attachment styles, suggesting that the models may further entrench those styles, which in turn reinforce those models. Other studies in this set show that infants also have different models of how babies will respond to caregivers, further supporting the idea of a feedback loop.

Source study: Johnson et al. (2010).

others’ perception that children with insecure attachment styles in infancy are less desirable (Jacobson & Wille, 1986).

Despite all the evidence of an association between infants’ attachment styles and their abilities and social tendencies as children, these studies do not unequivocally show that attachment style differences in infancy directly cause those later abilities and social tendencies. There are two alternative ways of interpreting this evidence. First, some infants’ temperamental features may elicit ineffective patterns of social interaction from others. These features might hamper the typical back-and-forth rhythms that help build ways for two individuals to come into better emotional and social synchrony. In infancy, these problems might lead to insecure attachments, and later they might cause more strained interactions with peers and other social difficulties. In this view, children’s social difficulties are not caused by insecure attachment in infancy; instead, insecure attachment and later problems with socializing might share a common cause, arising out of infant temperament.

A second interpretation for the link between infants’ attachment styles and the nature of their childhood relationships suggests that certain environmental conditions can foster insecure attachments and also affect later social patterns. For example, if a family is under extreme stress—say, from marital discord or poverty—the constant pressure could lead to insecure attachments that could last for several years. The effects could work through both children and parents. Stressed parents might be less able to fully engage with their infants and less sensitive to their needs, leading infants to see the parents as less reliable sources of comfort and safety. Infants in stressful environments might be poorly nourished or sleep deprived and less adept at communicating their states to their caregivers, which could lead to both less responsiveness from the caregivers and insecure attachment in infants and older children.

One study examined attachment patterns in families in East and West Germany shortly after the fall of the Berlin Wall. This was a stressful time: as the country was being reunited, many families were experiencing radical changes in their workplaces, homes, and networks of support. These social and political changes led to insecure attachments when parents had trouble adjusting to the changes (Ahnert & Lamb, 2001). In such cases, insecure attachment styles in infancy might be correlated with later social problems because both factors might result from the same environmental stressors. Similar effects may occur when one parent in a military family is deployed abroad. If the parent who stays with the children does not have adequate social support to handle the stress of the transition, the children may be at increased risk for insecure attachments (Posada et al., 2010).

It is also likely that these two explanations—one focused on the child's temperament and the other on the environment—interact to affect childhood patterns of social interaction. An infant with a difficult temperament can more easily trigger adverse behavior in most caregivers, which then exacerbates the infant's difficult behavior, and so on, in a downward-spiraling feedback loop. As these alternatives show, there is still much to learn about the development of insecure attachments and their effects later in childhood (Sroufe, 2002).

Long-Term Links between Infant Attachment Styles and Adult Relationship Styles Researchers have also explored whether adult relationship styles are related to infant attachment styles. While the connection is a complex one, some links between childhood attachment style and later relationship style as adults have been revealed with the help of sophisticated analytical models and methods (Cassidy, 2000; Fraley, 2002; Fraley & Roberts, 2005; Fraley & Shaver, 2000; Roisman, 2009). For example, one study revealed that styles of interaction between parents and their 13-year-olds were related to those children's styles of romantic relationships 8 years later, at age 21 (Roisman et al., 2001). Looking at infant attachment styles more directly, one longitudinal study has shown that the interactional style between a mother and her 18-month-old child does predict some aspects of the child's later relationship style with peers and partners (Zayas et al., 2011). In that study, researchers measured the mother's behavior toward the infant, rather than the infant's behavior in the Strange Situation, and found that the children whose mothers provided them with more sensitive care in infancy were less controlling at age 22. They also had less anxiety about partners rejecting or abandoning them and were less concerned about relying on those partners. Nonetheless, shared genotypes and environmental influences likely contribute to these links between infant attachment style and adult relationship style. For example, infants whose mothers are more sensitive caregivers might share with their mothers a genetic predisposition for interpersonal sensitivity that makes them less likely to be controlling as adults.

Although unusual interactional styles in infancy can predict social problems in middle childhood, adolescence, and even adulthood (Brumariu & Kerns, 2010; Collins & Sroufe, 1999; Sroufe et al., 1999), these links may not result specifically from events in infancy. Instead, they may grow out of a consistent and sustained pattern of problematic interactions that started in infancy and continued throughout much of childhood. Had the difficulties stopped after infancy, the long-term effects might have disappeared. Thus, problems in infancy do not necessarily cause problems in adulthood. Indeed, when struggling families manage to leave acute poverty after the infant's first year, and when infants start to have much more rewarding interactions, they usually do not suffer negative long-term consequences. Unfortunately, effects can work in the other direction as well. Those families that enter poverty and its attendant chaos often show a rise of insecure attachments (Weinfield et al., 2000). It is thus quite difficult to support the notion that irrevocable patterns of relating to others are established during a specific sensitive period. In short, even if infants show some problematic social behaviors, these interactional patterns can be modified to produce more fruitful and productive interpersonal behaviors and relationships.

Q: What are two possible explanations for the correlations between infant attachment styles and later social behavioral patterns?

Cross-Cultural Differences in Attachment Styles

Although Ainsworth conducted several studies of individual differences in attachment styles in Uganda (Ainsworth, 1967), most research on attachment styles has been conducted in Western countries, particularly on middle-class Americans. In this chapter, we have occasionally looked at effects in other countries and in other social classes, but it is important to more directly consider how attachment styles and patterns of child care can vary across cultures. This approach will enable us both to better understand what the common research techniques, such as the Strange Situation, are measuring and to understand the individual differences themselves. One strategy that can help shed light on the meaning of differences in attachment is to see whether they manifest similarly in different cultures.

Perhaps surprisingly, the relative incidence of different attachment styles, as measured using Ainsworth's Strange Situation, varies dramatically across cultures (Thompson, 1998; Van IJzendoorn & Kroonenberg, 1988). Consider, for example, the substantial cultural differences shown in Table 6.2. The majority of German infants studied were measured as insecurely attached (mostly avoidant, or Type A). Japanese infants showed no **avoidant attachments** whatsoever, and they were almost three times as likely as their American counterparts to show anxious (Type C) attachments. Finally, one group of Israeli children showed almost 10 times as many anxious attachments as Swedish children. Because the procedure used in the Strange Situation is relatively straightforward, it does not seem that these variations can be explained by simple methodological discrepancies in how the assessments were conducted (Harwood et al., 1995; Thompson, 1998; Van IJzendoorn & Kroonenberg, 1988). At the same time, it makes little sense to conclude that entire cultures are rearing most of their children in socially maladaptive ways.

Perhaps there are subtle ways in which the Strange Situation is inadequate as a measure of differences in attachment style across cultures. One possibility is that differences in child rearing across cultures influence the degree of "strangeness" that children experience in the Strange Situation. Consider, for example, that in most Japanese households, early separation of the mother from the child is strongly discouraged. Japanese infants are usually in close proximity to their mothers for longer periods of time than infants in other cultures. Similarly, some Israeli infants who live in a kibbutz community experience repeated contacts with familiar adults in the kibbutz and may hardly ever see strangers. Despite the differences in these experiences, both groups might be expected to show an increase in Type C responses in the Strange Situation because both Japanese and Israeli infants would develop expectations that caregivers would always be immediately available and responsive and therefore would show increased distress and anxiety when left alone with a stranger. On the other hand, in some parts of Germany, child rearing often emphasizes early independence from adults. If these children are more accustomed to separations and more frequently exposed to strangers, those experiences could easily lead to a greater incidence of Type A responses.

	Type A (Avoidant)	Type B (Secure)	Type C (Anxious)
Sweden	22	75	4
Israel	8	57	34
Great Britain	22	75	3
Japan	0	68	32
Germany	49	33	12
Netherlands	34	6	0
United States	22	66	12

TABLE 6.2 Attachment style across cultures. The percentages of infants with particular attachment styles, as measured by the Strange Situation, vary dramatically across different cultures. Those differences, however, may be less a reflection of differences in underlying attachments and more a reflection of differences in the perceived "strangeness" of different situations. (Percentages do not sum to 100 because some infants' styles could not be reliably coded, and some infants were coded as Type D.) Adapted from Thompson (1998).

The problem, then, is that the Strange Situation conveys very different levels of anxiety, depending on a culture's child-rearing practices. Ideally, a more consistent measure would involve exposing children from different cultures to equivalent levels of subjective "strangeness" and then looking for differences in attachment style. Although no perfect technique along these lines has yet been developed, other evidence suggests that cultural differences in attachment style have been exaggerated. In fact, the differences appear much smaller when the full Strange Situation method is not used. For example, one analysis focused on the infant's initial reaction to the Strange Situation before separation from and reunion with the mother occurred (Sagi et al., 1991). The researchers hypothesized that the ways that infants first size up a novel situation might be less vulnerable to cultural differences than their responses to separations. The initial reactions were thought to reveal, among other things, the infant's level of trust in the mother in a way that might be robustly measured across cultures. When such an analysis was undertaken, cultural differences did indeed become greatly reduced and often became nonexistent (Sagi et al., 1991). In particular, when infants were coded in terms of initial reactions only, it was still possible to code them into clear attachment style categories; then when cross-cultural comparisons were made between infants from Germany, Holland, Israel, Japan, Sweden, and the United States, most of the typical differences across cultures disappeared, with only infants from Sweden and Israel having somewhat different frequencies of classifications from the other groups. Of course, even the initial reactions might not be perfect measures, as they, too, could be influenced by prior cultural experiences and how unfamiliar those experiences made the initial situation seem.

Cross-cultural comparisons using different methods for studying attachment therefore illustrate the problems that can arise in applying an assessment technique to different

DEVELOPMENT AND SOCIAL POLICY

Day Care and Attachment

In many societies, the percentage of two-parent households in which both parents work outside the home increased greatly in the last few decades of the twentieth century. In 1975, 39 percent of American mothers with children under 6 years of age worked outside the home. That percentage increased continuously up to 59 percent in 1998, and in 2006 it was roughly 65 percent (Coontz, 2010; Cotter et al., 2008). These changes are coupled with other changes in Western families, especially because grandparents and other relatives are less likely to live nearby and so are not available to take care of the children when the parents go to work. In this context, day care can be viewed as either a liberating source of social support or a necessary compromise for dealing with economic necessity. Sometimes these views can coexist in the mind of a parent who is concerned about the impact of day care on his or her children.

It is important to understand that the range of day care settings and programs is enormous. Day care providers differ in their philosophies, caregiver-to-child ratios, training methods for staff, rates of staff turnover, and physical facilities. Given this wide variety of forms of day care and given the general trend toward increasing use of some form of day care in many cultures, the most pressing social policy questions revolve around what kinds of day care are associated with the most positive outcomes for children (see Figure 6.16).

FIGURE 6.16 Effects of day care. Many studies have examined the effects of day care on attachment style. The most investigated factors for links to attachment style are (1) the quality of the care itself, which can vary enormously across different day care settings, and (2) the amount of time spent in day care.

Some researchers argue that spending a lot of time in day care, usually defined as being cared for by individuals other than the parents for 20 or more hours a week, poses some risks for children even when the care is high quality. The most consistently negative research assessments of the effects of long hours in day care initially came from the Pennsylvania Infant and Family Development Project (Belsky, 1986, 2001, 2005; Belsky & Rovine, 1987, 1988). In that project, researchers measured Strange Situation responses in 1-year-olds who spent large amounts of time in day care during their first year of life and found that 43 percent of the infants were classified as insecurely attached to their mothers, as opposed to 28 percent of infants who experienced little or no early day care. Other studies in the 1980s reported similar effects (Barglow et al., 1987; Gamble & Zigler, 1986).

These early studies treated day care as the same across all of the studies and did not take into account other factors, such as the quality of the day care (for example, the ratio of infants to caregivers and caregiver training) and the differences in the children (temperament and gender) and in their families (for example, sensitivity and responsiveness of the parents to the child and stressors experienced by working parents). Some researchers expressed concern that these other factors may have also played a role in attachments between mothers and their infants who were in day care (Clarke-Stewart, 1989). Moreover, using the Strange Situation in these kinds of studies may have introduced problems similar to the ones introduced in the cross-cultural studies. Children who have spent much of their infancy in a day care center with strangers coming and going might have quite different adaptations to what is “strange” than infants who spent more time close to a parent. Extensive day care can thus be thought of as a kind of “culture” quite different from extensive home care, so it is important to be cautious in interpreting these differences in Strange Situation classifications, especially in light of later studies.

In the early 1990s, a massive U.S. study was launched to look more systematically at how both the quality and amount of nonmaternal child care related to many aspects of development. That study, known as the NICHD Study of Early Child Care and Youth Development, started with over 1,300 infants and continued to study over 1,000 of those children well into adolescence (NICHD, 2005). Although the results are complex and nuanced, several general patterns have been found consistently and replicated in other countries.

The researchers looked at the possible effects of both quality and amount of nonmaternal care in three areas: children's attachment style, their broader social functioning, and their cognitive and language development. They also asked if the effects varied depending on children's backgrounds. For example, would more at-risk children be more influenced by quality of care?

In this study, it was difficult to systematically link differences in children's attachment style to either the amount of time spent in day care or quality of care. Although low-quality care seemed potentially associated with insecure attachments at 15 months, the same link was not found at 36 months (NICHD, 2001). Moreover, while children who were in day care at an early age showed an initial advantage in self-confidence and social skills, these positive effects were relatively modest and tended to disappear with increasing age (Lamb, 1998; NICHD, 1998, 2001, 2003). With respect to broader social functioning, the amount of time a child spends in day care is associated with more aggression, more disobedience, and more challenges of adults in a child's early school years, but it is not related to higher incidences of psychopathology. This finding makes sense, given that children who spend much of their time with peers and away from their parents might well be less intimidated by adult authorities. Even into the teenage years, 15-year-olds who had been in more extensive day care as infants showed somewhat higher levels of risk taking and impulsivity (Vandell et al., 2010).

Nonetheless, these associations, while statistically significant, are not massive. More specifically, the correlations between amount of time spent in day care and variables like impulsivity levels or risk-taking tendencies are roughly at the 0.1 level. This means that the vast amount of variation across children is due to factors other than the amount of time they spent in day care. While any statistically significant correlations are of interest, it is important to keep their small size in mind (McCartney et al., 2010).

The effects of day care quality might seem to be easier to demonstrate, but they, too, can be hard to document consistently, especially with respect to attachment security and social behaviors. Better quality of care is, however, associated with higher levels of cognitive and linguistic development among children and even among adolescents (NICHD, 2001; Vandell et al., 2010). The higher the quality of care, the higher the children's scores on assessments of cognition and language. Moreover, children who spend more time in high-quality day care tend to score higher on cognitive and linguistic measures than do children who spend less time in such care.

Poor-quality day care has, unsurprisingly, been associated with more negative outcomes—but these relationships are not always easy to interpret. Some studies have found that kindergartners who had been in poor-quality day care showed more behavioral and social difficulties than those who had been cared for at home, whereas those who had been in high-quality day care showed no more difficulties than those cared for at home (Howes, 1990: Loeb et al., 2007). When children experienced poor-quality day care only after infancy, it still predicted later adjustment problems. It is also important to keep in mind that parents who seem least sensitive to their children's needs are also more likely to be less attentive to differences in day care quality. Some studies, such as the NICHD study, have tried to control for parent and child effects statistically, but there is still a strong possibility that these factors, as well as shared genotypes and shared environments, continue to influence the associations between day care quality and later outcomes. Without experimental studies that randomly assign children to different levels of quality care—which would obviously be unethical—it is difficult to tell.

As noted earlier, the amount of time that mothers spend at work does not predict attachment relations with their infants (Huston & Rosenkrantz Aronson, 2005). But the amount of *available* time a mother spends with her infant does predict the quality of the attachment relationship. Thus, when mothers have the time, whether they work or not, the extent to which they choose to use that time to interact in a high-quality manner with their child is related to the quality of the attachment. Even then, however, the causation appears to be that sensitive mothers who relate to their children well want to spend more time with them, not that the time spent itself causes the relationship to be better and makes the mother more sensitive.

A final question concerns whether the amount and quality of day care show different developmental associations for children from disadvantaged backgrounds. It now appears that these children benefit more than other children from high-quality care and large amounts of it and that they suffer more from lower-quality care (Anderson et al., 2003; Caughy et al., 1994; Dearing et al., 2009; Geoffroy et al., 2010). For these children, high-quality day care is most often related to higher levels of cognitive and linguistic skills rather than social skills.

Overall, high-quality child care is rarely associated with detectable long-term problems and is often associated with positive outcomes. These positive associations are especially strong for cognitive and linguistic development among children from disadvantaged backgrounds. The social policy implication seems clear. Poor families often have fewer options for child care, putting their children at higher risk for ending up in low-quality care. These patterns suggest that it is especially important to focus resources on making high-quality care available to the most disadvantaged children.

groups without considering whether they all interpret the technique in the same way. Failure to consider such culture-specific differences may lead to the belief that cultures show large differences in the incidence of different attachment styles, whereas a more culturally sensitive analysis might reveal deeper commonalities that suggest quite consistent ratios of the different styles across cultures. We should not underestimate the influences of culture on many aspects of a child's behavior, but in making cross-cultural comparisons, we cannot assume that a particular measure means the same thing to all participants.

The cross-cultural comparisons also highlight some of the limitations of the Strange Situation. Over its long history, it has produced many useful insights, but we must interpret it carefully, mindful of the setting. In addition to the problem of controlling for subjective impressions of strangeness, the measure tends to categorize children into one of three or four types, whereas many believe that differences in styles should be thought of as varying along a continuous dimension (Lamb et al., 1984). Researchers have developed other measures that try to avoid some of the limitations of the Strange Situation (Cassidy & Marvin, 1992; Thompson, 1998), but even these newer measures can be challenging to apply and interpret across all cultures. Variations in attachment styles certainly continue to be a topic of great interest; the challenge for future research in this area is to develop new ways of assessing attachment styles that are robust across all cultures and settings.

Q: What are some cautions to keep in mind when using the Strange Situation to study attachment styles across cultures?

Effects of Early Social Deprivation

As we have seen, different species form and maintain attachments in similar ways, though many of the specific attachment behaviors differ. In this section, we will explore what happens when human infants and other primate infants are prevented from forming normal attachments. Although laboratory experiments on humans would be unethical, experimental studies on other primates have enabled researchers to compare the effects of social deprivation on those primates with human children's developmental outcomes in several tragic real-world settings. We will consider which aspects of social contact are most important for developing normal attachments and whether the effects of early social deprivation can be reversed.

Social Deprivation in Humans

When children are deprived of the opportunity to form attachments, the effects can be devastating. These effects have been discussed for many years (Bakwin, 1942; Durfee & Wolf, 1933; Lowrey, 1940; Provence & Lipton, 1962). René Spitz's research on infants in Latin America in the 1940s has been especially influential (Spitz, 1945, 1946). Spitz compared two groups of infants. One group lived in a foundling home that had roughly one nurse for every eight infants. The infants rarely had the same caregiver for very long, both because of rapid staff turnover and because the nurses frequently rotated assignments. The babies could not see one another or the bustle of activities in the ward because bed sheets were hung on the railings all around the cribs to reduce drafts. Instead, each infant saw a largely featureless, white world during most waking hours. As Spitz put it, "The result of this system is that each baby lies in solitary confinement up to the time when he is able to stand up in his bed" (Spitz, 1945, p. 63).

The infants in the second group that Spitz studied were raised in a nursery because their mothers had been imprisoned. These infants were able to see out of their cribs and interact freely with other infants and caregivers. The nursery had a better caregiver-infant ratio, and there was less staff turnover than in the foundling home. In addition, the imprisoned mothers were allowed to interact with their babies for roughly 20 hours each week. The infants in the prison nursery also had toys and more opportunities to crawl about, but the nursery environment was not kept especially clean and there was not careful medical supervision. In short, foundling babies lived in an environment that was sterile in every sense of the word (antiseptically clean and devoid of any meaningful social activities and objects; see Figure 6.17), whereas the babies in the prison nursery lived in a less clean but more stimulating environment.

Deficits in Socially Deprived Infants In the first few months of life, neither the foundling home nor the prison nursery environment seemed to make much of a difference for the infants. After 4 months, however, dramatic differences emerged: the prison nursery babies showed relatively normal reactions, while the foundling home babies showed massive deficits. Four classes of adverse effects were most frequently observed in the foundling babies:

1. The infants became progressively less likely to move about. Locomotion of all forms, including exploratory crawling, diminished, and the infants tended to sit or lie in one place for hours.

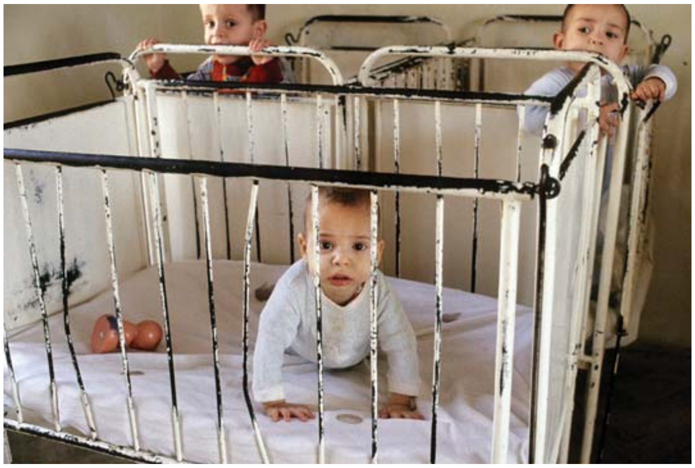


FIGURE 6.17 Social deprivation. Infants and children who grow up in orphanages with severe social neglect (as in this Romanian orphanage) often suffer devastating psychological and biological consequences.

2. The infants developed bizarre reactions to strangers and unfamiliar things, exhibiting terrified faces and gestures, screams, and wild rages directed at the unknown person or thing. The infants were extraordinarily unstable and hyperfearful. Sometimes, if a stranger remained present, the infants would suddenly frantically cling to the person.
3. The infants showed unusual, repetitive motor patterns, including incessantly rocking back and forth, biting or gnawing at parts of their own body, and banging their head against the crib**.** These sorts of behaviors are usually attributed to a need for stimulation, even at the cost of self-mutilation. Apparently, some situations can create such a need for stimulation that the obvious pain is not a deterrent.
4. Many of the deprived infants had disconcertingly vacant, expressionless faces. They had a faraway look in their eyes, seemed to look right through most people who approached, and seemed unaware of what was going on in their immediate environment.

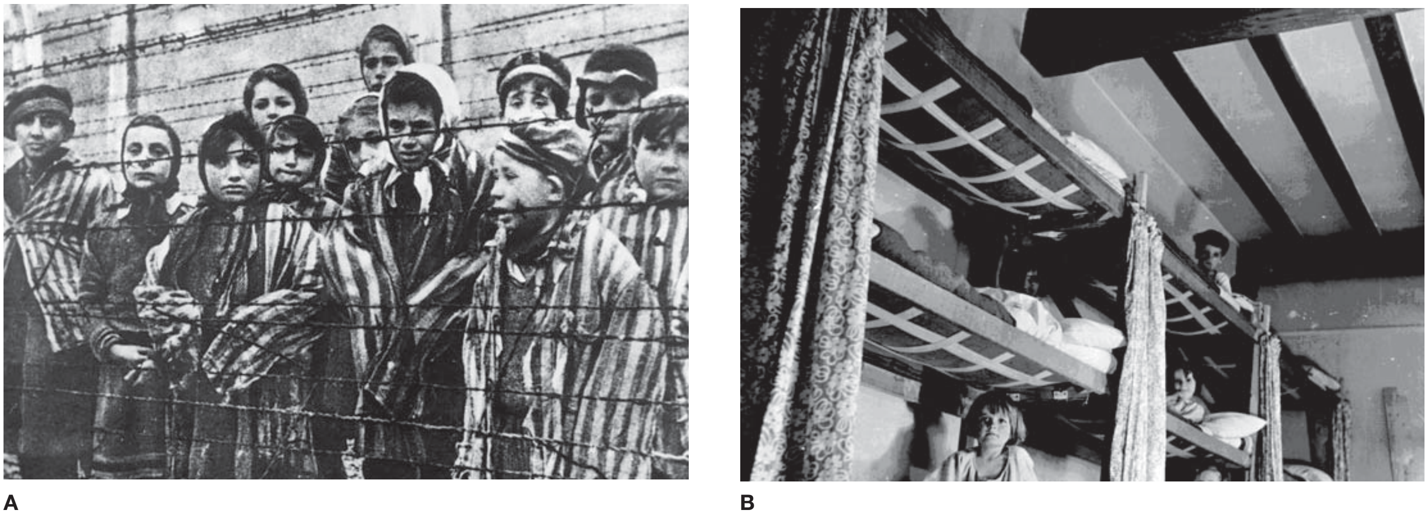
The most disturbing difference between the groups, however, was the mortality rate. Over 37 percent of the infants in the foundling home had died by the end of 2 years. By contrast, not a single child out of the 122 who were in the prison nursery died, even though the foundling home had better sanitary conditions and more frequent professional medical visits (Spitz, 1945, 1946). Thus, the foundling babies, whose physical needs of nutrition, physical warmth, and shelter were all met, had a significant chance of dying, whereas children in the dirtier, less physically healthy prison environment showed lower mortality rates. The foundling babies died of a variety of causes, including a measles epidemic, but Spitz argued that since the prison nursery children were exposed to a similar range and frequency of diseases, the foundling babies' social deprivation must have somehow made them more susceptible to the illnesses. (This hypothesis anticipated the finding that intense stress can reduce the immune system's response, making stressed individuals more susceptible to a variety of afflictions; Cohen et al., 2007; Gunnar & Vazquez, 2006; Maes, 1997; Schleifer et al., 1999.) The cliché that "man does not live by bread alone" never had a more vivid and depressing demonstration.

In another study, institutionalized infants' showed delays in motor behavior and language, as well as failure to interact with their peers or to seek out adults when in distress. Those who were still institutionalized at 10 to 13 months also showed impairments in deferring gratification, generalizing, and problem solving (Provence & Lipton, 1962). In short, deprivation is devastating, and its effects seem to be linked to deficient exposure to other individuals (see also Goldfarb, 1943, 1945, for other early studies on the devastating effects of early social deprivation). Nonetheless, more detailed studies were needed to pin down the specific causes. Further studies in humans, as well as companion studies with primates, have greatly helped narrow down the possibilities.

Q: What are some of the effects of long-term social deprivation in human infancy?

Untangling Causation After the Second World War, Freud's daughter, Anna, a major figure in psychoanalytic theory in her own right, and her colleague, Sophie Dann, published a paper about a group of six children whose parents had been killed in concentration camps during the war (Freud & Dann, 1951). The six children had each arrived separately at a concentration camp in Terezin, Czechoslovakia, when they were between the ages of 6 months and 1 year. It was unclear how much of an opportunity they had had to form specific attachments with their parents before arriving at Terezin, given the chaos in their families' lives shortly before they were sent to the concentration camps. The children remained at Terezin for almost 3 years and were cared for by various fellow prisoners, but they never had an opportunity to become attached to any of the adults, as the adults were constantly being relocated or killed or dying of disease and starvation at Terezin. The children survived through the efforts of many adults, and upon liberation in the summer of 1945, they were taken to England. There they remained in the care of Freud and her colleagues for approximately 1 year before being placed in foster homes (see Figure 6.18).

Despite the horrors of the camp and the lack of attachments to any adult figures, the children did form close bonds to each other. In fact, they were extraordinarily close



A
B

FIGURE 6.18 The mediating factor of close peer bonds. Anna Freud and Sophie Dann's studies of six children who had grown up in a concentration camp revealed that bonds formed among the children were able to mitigate many of the deleterious effects of being deprived of a constant set of caregivers. **(A)** Children behind barbed wire at a concentration camp in Auschwitz. **(B)** Children who had been separated from their parents during the war and brought to England to live in war evacuation residences, as were the six children in the Freud and Dann study.

and showed great distress when one of the six was absent. They also were quite wary of adults and took a long time to trust adults and show any attachments to people outside their group. Even with all their hardships, however, these six children seemed considerably better off than children who underwent more complete social deprivation. They were less withdrawn, did not show self-mutilation, and had relatively normal social relations among themselves except for being extremely "clingy" with each other. Apparently, the opportunity to interact and bond with peers was enough to protect these children from the intense emotional problems observed in more fully deprived infants. This study suggested that infants' need for nourishment might not be the most important factor motivating their attachments. It also showed that the role of nurturant older individuals in early social development is not as absolutely critical as most parents might think.

Later studies on deprivation have led researchers to suggest that in the first few months of life, interacting with any responsive social beings may be enough to put infants on a normal trajectory for attachment. Only later, after about 6 months, does the infant seem to need to form specific attachments to individuals. Thus, children isolated from their parents early on show few or no deficits as long as other responsive caregivers fill in during the first few months of life (Schaffer & Callender, 1959; Schaffer & Emerson, 1964). At that age, interacting with a variety of people is as beneficial for the infant as the same level of interaction with one person. Even if very young infants are able to recognize individuals and develop specific interaction patterns with them, they may not need such interactions with the same individuals at an early age. Instead, they simply need opportunities for social give-and-take with willing partners. Although infants can attend to the special distinctive properties of some social stimuli very early on, it seems to take time and practice to learn the nuances of those stimuli that form the foundation for specific, focused attachments.

Unfortunately, children still suffer from social deprivation throughout the world, and its effects remain as devastating as they were in Spitz's time. In Romania, a large number of children were abandoned to state-run orphanages during a period when Nicolae Ceausescu headed the country. When he fell from power in 1990, foreign researchers started to visit the orphanages and found horrendous conditions. There were often more than 10 children for each caregiver, making meaningful interactions impossible. Children who were younger than 2 were left lying in their cribs without stimulation for up to 20 hours each day. In recent years, one group of Romanian infants has been studied extensively—not to document deprivation effects, but to understand how the children responded when they were removed from their harsh environment and adopted into loving families.

This group of severely deprived children showed the same tendencies toward vacant expressions and rocking back and forth that were seen in the deprived children in earlier studies. As American and Canadian families began adopting these children, researchers started to ask about the developmental outcomes and adjustment of the children who had been adopted. One relevant study followed three groups of infants in British Columbia (Mainemer et al., 1998). One group had been in Romanian orphanages for at least 8 months before adoption. A second group had been adopted from Romanian orphanages at an earlier age, in the first 4 months of life. A third group, which served as a control group, consisted of Canadian-born, nonadopted children who were matched with the first group in terms of age and sex.

The researchers examined many aspects of the adopted children's development and their adjustment to their new circumstances and found complex patterns of effects. But one clear finding stood out. In most cases, the longer the children had spent in Romanian orphanages, the worse their outcomes. Even after 4 or more years in an adoptive family, they were more likely to have difficulties forming normal social relationships with their parents and others. Nonetheless, some of the children who had been in Romanian orphanages for more than a year seemed to recover fully after a few years in adoptive homes. It is less clear, however, whether these more fortunate outcomes were due to temperamental differences that made the children especially resilient or to especially effective patterns of child rearing in these adoptive homes or to both.

These studies also suggested that social deprivation can cause a general disengagement from the world that may also impede cognitive development. The Romanian children who had spent at least 8 months of infancy in orphanages had considerably lower intelligence test scores than Romanian children who had been adopted before they were 4 months of age. In one study, Romanian children who grew up in Romania with their parents had cognitive development scores averaging around 103 (on a scale where the mean is 100), while children who were in the orphanages for extended periods had scores averaging around 66 (Smyke et al., 2007; see Figure 6.19). The effects likely arose not only from less interaction of the children with their environment, but also from the lack of engaged adult caregivers to teach them and to support their ability to learn. But the cognitive differences may also have been related to differences in the kinds of children who grew up in families as opposed to those who were put in orphanages, as some of the institutionalized children may have had preexisting cognitive deficits. Nonetheless, the magnitude of the difference and its persistence across studies leaves little doubt that social deprivation has serious effects, not only on social skills, but on a range of cognitive skills as well (Kaler & Freeman, 1994).

Subsequent studies on the same children suggested that even at age 17, some children who had been in orphanages more than 8 months still showed residual cognitive effects, often taking the form of inattention and hyperactivity (Audet & Le Mare, 2011). Other groups of Romanian orphans adopted into British homes had similar arrays of problems related to the amount of time they had spent in institutions. They sometimes showed "disinhibited" attachments, meaning that they did not modulate their emotions well in social interactions, sometimes being overly friendly with strangers, other times being inappropriately unfriendly (Rutter et al., 2007). Disinhibited attachments appear to be closely related to indiscriminate attachments, mentioned earlier in the chapter, in which children are overly friendly with all adults.

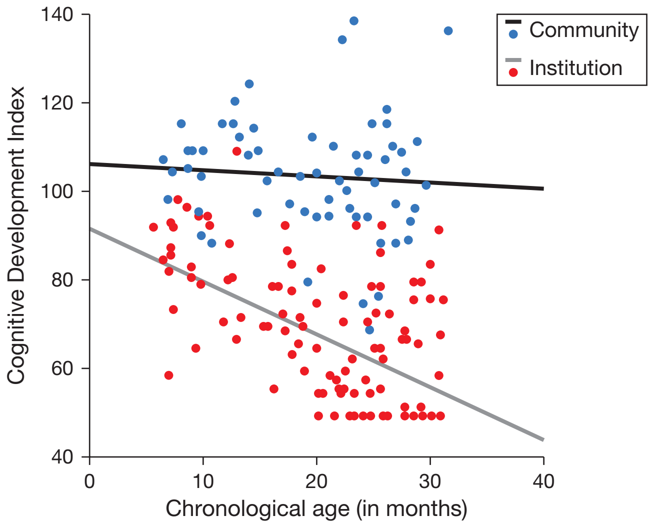


FIGURE 6.19 Cognitive development and social deprivation. Children who grew up in Romanian orphanages under conditions of severe social deprivation (labeled "Institution") showed markedly lower scores on tests of cognitive development than did children who grew up with their families in a nearby community (labeled "Community"). Thus, above and beyond the dramatic effects of social deprivation on social development and attachment, there is a strong effect on cognitive development as well. The lines roughly indicate the nature of the correlation between age and cognitive development, with no relationship for the community children and a strong negative one for the children raised in the institution.

These effects have been replicated in other settings throughout the world. For example, in one large-scale study of 342 children who had been in institutions in Russia, children as old as 18 continued to show cognitive and social problems (Merz & McCall, 2010; St. Petersburg–USA Orphanage Research Team, 2008). A particularly striking feature about the Russian study was that the facility was unusually clean, and the staff made an effort to meet the children's physical needs in terms of food, clothing, and shelter. Social deprivation alone in an otherwise very positive environment was nonetheless associated with much worse developmental outcomes, especially among children who were in the institutions the longest.

Q: What factors are most relevant to the effects of social deprivation on attachment?

Failure to form normal attachments can also have measurable biological consequences. One way of assessing stress is by measuring blood levels of the hormone cortisol, which is released by the adrenal glands in cyclical patterns over the course of each day and is involved in regulating the body's stress response. Unusually elevated cortisol levels generally indicate higher levels of stress. Studies of the relationship between cortisol levels and infants' stress response have found that insecurely attached infants are more likely than securely attached infants to show elevated cortisol levels in situations perceived as threatening (Gunnar, 2000; Gunnar & Vazquez, 2006). Secure attachments may therefore protect infants from mobilizing a stress response too soon. When children in Romanian orphanages were studied, researchers found that their cortisol levels tended to peak during midday as opposed to peaking early in the morning as in normal children (Carlson & Earls, 1997). Lacking secure attachments, the Romanian children may have found their day-to-day routine much more stressful than other children do.

Q: How might security of attachment be related to physiological responses to stress?

Any observational studies on the effects of institutionalization run the risk of confusing correlation with causation. Thus, perhaps children who leave institutions early are selected for adoption because they seem psychologically healthier. Once again, researchers have tried to control for such factors, but it is difficult to do so without an experimental study using random assignment. It is notable, then, that a series of studies that did use random assignment supported the earlier conclusions, reporting strong, unambiguous causal effects of institutionalization (Bos et al., 2010; Nelson et al., 2007; Zeanah et al., 2009). In one study, researchers followed 136 infants who had all initially been in an institution. At about 22 months of age, half of these infants were randomly assigned to home foster care and the other half stayed at the institution. The researchers assessed all the children at around 22 months and then again at 30, 42, and 54 months. Children who stayed in the institution showed higher than normal levels of some disorders, such as high anxiety and depression, whereas children who were assigned to foster homes showed a dramatic drop in levels of anxiety and depression, which continued to decrease toward normal levels over time (Zeanah et al., 2009). A more outward behavioral hallmark of institutionalized children, random repetitive movements, remained high in the institutionalized children, but dropped dramatically in children in the foster homes (Bos et al., 2010). Finally, children assigned to foster homes showed markedly better cognitive outcomes than those who remained in the institution (Nelson et al., 2007; Smyke et al., 2012).

Unfortunately, despite the clear negative effects of institutionalization in which there is marked social deprivation, it remains a reality for many thousands of children worldwide. Every time a family adopts a child from a part of the world where poverty, political crises, or disease cause many parents to give up their children, there is a real chance that the child may have spent much of his or her infancy in such an institution (Hawk & McCall, 2010), potentially causing the child to have both social and cognitive problems and atypical attachment styles. The good news is that, contrary to what might be expected, most children who have suffered badly in institutions make impressive recoveries when adopted or put into a foster care arrangement with warm, responsive caregivers (Van IJzendoorn & Juffer, 2006). Nonetheless, some children do show lasting problems well into adolescence and adulthood (Kumsta et al., 2010; Rutter et al., 2007; Smyke et al., 2012). This wide variation in outcomes between children who show near-complete recovery and others who continue to have major problems is of great interest to researchers, who are seeking to identify the most vulnerable children and devise interventions to give them a better future.

Q: How has random assignment been used to study the effects of social deprivation?

Deprivation Studies in Nonhuman Primates

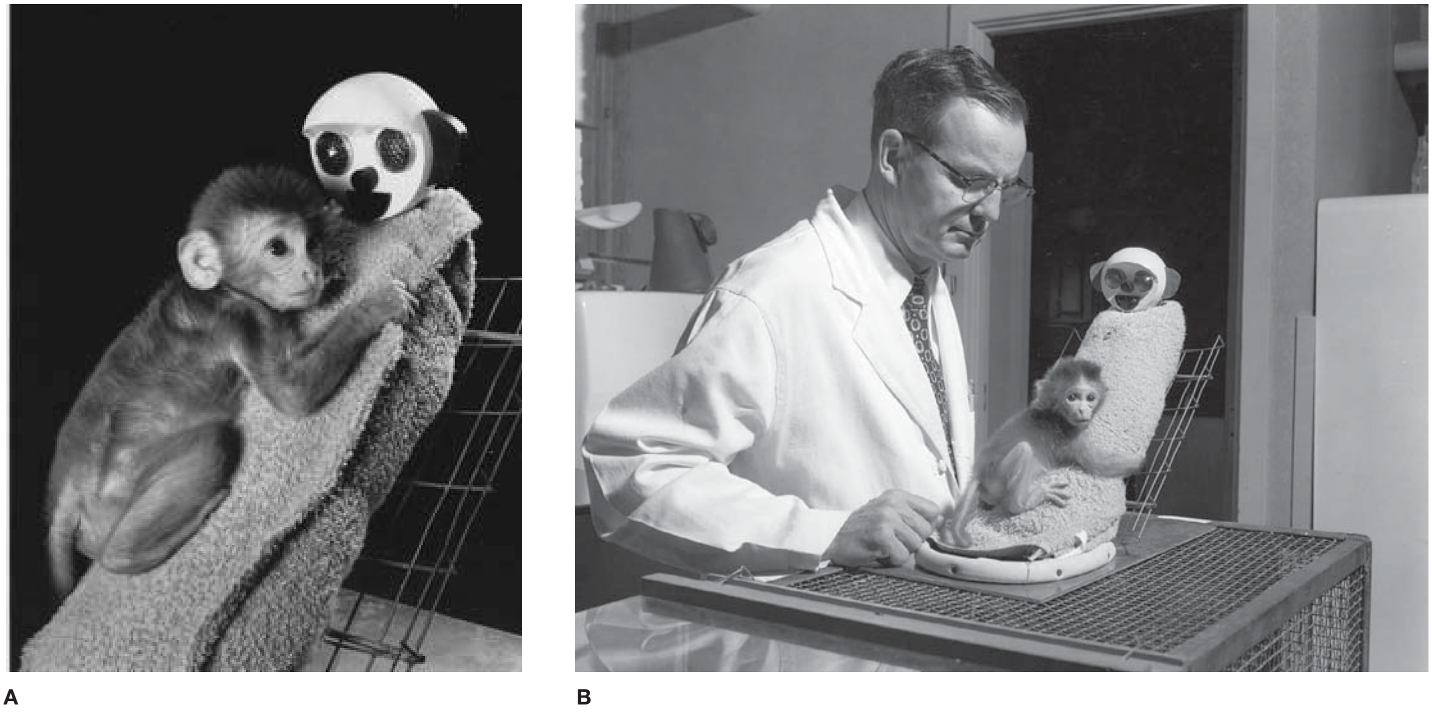
The earliest work systematically exploring nonhuman attachments was conducted by Harry Harlow and his associates in the 1950s and 1960s (Harlow, 1958; Harlow & Harlow, 1962, 1969; Harlow & Suomi, 1971; Harlow & Zimmerman, 1958). In his classic experiments, Harlow studied rhesus monkeys either in conditions that were analogous to human situations or in conditions that would not be possible or ethical to study in humans. Many of his studies with monkeys involved controlled simulations of the type of deprivation experienced by the Romanian orphans and by the infants Spitz had studied in the foundling home. The effects on Harlow's monkeys were often so devastating that today it would be exceedingly difficult to justify further research that would inflict such suffering on individuals of any species.

Tactile Stimulation and Physiological Needs Initially, Harlow simply wanted to know if severe deprivation had effects on monkeys analogous to those in humans, with the obvious research advantage of being able to conduct true random-assignment experiments from birth. In several studies, Harlow put very young rhesus monkeys into empty wire cages. These monkeys were given all the food they could eat, but they had no contact with any caregiver. After a few months in this environment, the young monkeys began to show behaviors similar to the behavior of deprived human infants: indifference to others and expressionless stares; clutching their heads and bodies, rocking back and forth, and banging their heads; and going into wild rages when approached by strangers. The parallels between the socially deprived monkeys and the infants studied by Spitz and others are striking.

In an attempt to narrow down the causes of these three classes of deviant behaviors, Harlow began to manipulate individual variables that might help the baby monkeys start to form attachments. In one of these manipulations, the infant monkeys were given a choice between a wire-frame "mother" that was roughly the size and shape of an adult monkey and a "mother" that was covered in furry terry cloth. The monkeys invariably preferred the terry-cloth mother and frequently rubbed their stomachs against the front of the terry-cloth mother for tactile stimulation (see Figure 6.20). Quite remarkably, the presence of the cloth-covered mother had a significant positive effect. Relative to the monkeys reared in empty cages or restricted to the wire-frame mother, those with a terry-cloth mother showed less extreme repetitive behavior and fewer rages, though they still feared strangers. As adults, they did not show normal social behavior with other monkeys, but they seemed to fare better than those reared without tactile stimulation.

Moreover, these monkeys formed a real attachment to the terry-cloth mother, which was evident in their responses when an unfamiliar object, such as a plastic, bug-like toy, was put in the cage. The alarmed monkeys would immediately retreat to the terry-cloth figure for comfort and protection. Although the terry-cloth figure was, of course, unresponsive, Harlow noted that it was at least "infinitely patient" with the frightened infant.

Apparently, a key element in the attachment behaviors that enable the young monkey to form bonds involves the particular sensation of clinging and rubbing against a furry surface. This tactile stimulation does not directly satisfy the infant's physiological needs, but the experience is clearly of vital importance. This study illustrates the idea of prepared attachment behaviors linked to attachment. The infant monkeys looked to the terry-cloth mother for protection, even though they had never been protected by "her" and never could be. Yet, there was a link between the behavior of rubbing against the fur of a monkey-like object and a feeling that the object would provide security and protection. This association could not possibly have been learned. Instead, it represents a connection between two attachment-related behaviors as part of a larger attachment complex.



A

B

FIGURE 6.20 Bonding with the terry-cloth mother. (A) Infant monkeys in the Harlow studies seemed to form strong bonds to inanimate wire-frame mothers wrapped in a furry terry cloth. Harry Harlow's studies on various deprivation conditions and their effects on attachment behavior served to strongly support the ethological perspective. **(B)** Harry Harlow is pictured here with one of the infant monkeys on the terry-cloth mother.

Harlow then tested the importance of tactile stimulation in a follow-up study by pitting the need for tactile stimulation directly against the infant monkey's need for nourishment. The infant monkeys in this experiment were each reared in a cage with two surrogate mothers: the simple wire-frame mother, which had a plastic tube on its front that supplied milk, and a terry-cloth mother that supplied no nutrition. The infant monkeys quickly learned to feed from the wire-frame model, but they regarded it solely as a food source. They spent most of their time clinging to the terry-cloth figure, scampering to the wire model only when they were hungry (see Figure 6.21). The monkeys clearly formed an attachment to the terry-cloth mother, even though the wire-frame mother was the one that relieved their hunger and thirst. In separate scenarios in which both mothers provided milk, the baby monkeys used the cloth mother exclusively (Harlow & Zimmerman, 1958).

These studies not only illustrate the central role of particular behaviors in forming attachments, but also point out problems with the traditional learning and psychoanalytic viewpoints described earlier in this chapter. The learning theorists attempted to account for attachment in terms of patterns of positive and negative reinforcement, in which receiving food should powerfully reinforce the bond with the food provider; yet, in these studies, the monkeys formed no attachment to the wire-frame figure, even when it served as a food source. The psychoanalytic theorists emphasized the act of nursing and the importance of oral gratification in forming early attachments; yet, the infant monkeys attached to the cloth figure that provided no oral gratification.

Of course, leaping to conclusions about humans based on animal studies poses risks. But Harlow's monkey studies clearly illustrate how some early behaviors might serve to support and maintain contact with caregivers. They also show that these behaviors can affect attachment more profoundly than other behaviors that service fundamental nutritive needs.

Q: How are some attachment behavior complexes "triggered" by certain features of artificial primate mothers?

Peer-Raised Infants In the natural world, infants typically form their earliest and strongest attachments to adult caregivers, which seems to imply that the adult's protective, nurturing role is crucial. In fact, we may have an exaggerated sense of its importance because alternative situations are so rare. As noted earlier in Freud and Dann's study of the group of six children who survived the concentration camp together, attachments to peers may provide much of what is needed for normal social development early in life. To test this idea, Harlow designed a monkey analog of the Freud and Dann study by raising monkeys in groups of six peers, with no older monkeys present (Harlow, 1969; see Figure 6.22). They were deprived of social interactions with adults but interacted freely with each other. These infants developed relatively normally, showing few of the deficits that characterized more deprived monkeys and human infants. They did show some social problems, such as difficulties in mothering new babies and fearfulness of strangers, but overall, their development was surprisingly normal.

Newer and more subtle analyses have illuminated some of the lingering problems in the peer-raised monkeys. These monkeys appear to have reduced levels of the neurotrans-

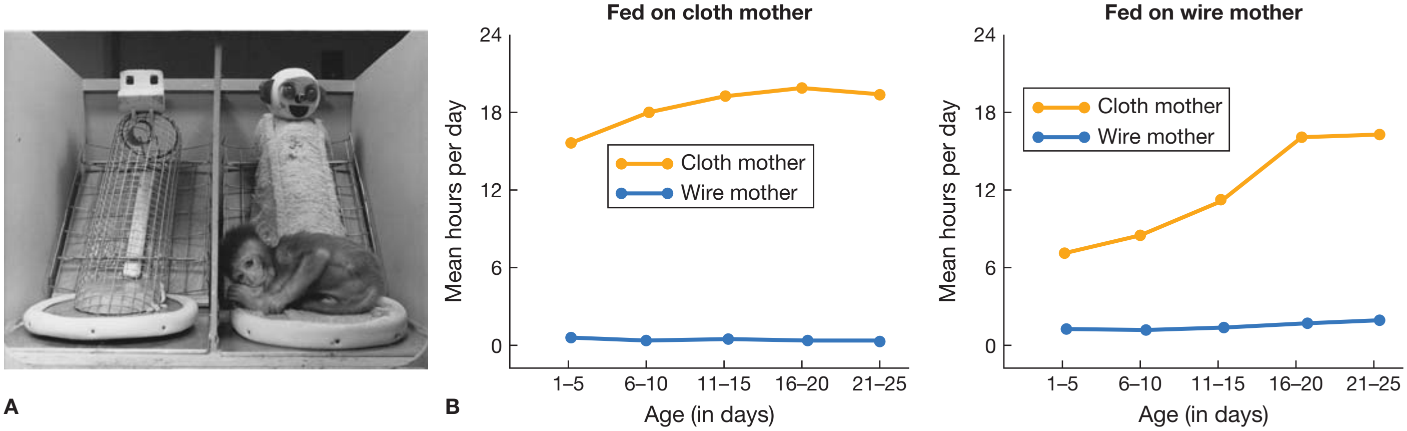


FIGURE 6.21 **Contact comfort.** **(A)** When monkeys are given the choice between a wire-frame "mother" and one covered in terry cloth, they not only show a strong preference for the terry-cloth "mom," but also tend to be less devastated by the effects of deprivation. **(B)** The monkeys went to the wire mother only to feed; they went to the terry-cloth mother, whether or not she provided them with milk, for the contact comfort she provided.

FIGURE 6.22 **Peer-raised monkeys.** Peer-raised monkeys who had no contact with adults developed fairly normally and would play and explore with each other.

mitter serotonin in their brains compared with monkeys raised by adults. Low serotonin levels have been associated with several psychological problems, including aggression and impulsive behavior (Bennett et al., 2002; Higley & Linnoila, 1997). Researchers theorize that the effects of early deprivation may arise largely from changes in two biological systems: a stress-buffering system related to cortisol levels and an impulse control system related to serotonin levels. Cortisol is part of the hypothalamic-pituitary-adrenal axis (HPA), which regulates the body's response to stress as well as regulating other body functions. The neurotransmitter serotonin is involved both in the activation and feedback control of the HPA. Serotonin is thought to play a role in early socialization and attachment by helping to regulate levels of anxiety in stressful social situations, such as separations from caregivers, so that the stress response is neither too extreme nor absent completely.

Perhaps most interesting is the discovery of how individual biological differences interact with environmental experiences. The gene known as *5-HTT,* which regulates serotonin levels, seems to have two alleles: a "long" form and a "short" form. Monkeys who were raised by their mothers showed normal serotonin levels, regardless of which version of the allele they had. But monkeys who were raised by peers—and thus lived in a more stressful environment than the one experienced by monkeys raised by their mothers—had different serotonin levels based on which version of the allele they had. Those with the long version of *5-HTT* fared pretty well when raised by peers, but those with the short version tended to show lower serotonin levels and more impulse control problems, including more aggression (Suomi, 1999). Thus, the form of the *5-HTT* gene that a monkey had seemed to predict how he would respond to this nonoptimal social environment (Bethea et al., 2004). We see here one possible biological basis for the individual differences in children's responses to stressful environments.

Of the many studies conducted with monkeys, rats, and humans, the vast majority converge on a finding that the *5-HTT* gene is involved in moderating or exacerbating the effects of stress (Caspi et al., 2003, 2010; Wankerl et al., 2010; but see also Risch et al., 2009). There are two kinds of effects. First, regardless of allele type, severe and very early deprivation leads to lasting differences in *5-HTT* gene expression, which can result in diminished serotonin responses for regulating stress. In effect, these changes can result in greater emotional reactivity to stress (Spinelli et al., 2010). One route for this effect seems to be through a pathway in which stress hormones increase methylation of DNA segments (the pairing of methyl groups to DNA; see Chapter 2), which regulates gene expression and in this case results in diminished serotonin activity (Champagne, 2013; Champagne & Curley, 2009; Ichise et al., 2006; Murgatroyd et al., 2009). Second, in monkeys and humans who have the short version of the *5-HTT* allele, the effects of stress are even more significant, including greater methylation and hence greater reduction in serotonin activity. Even in somewhat less stressful environments, those with the short version may experience epigenetic changes (environmentally induced changes in gene expression that in this case lead to reduced serotonin levels) and greater emotional reactivity, while those with the longer version may not be affected at all. We see here a biological example of a feedback loop in a gene-environment interaction. If an organism has a short version of the *5-HTT* gene, the effects of a stressful environment can be amplified, which in turn causes a higher stress response. This physiological response then causes an even more severe decline in the activity of the relevant gene, leading to even more stress reactivity, and so on, in a downward-cycling feedback loop.

A final interesting twist on the persistence of both short and long versions of the *5-HTT* gene is that the short version may have evolutionary adaptive value in some circumstances, which may be why it has remained in the general population. In a dangerous environment where high levels of vigilance and anxiety may enhance survival, organisms with short versions of the gene will more likely experience enduring epigenetic changes that make them more sensitive responders to potential dangers (Heiming & Sachser, 2010). The short version of the *5-HTT* gene may therefore lead to increased survival in some contexts, though it is now maladaptive for many human infants who are exposed to high levels of stress early in life. As is so often the case with genetic effects, the *5-HTT* gene is likely to be only a small part of the overall genetic story, with comparable gene-environment interactions occurring for several other quite distinct genes (Bogdan et al., 2012).

Critical-Period Effects?

Many early researchers assumed that there was a critical period during which social interactions had to be experienced. Researchers believed that if there was complete social deprivation during this period, the effects were irreversible. Certainly, many of Harlow's monkeys continued to exhibit bizarre behaviors into adulthood and as parents. This view was accepted until one of Harlow's associates, Stephen Suomi, looked more closely at possible ways of "rehabilitating" the monkeys reared in isolation. Using younger monkeys as "therapists," Suomi found that the isolated monkeys could gradually achieve almost full recovery by being taught how to be social (Suomi & Harlow, 1972; see Figure 6.23). In particular, Suomi selected juvenile monkeys that would interact freely with the isolated monkeys without hurting them and that would cling to them gently. Within a few weeks, the isolated monkeys began responding to these overtures by clinging back and approaching the juveniles to interact with them. As they reciprocated in these ways, the symptoms of their deprivation started to disappear.

This successful rehabilitation accords nicely with a major change in views concerning critical-period effects in human infancy. Following Freud's lead, many early theorists were convinced that a child deprived of attachments in the first 2 to 3 years of life was doomed to an "affectionless" life of failing to connect with others or form meaningful relationships (Bowlby, 1951). More recent evidence seems to point toward some reversible outcomes, although the amount of evidence is not extensive. One longitudinal study of children reared in a socially impoverished institution from birth until 2 years of age or older suggested that having appropriately affectionate adoptive parents could sometimes undo the children's early social problems (Hodges & Tizard, 1989; Tizard, 1977). This is not to minimize the negative effects of an infancy spent in institutions that deprive infants of normal social contact and interactions; the children did appear to be at greater risk for problems. Still, many of the difficulties associated with institutionalization can be reversed, providing that the children are then placed with caregivers who can give them the time, attention, and affection they need (Schaffer, 1990).

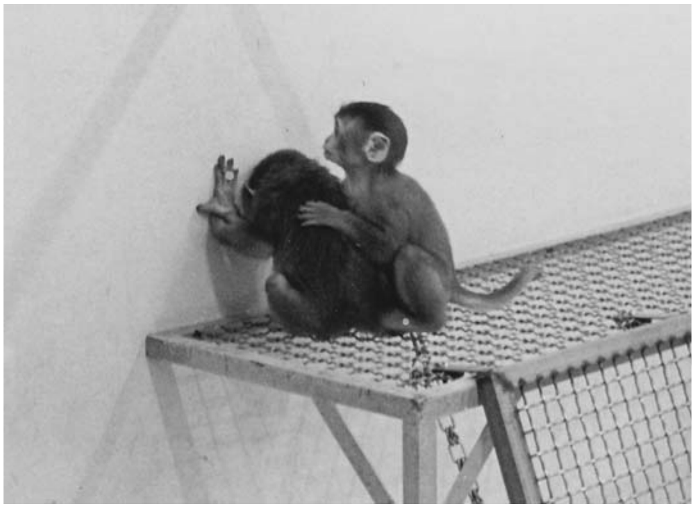

FIGURE 6.23 Monkey therapists. Younger monkeys would comfort monkeys who had been reared in isolation and teach them how to play and be social.

At the biological level, there may be an early critical period in utero and during infancy when methylation occurring in response to stress may lead to effects that may be irreversible after infancy (Murgatroyd et al., 2009). Researchers are still asking whether the right kinds of supportive environments could possibly reverse these early effects, perhaps through demethylation (a process through which a methyl group attached to a segment of DNA is removed, thereby often restoring a function). But given that some forms of early methylation in utero have been argued to be irreversible (Le Bouc et al., 2010), there may in fact be a critical period at the biological level. Early changes in *5-HTT* pathways could set a developmental course for certain neural circuits related to emotional regulation. Even so, the existence of a critical period does not mean that an attachment style is fixed. Instead, it means that a child might be at risk for being more emotionally reactive. This might increase the odds of some forms of insecure attachment, but it does not predestine them.

There is intense interest in those cases in which the effects of early deprivation may not be fully reversible even in the most supportive later environments. Thus, while supportive environments do seem to be able to largely reverse withdrawn forms of attachments resulting from adverse early experiences, it seems much more difficult to reverse disinhibited forms of attachment (Smyke et al., 2012). The reasons for this difference are not well understood, but it is possible that the disinhibited cases set up a type of reward circuitry that becomes fixed in the child's brain. One important implication of irreversible effects is that rehabilitation efforts might be more effective if they focused on helping children (and eventually adults with the same problems) learn to better understand how to read and respond to social cues that can lead them into inappropriate behavior rather than trying to eliminate disinhibited social behavior itself (Smyke et al., 2012).

The neurobiological foundations of critical-period effects for attachment styles and other social behaviors are not well understood, partly because the effects themselves are still being uncovered. Researchers suggest, however, that such effects may result from either incomplete genetic coding or miswiring of particular circuits supporting social behavior (Nelson et al., 2011). In the Romanian random-assignment study mentioned earlier, children who were institutionalized had smaller gray matter cortical volumes (which are thought to reflect the degree of interconnectiveness of dendrites) than those who were not institutionalized. While the same study did suggest that white matter volume might be increased by shifts to more socially supportive environments, the declines in gray matter volume may be more irreversible and the possible locus of critical-period effects (Sheridan et al., 2012).

As we have seen, a better understanding of where critical or sensitive period effects might occur for attachment and related behaviors does not lead to "giving up" on a child who is so identified. Instead, such findings might lead to alternative and more effective ways of helping the child learn to develop strategies for avoiding situations that might result in socially dysfunctional behaviors. Or it may be possible to teach the child to develop compensatory strategies that would allow him to thrive in just those situations that normally might pose substantial risks.

Q: What has recent research suggested about the view that there is a critical period for the formation of normal attachments?

Conclusions

Infants construe the social world differently from the way they see the inanimate world. Beyond simply preferring social stimuli, infants expect certain patterns of interactions with other social beings, and their expectations undergird the formation and maintenance of attachments to specific individuals.

The ethological perspective, with its emphasis on the differences and commonalities between humans and other species and the adaptive functions of those differences and commonalities, has repeatedly proved to be the most successful way of understanding the origins of social bonds. Looking at specific social behaviors and their functional roles has revealed that many species' young must solve similar problems, such as signaling a caregiver, maintaining an interaction, and perceiving danger by watching others. These common developmental challenges have fostered different solutions across species. Despite the considerable differences in the details, however, the ethological perspective has yielded important insights about the functional similarities that underlie different species' attachment behaviors.

Forming attachments is not only an aspect of cognitive and social growth, it is essential to normal development. When infants and children are deprived of the opportunity to form attachments, the effects can be devastating for their mental and even physical health. While there are different attachment styles, which are often stable over time and seem to emerge out of a complex set of interactions between the child's own temperament, the ways in which parents and others relate to the child, and even how the culture views appropriate forms of intimacy at different points in development, there is still a large amount of common ground shared by all infants that enables them to form attachments. All infants, regardless of their attachment style, set up and maintain those bonds through an attachment complex consisting of signaling behaviors and proximity behaviors. All infants also have implicit linkages between different attachment components, such as inferring that a highly social and responsive caregiver will be a protector in times of threat.

In the next chapter, we turn to a deeper discussion of several topics touched on in this chapter that relate to attachment and early social relations. As we consider the development of emotions, temperament, and personality, we will ask whether the themes that have emerged from our discussion of the infant's social world, such as evolutionary adaptations, feedback loops, and gene-environment interactions, apply there as well.

STUDY AND REVIEW

SUMMARY

Developing Bonds between Infants and Caregivers

- Human infants and the infants of other species form bonds to those who take care of them and behave in ways that set up and maintain proximity to their caregivers.
- Bonds between infants and caregivers develop out of an ability to pick out and partially understand social beings, with human infants normally developing specific bonds to particular individuals soon after the sixth or seventh month of life.
- Shortly after infants seem to have a bond to specific individuals, they also show marked separation distress (also called separation anxiety) when one of those individuals leaves them alone or with a stranger.

Early Perspectives on Infants' Bonds with Others

- Psychoanalytic views of infant bonds overemphasized the importance of breastfeeding and the centrality of the infant's bond with the mother as opposed to bonds that the infant forms with others. Freud's theory of these bonds emerged out of his account of psychosexual development based on drives, instincts, and sources of pleasure. While many of Freud's specific theories have not held up, he and other psychoanalytic theorists did raise enduring questions about the importance of early experiences, sex differences, and the relevance of an infant's beliefs about others.
- Learning theory approaches to parent-child bonds focused on how environmental contingencies reinforced or discouraged certain behaviors and how infants formed bonds to positively reinforcing stimuli. They neglected possible roles of infants' mental states and beliefs and had difficulty explaining how bonds endured when children are in abusive families.
- John Bowlby's ethological approach has become the dominant perspective for studying how infants form bonds with others. It considers such bonds as part of an attachment complex and focuses on the attachment behaviors that set up and maintain bonds between offspring and caregivers. It also considers analogous systems at work in many other species and examines the similarities and differences in the ways that offspring in other species attach to their caregivers.

The Underpinnings of Attachment

- Attachment behaviors ensure that infants and parents become linked together through strong affectional bonds. They can include signaling behaviors, such as smiling, crying, and merely being cute. They can also include actions, such as following or clinging or touching.
- All the attachment behaviors are embedded in loops of interactions between caregivers and infants that serve to bring them into close proximity and then maintain that proximity.
- Several cognitive systems seem to undergird the ability to form attachments. One particularly important ability is a sensitivity and preference for contingent responding, with parents and children in different cultures having different response routines.
- Social referencing, the use of others' expressions and behaviors to make inferences about how to behave in a situation, is an important way to build bonds between infants and caregivers.
- Joint attention and gaze following, in which a child and another person simultaneously attend to and follow the same object or event, are critical mechanisms for developing a set of shared experiences between children and caregivers, which in turn helps each partner better understand and empathize with the other.

Individual Differences in Attachment Style

- There are striking individual differences in attachment style between infants and their parents that are based on how they relate to each other and on expectations about how they will respond to each other in particular situations. Mary Ainsworth developed a method known as the Strange Situation for measuring differences in attachment style. Four types of attachment styles are most commonly discussed: Type A, or insecure/avoidant attachment; Type B, or secure attachment; Type C, or insecure/resistant (or anxious) attachment; and Type D, or disorganized attachment.
- There are several possible causes of different attachment styles. These include parental behaviors, children's effects on parents, interactions between parent and child effects in various forms of feedback loops, and genetic influences.
- Early attachment styles may have long-term consequences for a child's development. There are associations between early attachment styles and both social and cognitive abilities and tendencies in childhood and adolescence, but the causal account is difficult to untangle. The child's own temperament may elicit certain kinds of responses in others, a constant stressful environment may cause problems at multiple ages, and temperament and environment may interact to amplify or reduce effects.
- There are substantial cross-cultural differences in attachment style as measured by the Strange Situation, but it is difficult to know whether these differences translate directly into dif-

ferences in attachment quality. Interpreting these differences is complex because what is considered a “strange” situation by parents and infants in one culture may be perceived very differently in another culture.

Effects of Early Social Deprivation

- Early deprivation of normal social interactions can have a devastating impact on both humans and other animals, resulting in repetitive motor behaviors and maladaptive patterns of interaction with others. The lack of social interactions early on can result in high mortality rates in infants in settings where such social deprivations are the norm, even if those settings are clean and provide ample food and shelter.
- The effects of deprivation are associated with physiological measures, such as high levels of cortisol and low levels of serotonin. In addition, certain infants may be genetically at risk and particularly devastated by such environments.
- There may be mediating effects in situations of deprivation, however, including the presence of a close group of peers among human infants or “monkey therapists” and tactile stimulation among rhesus monkeys. Although many effects of deprivation can be reversed when children are shifted to more socially rich forms of care, concerns remain about potential long-term effects in at least some children, effects that may be mediated through epigenetic changes in stress regulation systems.
- In some cases, there may be critical-period effects in humans in which severe deprivation may lead to attachment styles and related social deficits that may not be fully reversible in later life, no matter how supportive the environment.

THOUGHT QUESTIONS

1. Difficult life circumstances or more intrinsic personality issues can make some biological parents less able to effectively interact with their children than foster parents. In one series of studies, children were placed in institutions before they were 4 months of age and were then returned to either their original parents or to adoptive parents (Tizard & Hodges, 1978; Tizard & Rees, 1974; Tizard & Tizard, 1971). Both groups showed signs of institutionalization when they first were adopted or reunited, but over the next few years, the adopted children seemed to fare better than those returned to their natural parents. Loving caregivers seemed to undo the effects of deprivation more effectively than biological parents whose lives were otherwise more stressed. Are there any circumstances in which it would be appropriate for a court to order that children be taken away from biological parents who are not abusive but who are providing grossly inadequate social environments for their children? If so, when would this be justified? If not, why not?
2. Suppose that a pediatrician is concerned about a 1-year-old because the child exhibits a high level of insecure/resistant (anxious) attachment. The pediatrician consults with you as an expert in developmental psychology. What sort of interventions might you devise with respect to modifying parental behavior, the child’s environment, and the child’s own temperament so as to reduce the level of insecure attachment behavior?
3. Some have argued that males in general are less sophisticated in social cognition than females. How much might such a difference influence the development of attachments in boys and girls?
4. Imagine that you and your partner both have jobs with minimal parental leave policies and that you have to put your 2-week-old infant in full-time day care. Design a plan for evaluating the 16 day care centers in your community that would enable you to choose the one that offers the best opportunity for the social development of your child.

Conclusions

Summary

Not long ago, in a supermarket on a busy Saturday morning, I noticed two infants who were showing very different emotions and patterns of interaction with their mothers. Both infants were about 12 months old and were being wheeled about in shopping carts by their mothers. The first infant, a girl, seemed delighted by the visit to the supermarket. As her mother occasionally handed her an item to drop into the cart, she received each one with a smile. She often laughed or looked happily at her mother, and her mother responded positively in return. Likewise, she readily smiled at strangers. The second infant, a boy, seemed angry and upset about being in the supermarket. Scowling at his mother, he either angrily rejected items she handed him or insisted on holding on to them, even though his mother wanted him to put them into the cart or back on the shelves. He avoided strangers' looks and yet also seemed fearful of them. Meanwhile, the boy's older brother, who was around 7 years old, was clearly embarrassed by his sibling's behavior.

Simple interactions like these are repeated countless times a day in different venues around the world and illustrate several phenomena that this chapter explores. Most notably, we will see that young infants show a variety of emotional states as well as individual differences in their emotional responses to the same situation. Looking at infants' early emotional states, as well as the variability in their emotional responses, will help us address the question of how a child's emotional repertoire develops over time. We will also see that there seem to be intrinsic differences in how different infants respond and behave in particular settings. Such individual differences in disposition are known as *temperament* and tend to be quite stable in infancy. Moreover, we will see that when an infant comes to perceive and understand the social world, some of the most salient aspects of that world concern the emotions and personalities possessed by social beings, attributes that make each person a unique individual, distinct from all others. Infants themselves are social creatures, and it is of great interest to know how their emotions and personalities develop.

We will start by considering how an infant's emotions develop in the first couple of years of life, focusing first on the nonverbal measurements of emotions that researchers use with infants. We will ask how many distinct emotions seem to be present shortly after birth and how both the number of emotions and the complexity of emotions increase over time. We will examine how infants learn to perceive and think about emotions in others, how they learn to regulate their own emotions, and how emotions might have evolved. We will then turn to differences in temperament and consider how those early differences relate to later differences in personality. We will look at how behavior patterns in infancy, such as emotionality, activity level, and sociability, may contribute to later personality traits. And we will see how the infant's ability to shift attention and the tendency to be inhibited or uninhibited are related to biological bases for temperament. We will also consider how "goodness of fit" between an infant's temperament and the environment affects the child's development and personality.

This chapter revisits several major themes and introduces some new variations. We will see, for example, how feedback loops often help create and sustain patterns of emotional responding—within the individual, between the individual and the inanimate environment, and between two individuals. On a related note, we will see once again how deeply intertwined cognitive and social/emotional development are and how a full understanding of psychological development requires an understanding of their constant interactions. This chapter also returns to the contrast between the traditional empiricist and nativist views of the developing mind. We will consider the extent to which the newborn infant already possesses characteristic emotions and other components of a full personality and the extent to which emotions and other aspects of personality emerge through experience.

Emotional Development

Anyone who has spent time around a newborn has observed what appear to be displays of emotion, but exactly which emotions do newborns feel? To tackle this question, we need to define emotions precisely—which is a notoriously difficult task, even though everyone has a sense of what emotions are (Izard, 2009). Here we will consider **emotions** to be transient states that correspond to physiological and cognitive processes associated with distinct internal sensations, or feelings.

The physiological, cognitive, and behavioral components of emotions can take several forms. For example, physiological processes may correspond to the effects of hormones on bodily states as well as to changes in the activity of specific neural circuits. Thus, rapid increases in heart rate may be associated with certain emotions, and higher levels of the hormone oxytocin in the brain may be associated with increased feelings of trust and affection. Cognitive processes can range from how an individual appraises a present situation to the influences of memories of past experiences. Behavioral processes can include tendencies to engage in particular actions in particular contexts (for example, cringing when called on in a meeting or crying at weddings). These components can be further subdivided and elaborated, but this brief list is sufficient to illustrate how emotions emerge from a confluence of several components of quite different types. As always, interactions between all these components also occur frequently. Thus, bodily arousal may influence cognitive appraisals, and cognitive appraisals may influence bodily arousal. We will see that this complex web of interactions is often at the heart of understanding specific emotions.

Approaches to Emotional Development

Because infants cannot tell us in words what they are experiencing, we must find ways to infer what they are feeling and thinking. For the most part, researchers have used infants' facial expressions to infer their emotional states. Charles Darwin pioneered this method in the late nineteenth century through careful observations of his own son (Darwin, 1877; see Figure 7.1). Darwin assumed that facial expressions were good indicators of underlying emotional states and that when combined with contextual cues and other infant behaviors, facial expressions could be used to identify several distinct emotions from the beginning of life. Darwin was also deeply committed to the idea that in both humans and other animals, displays of one's own emotions and perceptions of emotions in others serve as adaptations that regulate social interactions. Thus, if a person displayed anger toward someone else, the other person might know to avoid a confrontation that could end up hurting both of them.

While emotional displays may include body posture and vocalizations, Darwin focused heavily on facial expressions, as have most researchers on emotion who came after him. Methods that measure facial expressions are the easiest to use for studying emotions in infants and young children, and they have often been supported with other methods, such as observing body posture. There is now a vast body of research on the use of facial expressions to infer emotional states in both infants and older individuals. Studies of adults have provided a great deal of converging evidence that it is often possible to infer a person's emotional states based on judgments about that person's facial expressions (Ekman & Friesen, 1975; Izard, 1979). The correspondence between expression and emotion is not perfect; some expressions are difficult to interpret, and some people can mask their emotions more effectively than others. But on the whole, we rely heavily on others' facial expressions to infer how they feel (Ekman, 1973). These inferences seem to work the same way in adults, schoolchildren, or toddlers, so most researchers have assumed that infants' facial expressions signify similar emotional states. Although it can be more difficult to tell one emotion from another in young infants, examining infants' facial expressions and the contexts in which they occur (for example, frightening versus comforting situations) can help researchers develop theories about which emotions are present early on and how they change with development.

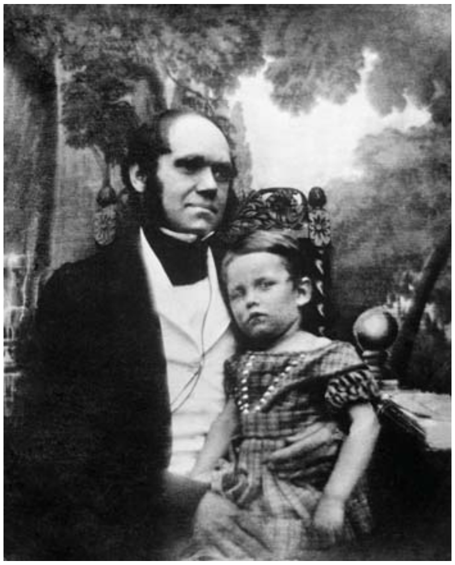

FIGURE 7.1 **Darwin and infant facial expressions.** Charles Darwin took careful observations of the facial expressions of his son William (nicknamed Doddy). This 1842 daguerrotype shows Darwin (age 33) with Doddy (age 3). This is the only known photograph of Darwin with a family member.

To study infants' facial expressions, researchers have developed coding systems for scoring the different expressions and assigning them to categories of emotions. Using such coding systems, which are based on analyzing the muscular and anatomical components that vary across facial expressions, they are able to achieve quite high levels of reliability for identifying expressions (Ekman & Friesen, 1978). But it is always a leap to know for sure that the expressions people agree on really do correspond to particular underlying emotional states. Nonetheless, most researchers believe that, combined with other cues, such as the context and infants' vocalizations, these kinds of inferences about infants' specific emotions are warranted.

Based on these observations, infants' emotions appear to show a general pattern of differentiation that progresses from birth onward. One way to describe this differentiation is to classify infants' emotions as either positive or negative and then ask about further divisions into more nuanced emotions within each of those categories. But researchers disagree about the extent to which newborns display particular emotions that go beyond general positivity and negativity. Some maintain that early on, infants simply haven't learned enough about how to use their emotions to guide their expression in more channeled ways (Witherington et al., 2010). This argument is based on the notion that emotions are a kind of communication system that helps regulate interactions with others. In this view, infants' emotional communications are shaped through development as their expressive skills and their needs become more refined.

Others see infants as endowed, largely from the start, with a set of distinct emotions, each of which was selected for through evolution to serve a certain role, such as fear guiding us to avoid danger and joy drawing us to approach something desirable (Ekman, 1992; Izard, 1994). Although it might be difficult to discern different facial expressions for a full set of emotions right at birth, scholars from this tradition still hold that the different emotions emerge largely as a function of physiological maturation rather than primarily through learning. This approach leaves open the questions of whether infants' expressions directly indicate the full variety of emotions they feel and whether expressions that emerge later are nonetheless largely innate (Izard, 1994).

Though emotions are usually thought to arise without conscious effort, they can be thought of as ways of mobilizing ourselves to take action toward a goal (Campos et al., 2003; Saarni et al., 1998). This is the **functionalist approach** to emotion, and it stresses the function of emotional responses. Table 7.1 describes four emotions. Each involves particular kinds of dynamics that elicit the emotion and maintain it. Each emotion serves clear functions, both for our own internal regulation and for regulating and managing social situations. Feeling anger, for example, can get you to channel your resources in a different direction as well as warn others not to get in the way. Sadness conserves energy and encourages nurturance from others. In this view, emotions are elicited not by an event itself but by our own "appreciation" of how the event relates to our personal goals (Campos et al., 2003; Saarni et al., 1998).

One important way that emotions help us achieve goals is by signaling information—that is, communicating—to others. Thus, we tend to treat people who appear to be angry quite differently from the way we treat those who seem to be sad. This signaling function can enable infants to achieve goals that would otherwise be unattainable given their limited physical abilities and restricted mobility. An infant who is afraid of another person and wants to avoid him can convey fear through facial expressions and body postures. In many cases, that conveyed emotion will affect a caregiver's behavior—for example, leading the caregiver to pick up the infant and carry him away or to hold him protectively—which will enable the infant to avoid the perceived danger. Thus, it is highly adaptive for infants to have a repertoire of emotions to communicate in different settings, enabling them to involve others in helping them achieve their goals. In this way, infant displays of emotion can be seen as having strong functional or evolutionary roles.

Differentiation of Emotions in Infancy

Most theorists see the newborn as having undifferentiated emotions, perhaps only having global positive and negative emotional states (Bridges, 1932; Lewis, 2008). Out of this rudimentary distinction, more mature emotion categories gradually differentiate. Figure 7.2 shows one suggested sequence of differentiation (Lewis, 2008). The earliest emotions present at birth may be little more than contentment, interest, and distress. By around 3 months, these become joy, surprise, and distress. At around 4 months, distress becomes further differentiated to include anger, and then at 6 months, fear emerges.

Basic Emotions By the time they are 6 months old, infants show at least six **basic emotions** (sometimes referred to as primary emotions)—joy, sadness, disgust, surprise, anger, and fear (Campos et al., 1983; Campos & Barrett, 1984; Izard, 2007; Izard & Malatesta, 1987; Lewis, 2008; Saarni et al., 1998). These emotions are considered "basic" for two main reasons: (1) they appear very early in development, and (2) they are considered human universals, in part because people in an extraordinary range of cultures are able to infer these emotions consistently from facial expressions (Ekman, 1973, 1994). These basic emotions are considered the foundational components from which the other emotions later emerge (see Figure 7.3).

Parents can usually tell if their infant is in a positive or negative emotional state. Infants often indicate their posi-

Emotion	Goal	Action
Disgust	Avoid contamination or illness	Prevent substances from entering the body or coming into close contact with the body.
Fear	Maintain integrity of self	Engage in behaviors (flight or withdrawal) that enable us to avoid danger, monitor danger, or escape from danger.
Anger	Any end state that the child wants	Communicate desires or display power or dominance.
Sadness	Any end state that the child wants	Conserve energy by disengaging or withdrawing.

TABLE 7.1 Emotions and goals. Emotions can be thought of as ways of mobilizing ourselves to achieve certain goals. Here four basic emotions—disgust, fear, anger, and sadness—are described in terms of the kinds of goals and actions involved when we feel each emotion. Adapted from Saarni et al. (1998).

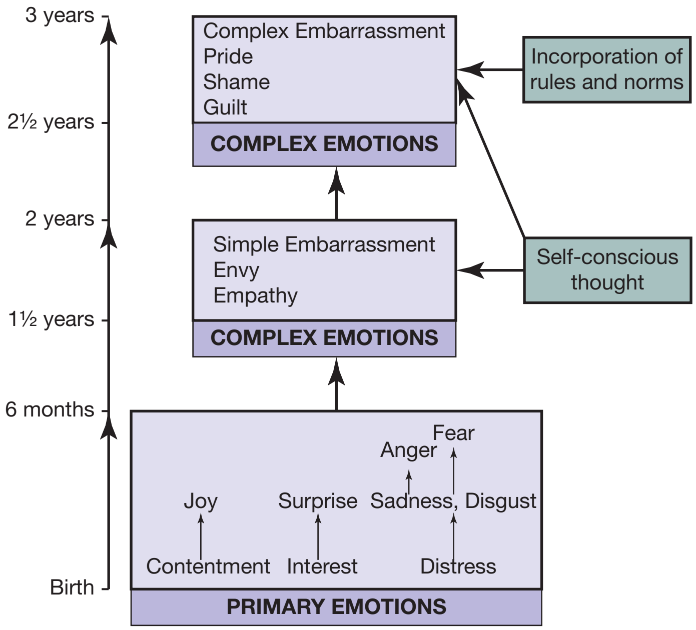

FIGURE 7.2 The differentiation of emotions in the first 3 years of life. According to one model of development, very young infants may start out with little more than the emotions of contentment, interest, and distress. Sadness and disgust may emerge at around 3 months, followed by anger at around 4 months, and fear at about 6 months. Other more complex emotions emerge in the following 2½ years. Embarrassment takes an extended time to develop, with simpler versions based on self-consciousness emerging earlier than more complex versions based on violation of rules. Adapted from Lewis (2008).

tive states through smiles, which can be interpreted as happiness, contentment, or satisfaction with the current state of affairs. As we will see, very early smiles may relate most often to internal states, such as feeling full, warm, and comfortable. As mentioned in Chapter 6, the stimuli that elicit the most smiles change with development, from mostly internal cues in newborns, to general social stimulation in the first few months, to the smile of recognition of specific individuals at around 6 months.

Infants' positive emotions can vary from gentle contentment to exuberant joy. These emotions can be expressed when an infant achieves a simple form of mastery, like shaking a rattle to make a sound, or engages intensely with another person, leading to a rapt state of focused attention. In each of these situations, the infant's smile may show subtle variations, such as an open or closed mouth and a strong or weak raising of the cheeks (Messinger, 2002), so consistently coding each of these variations of smiles and linking them to particular forms of happiness is a challenge for even the most careful researchers. Even in adults, different forms of happiness seem to fade gradually into each other rather than being sharply defined. In contrast, negative emotions are often seen as more clearly distinct from each other in adults, but less differentiated in infants.

Just as it is usually obvious when an infant is in a positive emotional state, it is also clear when an infant experiences negative emotions. Initially, however, it is difficult to distinguish specific negative emotions, as all negative emotions in infancy seem to be variations of distress (Camras & Shutter, 2010; Matias & Cohn, 1993). In fact, some researchers argue that negative emotions, such as fear, sadness, and anger, cannot truly be distinguished in newborns and very young infants because these infants actually experience something more like general negative emotion (Camras et al., 1993, 2007; Oster et al., 1992). If a newborn receives a shot from a doctor, becomes uncomfortably tangled up in bedding, or is simply hungry, a negative facial expression, often accompanied by crying and postural cues to discomfort, is an unmistakable sign of distress. Caregivers usually feel strongly compelled to respond, and in that sense, even a general, undifferentiated negative emotional state fulfills a signaling function.

By age 2 months or so, general negative emotions start to differentiate into at least the categories of sadness and anger (Izard et al., 1995). Sometimes the same situation may elicit different emotions in different infants. One infant who is frustrated may display anger and may attempt to change the environment to attain her goal, whereas another infant may show sadness and give up. As infants encounter more and more situations in which they have goals and desires that are not instantly met, they come to show both sadness and anger responses more frequently. An infant can also oscillate quickly between sadness and anger in the same situation or may show ambiguous negative states that are hard to tell apart (Camras & Shutter, 2010).

Fear, which will be discussed more extensively later in this chapter, does not seem to be clearly evident until around the sixth month of life, typically several months after sadness and anger (Izard, 2007). Infants around 6 or 7 months old most often show fear in response to strangers, and it can be quite a shock for parents to find their infant suddenly terrified when someone unfamiliar drops by. Infants at this age also typically show fear when faced with other kinds of unknown things, such as an unusual zoo animal or even an unfamiliar toy (Bronson, 1972). They may also begin to display fear in laboratory settings, such

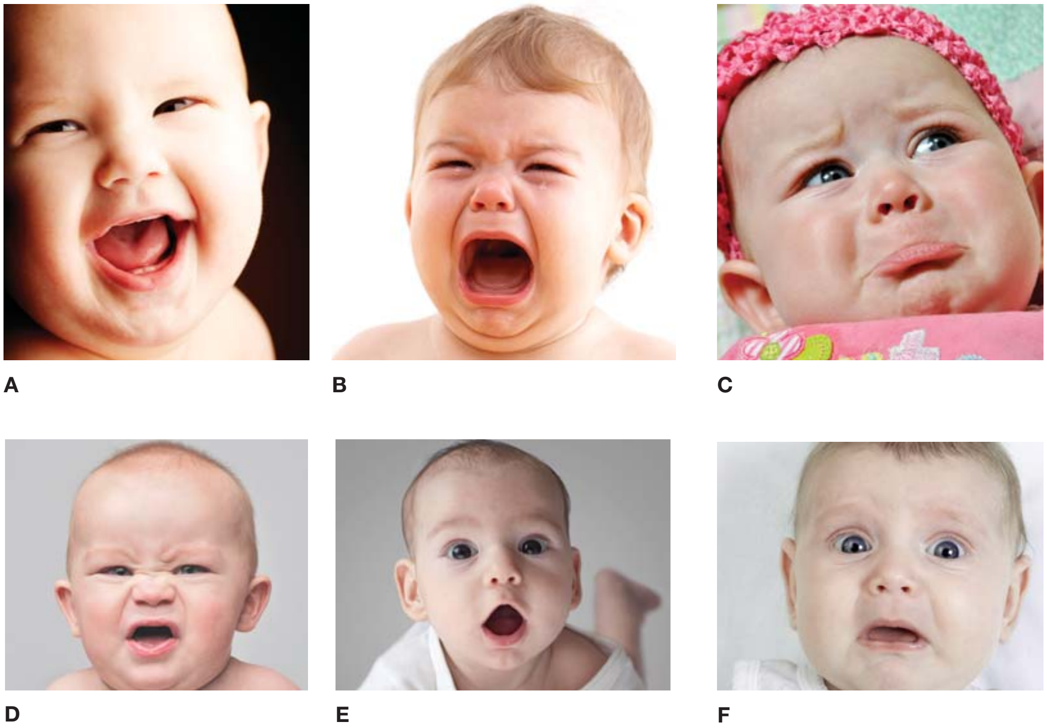

FIGURE 7.3 Facial expressions of basic emotions in infants. Facial coding systems have identified emotions based on infants' facial muscular movements and the positioning of their forehead, eyebrows, eyes, cheeks, and mouth as they are experiencing particular emotions. Facial expressions are social signals to others that enable infants to communicate what they are feeling. Pictured here are infants showing **(A)** joy (indicated by narrowed eyes and widened mouth with corners raised), **(B)** anger (indicated by brows drawn together and lowered and wide-open square mouth), **(C)** sadness (indicated by brows raised and angular, narrowed eyes, downturned mouth, and protruding lower lip), **(D)** disgust (indicated by gaping mouth and lower lip and flattened protruding tongue), **(E)** surprise (indicated by raised and prominently arched brows, widened eyes, and gaping mouth in an O shape), and **(F)** fear (indicated by raised and straightened brows, widened eyes with tense lower eyelids, and horizontally retracted lips).

as when they are on the visual cliff, although this usually emerges at somewhat older ages (Campos et al., 1978; Hiatt et al., 1979; see Chapter 6).

Why would fear appear later than anger and sadness? The answer is not yet clear. One possibility is that figuring out that a situation is potentially threatening may require more complicated mental representations compared with simply noticing feelings of discomfort or recognizing that a goal is being blocked. Assessing the threat level that a situation poses may involve interpreting it in some detail, which may be beyond the ability of a very young infant.

Interestingly, the developmental sequence in which the basic emotions appear in infancy roughly corresponds to the order in which these emotions are thought to have evolved. Thus, using the terms in Figure 7.4, the most primitive kind of emotion might simply be arousal that is neither positive nor negative. Even the emotions of human newborns do not seem to be this undifferentiated, but some very simple organisms, such as insects, might just be experiencing different levels of arousal. Figure 7.4 then shows a split between positive arousal, or excitement, and negative arousal, or apprehension, which can be seen as an initial emerging divide between the positive and negative emotions (Nesse, 2004). From this point, the positive emotions, or those based on desire, differentiate into narrower categories, such as physical pleasure and acquisitive pleasure derived from material gains, as well as love, friendship, and pride. The negative emotions, or those based on fear, similarly differentiate into pain, sadness, grief, anger, and shame. Although these are not precisely the same categories of emotion normally identified in infants, and their order of emergence is a bit different from the developmental sequence in infants (fear may have appeared earlier than anger and sadness in evolutionary history), the broad parallel between development and evolutionary history is clear.

When a developmental progression corresponds to the course of evolution in this way, the common sequence is often explained by considering how the earliest-emerging components are necessary for the organism's survival. This kind of explanation can easily be applied to both the development of basic emotions at the individual level and to the evolution of these emotions at the level of a

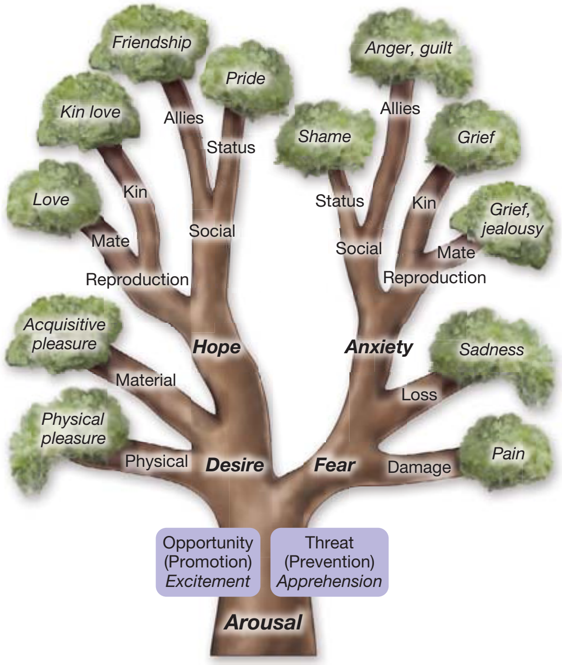

FIGURE 7.4 Evolution and development of emotions. Depicted here is one researcher's phylogeny of emotions. The emotions that appear first in development may have been those that were functionally the most important in evolution and therefore the most conserved across species. From Nesse (2004).

whole species. Even the simplest organisms need to know when to seek out opportunities through positive, exploratory behavior and when to avoid threats through more wary, guarded behavior. Perhaps these two fundamental responses then differentiate into more nuanced types of emotions in more sophisticated organisms. The basic tendency toward apprehension and caution gives rise to fear, pain, and sadness, while the basic tendency toward excitement and approach differentiates into different forms of desire and pleasure. Over the course of this process, as emotions become more subtle and specific, they become increasingly useful in guiding behaviors toward desired goals and away from feared threats. For complex organisms that interact in sophisticated social systems, more elaborate emotions such as guilt and pride help maintain stable relationships and therefore help promote the organism's survival and reproduction.

Complex Emotions Emotions that build on and occur developmentally later than the basic emotions are known as **complex emotions**. They emerge from various combinations of basic emotions and through the introduction of more complex supporting cognitions about a situation. For example, the complex emotion of shame involves *sadness* at losing the respect of another, combined perhaps with *anger* at oneself for doing so and some degree of *fear* about the consequences. Complex emotions develop later than the basic emotions because they involve more complex kinds of goals, such as maintaining a level of standing among peers. Such goals are at least partly socialized and vary across cultures more than basic emotions do. It may seem implausible that six basic emotions could give rise to the full emotional range. But all the possible combinations of those six basic emotions, each of which can be felt at different intensities, can yield thousands of complex emotions. Thus, this theory has the power to describe the course of emotional development, from a small set of basic emotions in infancy to the rich emotional experience of adults.

One key difference between basic and complex emotions is that many complex emotions are also **self-conscious emotions**, meaning that the emotional experience itself requires some degree of self-awareness (Lewis, 1993). Guilt, shame, embarrassment, and pride are all self-conscious emotions, as are jealousy, envy, and empathy. In each case, the emotion seems to require a sense of self in relation to others, whether it involves feeling superior to others (pride), feeling that something private about us has been exposed to others (embarrassment), or feeling that others are more fortunate than we are (envy). Young children first show self-conscious emotions at around age 1½ or 2, at around the same time they are developing other aspects of a more sophisticated self-awareness. Around this same age, children first begin to sense that they should abide by certain social standards, and they begin to become aware of others' mental states and concerned about what others think of them (Lagattuta & Thompson, 2007). The emergence of self-conscious emotions is closely related to this increasingly elaborate sense of self. Complex emotions may also use different neural circuitry from basic emotions. Basic emotions seem to be more closely linked to the **amygdala**, a brain structure that, among other functions, is known to be involved in forming memories of emotional events. Complex emotions seem to involve other brain regions in interaction with the amygdala (LeDoux, 1996).

It is useful to consider some complex emotions in more detail so as to understand how they differ from each other and can reflect the particular culture in which a child develops. Consider, for example, shame, the feeling of wanting to hide from others' view, or to be invisible. Shame can be intensely painful and uncomfortable, and it primarily leads to inactive behaviors aimed at being less noticeable (Lewis, 1993).

Guilt, in contrast, is a more specific feeling of having failed and wanting to remedy the situation (Lewis, 1993). We might regret having carelessly broken someone else's toy or having been cruel to a vulnerable friend. It is an emotion that tends to lead to actions to try to reduce the guilt—perhaps trying to compensate someone who was wronged (being especially nice to a recent victim) or deciding to act in a more upright way to demonstrate our good character to ourselves and others after causing harm. It has been argued for some time that some cultures tend to socialize children primarily through feelings of shame, while others do so through feelings of guilt (De Vos, 1973). One such proposal argued that Japan was a "shame culture" and that many Western cultures were "guilt cultures" (Benedict, 1946), but such a simple dichotomy is now viewed as an oversimplification. People in both kinds of cultures invariably feel both shame and guilt in different situations (Creighton, 1990). Nonetheless, the general point is that cultures may bias their members over the course of development to interpret situations in ways that lead to a preponderance of one emotional response over another (Tang et al., 2008).

As a final example of a complex emotion, consider embarrassment, an emotion that typically occurs when we realize that we stand out because we have violated a social convention or simply are receiving unwanted attention. It may often be expressed in an attempt to restore social relations after violating a norm or in an attempt to reduce the unwanted attention (Keltner & Anderson, 2000). Embarrassment may be one of the earliest complex emotions to emerge (Lewis, 1993), and, in contrast to shame, it is not always negative. Thus, excessive praise can evoke embarrassment even though the situation is far from shameful. Embarrassment has been experimentally induced in this way in children as young as 2 years old by "overcomplimenting" them on their appearance or abilities, and presumably it is felt because the children feel that they are receiving unwanted and perhaps undeserved levels of attention (Lewis et al., 1989). In addition, at about the age at which children first seem to understand that mirror reflections are representations of themselves rather than of a separate individual (see Chapter 13), they are also easily induced into embarrassment. This suggests that the developing ability to think about the self might relate to the emergence of this emotion.

While full-fledged complex emotions seem to develop from combinations of basic emotions, intriguing precursors to some complex emotions may appear in young infants. Thus, some early "emotions" may reflect evolutionarily prepared ways of influencing others (for example, a coy smile eliciting interaction), while not necessarily meaning that the infant is experiencing the emotion as an adult might. These early emotions may be present early on and serve certain functional roles but may not yet have the supporting cognitive structures found in older infants and children.

Adults often express **Machiavellian emotions**, which are meant to influence others and not simply to reflect an internal state. It may be that young infants are evolutionarily prepared to display certain Machiavellian emotions to caregivers so as to elicit a response from an adult, even if the infants are not really feeling what seems to be expressed (Campos et al., 2003; Griffiths, 2003). Thus, Machiavellian emotions can serve as "shortcuts" that don't require the infant to actually have a particular feeling in combination with certain cognitions about the self and others. Instead, the infant might merely need to know that a certain facial expression or posture has brought positive results in certain kinds of situations, such as those that seem threatening. The infant may need to have some sense of the emotion's function in terms of what it can elicit or accomplish, but perhaps not the complex interplay between a basic emotion and various cognitions. Many dog owners will confess to being easily manipulated by a certain posture and a baleful look, even though the dog may not really be having the thoughts and feelings that seem to be present.

Other researchers argue that several complex emotions, including shyness, coyness, shame, and jealousy, may be present in rudimentary forms surprisingly early in infancy (Campos et al., 2010; Draghi-Lorenz et al., 2001; Hart & Carrington, 2002; Reddy, 2000; see also Hart, 2010; Hart et al., 1998, 2004). Consider the case of jealousy. In one study, infants as young as 5 months seemed to show distinct jealousy. The infants in the study watched their mother expressing great affection either to another infant or to an adult. On seeing their mother attending to another infant, more than half the infants in the study showed marked distress; yet when their mother expressed affection to an adult, only 10 percent became upset (Draghi-Lorenz, 2000). Similarly, and perhaps even more surprisingly, 6-month-old infants showed greater negative responses when they saw their mother pay positive attention to a lifelike baby doll than when their mother showed the same attention to a book (Hart & Carrington, 2002; see also Hart et al., 1998, 2004).

How can we explain these very early displays of such a complex emotion as jealousy? One possibility is that although infants do not have a complex understanding of social roles, they may still make the simpler distinction between interactions that only involve adults and those that take place between adults and infants—and view the latter as a threat to their own goals of social interaction (Draghi-Lorenz et al., 2001). Thus, the infants' expressions of jealousy may mostly reflect anger that someone else is getting a resource (adult attention) that they desire. Another possibility is that jealousy is a less complex emotion than it initially seemed, since it serves the adaptive function of ensuring that babies are not deprived of the adult affection and other resources that they need.

The accounts of emotional development described so far tend to omit the role of social and cultural contexts in further differentiating and shaping emotions, for even if those accounts advocate a great deal of predetermined structure, they must also recognize significant experiential effects as well (Camras et al., 1990, 1991, 2007; Malatesta et al., 1989). Infants appear to gradually become "tuned" to the general sets of emotions they see most often around them—for example, in their parents' expressions and actions. We have all seen remarkable similarities between infants (or older children) and their parents and caregivers, not only in their expressions but also in their particular ways of experiencing emotions. Thinking of this process as a tuning of a preexisting system to particular sets of inputs is one way of capturing the important social and cultural influences. These processes can continue throughout the lifespan. One particularly intriguing case is whether certain types of personal failings are experienced in terms of shame versus guilt, depending on the culture. As we noted earlier, members of Western cultures may be more likely to react to certain experiences by feeling guilt, whereas those in some Eastern cultures may be more likely to feel shame in comparable situations. This difference might well reflect how a common and shared shame/guilt complex becomes tuned to particular cultural and social expectations (Crystal et al., 2001; Wong & Tsai, 2007).

Moral Emotions? Psychologists used to think that the ability to judge right from wrong developed fairly late in childhood as a preschooler or young elementary school student became immersed in the values of his or her culture. Such cultural factors are certainly important (we will consider them when we look closely at moral development in Chapter 12), but recent studies suggest that some facets of morality may emerge as part of an infant's emotional repertoire. The idea that emotions are part of moral judgments is actually an old one (Hume, 1739–1740/2000) that has seen a major rebirth in recent years (Haidt, 2003). These studies are part of a new wave of research on the "moral lives of babies" (Bloom, 2010; Wynn, 2008). Scholars in this area are quick to caution that these "moral emotions" in infants are not the same as mature moral reasoning and judgment. Still, this research suggests that preverbal infants may have some intuitive sense of right and wrong—that some core moral intuitions may emerge very early, guided by emotional likes and dislikes toward social agents (Hamlin & Wynn, 2011; Hamlin et al., 2011).

It appears that infants react to "mean" and "nice" social agents in much the same way as older children and adults. One study that investigated these capacities built on the classic study described in Chapter 5, in which infants watched a cartoon showing a triangle that "helped" a ball move up a hill while a square "hindered" its attempts (see Figure 7.5). The researchers then measured the infants' reactions to other cartoons in which the ball approached either the triangle (the helper) or the square (the hinderer; Heider & Simmel, 1944). When the ball approached the hinderer, infants as young as 10 months looked significantly longer (Hamlin et al., 2007; Kuhlmeier et al., 2003). This response suggests that the infants were surprised to see the ball approach the shape that had been "mean" to it as opposed to the one that had been "nice."

When the task was changed so that infants watched an enactment on a display stage of the cartoon event with small geometric solids (with eyes attached to make them look more animate) and then were allowed to choose to play with either the triangle helper or the square hinderer, even 6-month-olds more often chose the helper. By repeating the experiment with different shapes in the various roles, the researchers determined that infants seemed to like the helper more than the hinderer based solely on their actions, not their appearance (Hamlin et al., 2007). Ongoing research is asking if infants have comparable emotional reactions to "friends" and "punishers" of mean and nice agents and whether infants seem to extend these reactions to members of the social groups to which the agents belong (Bloom, 2010).

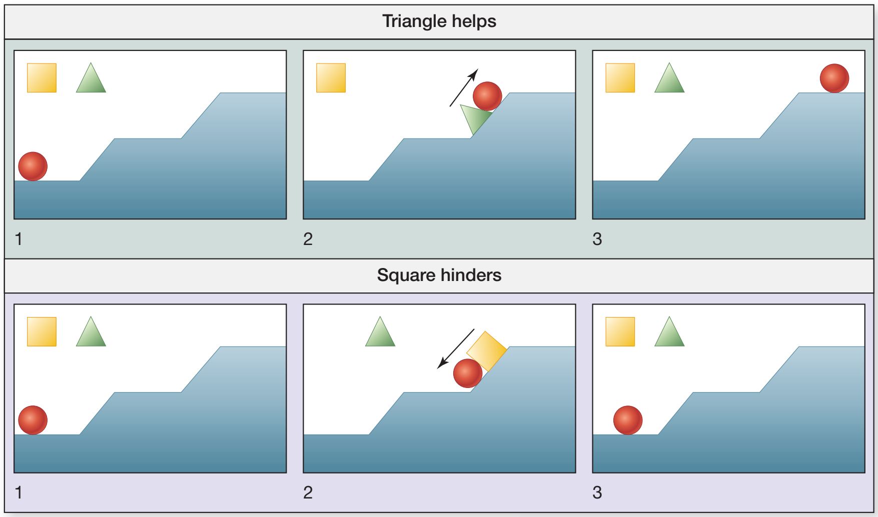

FIGURE 7.5 Helping and hindering. When video clips were shown in which geometric shapes either helped or hindered another geometric shape (here, a ball) climb up a ramp, 12-month-old infants looked longer when a later video clip showed a ball "choosing" to approach the hinderer (here, the square) rather than the helper (here, the triangle). Adapted from Kuhlmeier et al. (2003).

Q: Provide an example of how different cultural experiences might affect a particular emotion.

Perceiving and Thinking about Emotions

We have seen that within the first few months of life, infants display several distinct emotions and that many more emotions emerge in the next couple of years. From very early in life, emotions also play an important role in social interactions, and infants not only have and display emotions, but they soon become able to perceive and think about emotions in others. These abilities are critical to infants' and young children's social and cognitive development as well as to their capacity to regulate their own emotions.

Recognizing Emotions in Others In many ways, even young infants seem sensitive to others' emotions, and they often respond to expressions of emotion in appropriate ways. Long before being able to understand a parent's sentences, infants seem to understand the emotions conveyed in her tone of voice. Thus, certain intonations of alarm in a mother's voice will make an infant more cautious (Fernald, 1992). Using both visual and auditory cues together, infants as young as 4 months are able to respond differently to several different emotions, such as happiness, sadness, and surprise (Walker-Andrews, 2008). Even when listening to unfamiliar languages, infants as young as 5 months will respond differently, depending on the tone of voice (Fernald, 1993). By 7 months, infants' brains respond more strongly in the right inferior frontal cortex when they hear a happy intonation than when they hear a neutral tone (Grossmann et al., 2010). Around this same age, infants are also able to distinguish between others' expressions of several basic emotions, such as happiness, sadness, anger, and fear (Hoehl & Striano, 2010; Leppänen & Nelson, 2006).

Infants can also use visual and auditory signs of others' emotions to guide their own behavior (Hertenstein & Campos, 2004). If a 1-year-old infant at the edge of a visual cliff notices alarm in his parent's voice or face, the infant will be less likely to venture out on the cliff (Sorce et al., 1985). Similarly, if an infant is shown a novel toy and his parent, or even a stranger, reacts with fear, an infant as young as 10 months will clearly avoid the toy (Mumme et al., 1996; Mumme & Fernald, 2003). As described in Chapter 6, watching the expressions and actions of others who know more about an unfamiliar or potentially dangerous circumstance is called *social referencing*. Infants use their parents' reactions as cues to interpret ambiguous situations, and the effect of social referencing in these situations can be quite pronounced. In these circumstances, infants show a strong tendency to respond more powerfully and consistently to negative emotions than to positive ones, a phenomenon called the **negativity bias** (Vaish et al., 2008). The negativity bias may occur because there is a larger cost to ignoring or misinterpreting negative emotions than positive ones. If someone misses another person's expression of anger or fear, there is a good chance of experiencing harm, whereas the stakes are lower for overlooking an expression of joy or pleasure. This bias may be seen as an early-developing aspect of the human tendency to be risk averse (Rozin & Royzman, 2001).

It is not hard to spot young children actively using social referencing to look for clues from a parent about how to interpret an unfamiliar scenario. I was keenly aware of this behavior in one of my children when we were riding a gondola up the hill at a ski area when he was an infant. As the swinging gondola rocked and bumped, he looked mildly anxious, but he frequently glanced at my face and calmed when he saw that I was relaxed. Then the gondola stopped unexpectedly for a long period, and the ski area staff warned that because of an equipment breakdown, we might have to be lowered from the gondola to the ground by emergency rope. In the middle of that conversation, the gondola slightly lurched and I jerked; my son instantly began crying inconsolably. Infants and young children can be extremely sensitive to the smallest of cues. (Fortunately, they fixed the gondola, but it felt like a very long trip up and down the mountain.)

By the age of 9 months, infants not only use others' emotional states to gauge whether they themselves should be cautious in a particular situation, they also use this information to make inferences about other people's future behaviors. In one study, infants observed a person gazing unhappily at an unfamiliar object in one experimental condition, and they saw another person gazing happily at the same object in another experimental condition. They then saw a person's hand holding the object, but the face was obscured so the infants couldn't tell which person it was. Finally, the person's face was revealed, and the infants looked longer when the person they saw was the one who had previously been unhappily gazing at the object (Barna & Legerstee, 2005). Thus, by 9 months, infants use the emotional states of others to infer how they will likely interact with novel objects. When they saw the person with an obscured face holding the object, they assumed it must be the person who had the happy expression, and they were surprised when the person with the unhappy expression was revealed instead.

These examples illustrate that infants can clearly perceive the difference between a generally positive or negative emotional reaction. But it is not yet known whether they can perceive the subtle nuances that emotional expressions communicate, such as distinguishing disgust from fear, or curiosity from fondness. Yet, just as in the case of interpreting ambiguous situations, it appears that at least around the first year of life, infants more heavily weigh negative information in making attributions and inferences about others (Vaish et al., 2008). For example, when infants see adults show either positive or negative reactions to toys, their choice of toys to play with is driven much more by negative reactions than by positive reactions (Hertenstein & Campos, 2004). Nonetheless, when prior attention to an object is pitted against having shown a negative emotion to an object, 14-month-olds will often assume that the actor will still act on the object that had been attended to even though it was accompanied by a negative reaction (see Scientific Method box). Thus, inferring actions engaged in by others from their emotions can be difficult for older infants when attentional cues are also involved. When an infant expects that an actor will act on an object that the actor had both attended to and regarded positively, that task is easier since both cues work in the same direction. When they are in conflict, prior attention seems to drive expectations.

Emotional Contagion Perceiving what others are feeling often influences the observer's own emotional states, in some cases involving the transmission of the same emotion to the observer. One of the most basic forms of this transmission of emotions is known as **emotional contagion** (Hatfield et al., 1994), and it takes place when someone around us feels a particular emotion and we subsequently seem to "pick it up" and feel the same way ourselves. By 6 months of age, infants, too, seem to pick up emotional states from others and show those emotions at a similar level of intensity (Haviland & Lelwica, 1987; Hay et al., 1981). The cliché is that "laughter is contagious," but emotions such as happiness, sadness, and fear can all be contagious. Perhaps because of the negativity bias, infants seem especially sensitive to distress, both in adults and other infants. Even newborns show distress at hearing other newborns in distress, with distress continuing to be especially contagious throughout the first year of life (Geangu et al., 2010). In fact, infants' early ability to notice and understand others' emotional states may be closely tied to this ability to "catch" others' emotions.

Although we do not fully understand the mechanisms underlying emotional contagion, it may be related to empathy, which is a sensitivity to the emotional states of others. Andrew Meltzoff and Keith Moore (1998) speculated that social imitation in newborns may be a critical component of learning how to sense the emotional states in others. In Chapter 4, we considered studies (including pioneering work by Meltzoff and Moore) showing that newborns who are only a few weeks old are surprisingly capable of imitating facial expressions. These abilities to imitate not only require remarkable perceptual-motor integration, as described earlier, but may also reflect some of the earliest ways in which emotional contagion spreads from one person to another. The act of making a facial expression may be closely related to the emotions associated with that expression (Niedenthal et al., 2010). Several researchers have suggested that this process may be mediated by *mirror neurons*. Recall that these neurons fire when an individual either engages in a particular action or observes someone else performing that action, as described in Chapter 4. Mirror neurons may play a role in emotional contagion by linking action and perception such that the same neurons fire when a person either expresses an emotion or observes that emotion in others. Thus, when someone perceives a particular facial expression—say, an expression of sadness—mirror neurons may be activated that enable the perceiver to immediately express that emotion as well and, in doing so, potentially convey that emotion to yet another individual. Nonetheless, there is considerable controversy about exactly what cognitive and emotional processes correspond to mirror neuron activity in humans and whether they actually support the processes involved in emotional contagion (Decety, 2010).

Q: What is emotional contagion, and how might it first emerge in development?

Emotional Regulation in Infancy

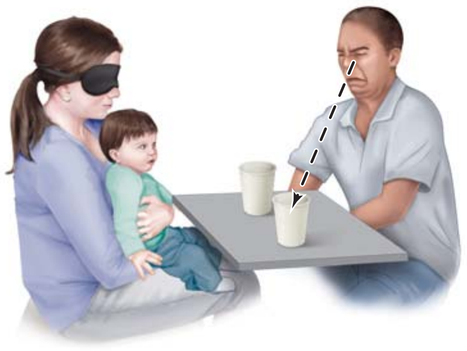
We all have done or said something in a heated moment that we later regret. Anger, sadness, fear, and many other emotions can seem to "take over," and if unchecked, they can cause great difficulties. In their daily lives, most adults manage to keep the swings of their emotions within a fairly moderate range, but infants and young children are far less adept at avoiding outbursts or getting their surging emotions under control. Infants can work themselves into a state of uncontrollable distress that seems to feed on itself until they eventually cease crying from pure exhaustion. Children may fly into tantrums or become inconsolably sad. What is different about infants and young children that makes it more difficult for them to regulate their emotions, and how does the ability to regulate emotions develop?

Through processes of **emotional regulation**, we influence the emotions we experience, when and how we experience them, and how we reveal our emotions to others (Gross, 1998). Emotional regulation includes conscious processes, such as actively and deliberately suppressing emotions, as well as unconscious processes, such as automatic actions or habits that reduce the intensity of an emotional experience. We

SCIENTIFIC METHOD: Inferring Actions from Emotions

Hypothesis:

Preverbal infants can use the emotional states of others to infer their actions.



Method:

1. In a familiarization trial, 14-month-old infants sat on their mother's lap and watched an actor repeatedly show either a joyous reaction or a disgust reaction to one of two cups.
2. Infants then saw the actor with a neutral face either reach into the cup (attended cup) the actor had looked at on prior trials or reach into the other cup (unattended cup) he had not looked at before.
3. Experimenters recorded how long infants looked at the events when the actor's hand went into the attended cup and when it went into the unattended cup.

Results:

Infants looked longer whenever the actor reached into the cup that was not attended to before, regardless of whether the actor showed a joyous reaction or a disgust reaction.

Conclusion:

Even older infants seem to have difficulty inferring actions of others from their emotional states and instead seem to assume that people will act on things that they have previously attended to, even if they showed negative emotions while attending.

regulate positive emotions as well as negative ones. You might, for example, attempt to dampen your joy at winning a contest when you realize that your best friend lost and is terribly disappointed. Finally, emotional regulation can involve external factors, such as a parent soothing an infant, or internal factors, such as an infant purposely shifting his attention away from a frightening image (Eisenberg et al., 2010; Fox & Calkins, 2003; Thompson, 1994). These facets of emotional regulation, among others, have been explored extensively in adults (Gross, 1998). From a developmental perspective, three aspects of emotional regulation are especially important in infants: situational factors, attentional deployment, and response modification. In addition, for younger infants, the parents play an especially important role in regulating infants' emotions, as infants under 6 months have a relatively limited repertoire of ways to regulate their own emotions.

Situational Factors One way of regulating infants' emotions is to change the situation in which they are immersed, a method called **situation modification**. The change may be caused by a parent or other caregiver, and early in development, these adult-driven modifications will usually predominate in soothing the infant, such as when a parent removes a frightening toy or takes the infant out of her crib. Even young infants, however, can modify a situation themselves. Once infants are able to move about, they can sometimes modify a situation by moving away from something they find unpleasant—perhaps crawling away from the deep side of the visual cliff. They can also modify a situation with a facial expression, vocalization, or gesture. If an infant is frightened by a loud stranger, she might show an alarmed face, causing the stranger to become quieter and more soothing, thereby changing the nature of the situation. An infant who is distressed at being unable to reach a desired object may also modify the situation by gesturing to a caregiver, who then makes the object attainable. Young infants, too, may elicit parental help through crying, but this situation is somewhat different from the others, as the infants may be unable to calm themselves without parental intervention (Kopp & Neufeld, 2003).

Early on, infants are usually better able to modify the situation they find themselves in than to select the situation they prefer, as they are very often plopped into a setting by their caregivers with little chance of escape. In the early years, a responsive adult is more likely to notice an infant's negative reaction to a situation and then select a different situation on the infant's behalf. Once they can crawl, infants may be able to select a situation themselves, perhaps moving from one room to another to stay close to their mother or to avoid a frightening dog. Over the course of development, the **situation selection** method of regulating emotions becomes increasingly important as the infant becomes able to take actions that enable her to approach pleasant situations or avoid unpleasant ones.

Attentional Deployment Our attentional skills are closely related to our emotional experiences. Someone who finds it difficult to disengage from upsetting stimuli may become increasingly distressed and unable to regulate that emotion. When we use **attentional deployment** to regulate our emotions, we direct our thoughts in a way that makes a situation feel less emotionally charged. This is generally done through distraction, focusing our attention on a less adverse aspect of a situation or thinking about something else completely (see Figure 7.7A). Among all the methods of regulating emotions, infants are thought to use attentional deployment most actively. For example, they will sometimes change the focus of their attention by looking away from an unpleasant stimulus to a more neutral one. In the still-face procedure discussed in Chapter 6, infants will sometimes look away from the mother's impassive face, apparently in an effort to keep it from making them feel unhappy (Mesman et al., 2009; Striano & Liszkowski, 2005). Twelve-month-olds use similar attentional strategies to regulate their emotions in the Strange Situation (Braungart & Stifter, 1991).

Following from the infant's rudimentary skill of looking away in contexts like the still-face procedure, the ability to regulate emotions by redirecting attention develops significantly throughout infancy and early childhood, resulting in an increasing ability to avoid overexposure to negative stimuli and to achieve an optimum amount of exposure to positive stimuli. For example, a preschooler might become more skilled at not just looking away from a troubling sight, but also at purposely focusing on something else to more actively distract himself (Zelazo & Cunningham, 2007). As we will see in Chapter 17, attentional deployment strategies continue to be used throughout the lifespan.

Response Modification Another method of emotional regulation is **response modification**, which involves managing an emotional reaction by directly influencing the physiological response itself—for example, relaxing muscles or slowing the heartbeat—or by engaging in an activity that indirectly leads to a change in the expression of an emotion. The conscious use of strategies to manipulate the bodily state may be relatively late emerging, but self-soothing behaviors, such as thumb-sucking, can begin quite early (Stifter & Braungart, 1995; see Figure 7.7B). Later in infancy, at around 1 year, infants start to learn to inhibit motor movements associated with either extreme distress or overexcitement (Fox & Calkins, 2003). Over time, children learn increasingly subtle response modification techniques to handle strong emotions, such as counting to 10, taking a deep breath, or eating a favorite snack. As with attentional deployment, our response modification strategies continue to develop over the lifespan as we learn how to engage in behaviors that either reduce anxiety or increase arousal.

One form of response modification, namely the suppression of certain emotions, seems to be heavily influenced by culture. Many studies have shown how adults socialize children not to display certain emotions even when they are feeling them strongly, and these **display rules** governing what kinds of emotional expressions a particular group considers appropriate can vary dramatically across cultures (Hofer & Eisenberg, 2008; Thompson, 2011). For example, Iranian children are socialized to suppress their emotions more than Dutch children, especially when in the presence of family members. On the other hand, when Dutch children do suppress their emotions, they tend to do so more in the presence of peers (Novin et al., 2009). As another example,

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

The Effect of Parenting on Emotion Processing in Children

Early interactions between parents and their children may have a major influence on how children interpret what others are feeling. Important recent research is investigating whether growing up with abusive or emotionally inappropriate parents influences children's ability to perceive and interpret the emotions of others. One study examined the ability of 9-year-olds to detect emotional facial expressions, comparing the emotional sensitivity of children of abusive parents with that of children whose parents were not abusive. To test the children's sensitivity to even the earliest traces of particular expressions, the researchers showed them a digitally altered series of images of the same face, with the images gradually transforming from a face with a neutral expression to a face with a strong emotion, such as extreme anger (Pollak et al., 2009). When viewing the photo series that progressed from neutral to angry faces (see Figure 7.6), children of abusive parents identified anger at an earlier point in the series than the children whose parents were not abusive. But the abused children and those in the control group were equally sensitive to sad, fearful, happy, and surprised expressions. These findings suggest that abused children are especially prone to identifying ambiguous expressions as angry ones and therefore are more likely to interpret other people's expressions as being angry in real-life situations.

In another study, researchers looked at the kinds of facial and vocal emotional expressions produced by mothers who were either abusive or nonabusive (Shackman et al., 2010). When researchers rated their expressions, the abusive mothers showed facial expressions that were less typical of anger (for example, showing less intensity in lowering and contracting their eyebrows, which are typical expressions of anger) than did nonabusive mothers when they were angry. Even more important, the children of abusive mothers showed corresponding deficits in their ability to process their mother's angry expressions, having more difficulty in sensing their mother's anger. Moreover, the children of abusive mothers were more likely to be anxious, depressed, and aggressive than were the children of nonabusive mothers, possibly because of the greater uncertainty about their mother's emotional state. Other scholars have likewise found relationships between mothers who are chronically depressed and their children's abilities to identify and describe the emotions of others (Raikes & Thompson, 2006). Measures of children's neural activity associated with interpreting emotion also show differences related to their early experiences. In one study, infants and toddlers who had been institutionalized in orphanages in Romania viewed emotional faces while researchers monitored the electrophysiological activity in their brains. Compared with children who grew up in normal homes, they showed much less response in a component of electrical waves called P1 (Moulson et al., 2009). It also appeared that leaving the institution and spending time in foster care could gradually lessen these effects (see Chapter 6). Several researchers are now documenting a diverse set of such biomarkers (ranging from electrophysiological to hormonal measures) that are associated with particular social experiences with caregivers and the ability to process emotions (Strang et al., 2012).

As in so many other cases, it is difficult to be sure if abusive or depressed parents actually cause the changes in how children perceive and think about emotions. An alternative expla-

contrast the emotional expressions of children who grow up in agrarian farming families in the Nso culture in northwest Cameroon with those of urban, middle-class children growing up in northern Germany. In the Nso culture, children are socialized early to suppress any signs of negative emotions. By comparison, German children are socialized to express emotions readily, especially positive emotions that may be seen as markers of their autonomy and individuality (Keller & Otto, 2009). Yet, while some forms of response modification, such as a general suppression of negative emotions, may begin to be instilled during infancy in many cultures, the more nuanced ways of following cultural display rules in specific contexts continue to develop well into middle childhood.

Thus, well before the first year of life, situational selection, attentional deployment, and response modification each play a role in regulating infants' emotions. All three processes are present early on, and they become more sophisticated in the months and years that follow. In addination is that some of the same factors that cause parents to be abusive or depressed may also affect their children's abilities to perceive and understand emotions. For example, some abusive parents may have genetically predisposed biases in how they perceive and understand emotions that contribute to their abusive behavior. If so, their children may inherit these predispositions and show similar problems perceiving and interpreting what others feel. Another possibility is that some kinds of environments are so stressful that they can cause both parents and children to perceive and understand emotions differently. Such alternatives need to be explored more fully, but the finding that abused children are sometimes *more sensitive* to negative emotions suggests that these children have fairly complex differences in emotional processing, rather than simple deficits.

It is critical that we learn how early such emotional processing differences appear in these children's behavior in order to understand whether interacting with emotionally dysfunctional parents is a root cause. That research, in turn, will help researchers determine when negative effects of abusive parenting first appear. Taken together, these future research findings will help guide practitioners in their decisions concerning how to better intervene and help children who grow up in such environments.

tion, these processes interact from a very early age. An infant may modify a response in a way that also deploys her attention in a different manner and that consequently modifies her situation. As each of these processes becomes more sophisticated and interacts with the others, they collectively offer many ways for cultures to exert their own influences and create culturally unique patterns of emotional modulation that go beyond these early forms. Finally, as children grow older, they develop new emotional regulation processes. One example involves cognitive reframing or reappraisal (Gross, 1998), which consists of rethinking a situation to interpret its negative aspects in less upsetting or more positive ways. There is not yet any evidence that infants are able to use this kind of cognitive reframing, but such a process may yet be shown to have precursors in infancy. Interestingly, the neural circuits involved in distraction and reappraisal during emotional regulation have several distinct components, which may help explain why these two forms of regulation have different developmental trajectories (McRae et al., 2010).

A

B

FIGURE 7.7 Emotional regulation. All infants learn to regulate both unpleasant and pleasant emotions, a process that involves several components that can take many years to fully develop. **(A)** Infants can use attentional deployment and learn to redirect their attention elsewhere if an aversive event (for example, a competitor with a toy) is troubling them. **(B)** Infants can also use response modification. For example, self-soothing, by putting a hand or a thumb in one's mouth, can be a surprisingly effective technique for some infants.

Q: In what ways are infants less able to regulate their emotions than older children and adults?

Evolutionary Preparedness and Emotional Development

In some cases, the developmental paths of emotions may be strongly constrained because the child is *prepared*, in the evolutionary sense, to experience distinctive emotions in certain well-defined situations. As described in Chapter 4, many species learn some associations more readily than others because they involve behaviors that are especially important to the species' survival in its natural environment. Likewise, humans might be prepared, even in infancy, to more quickly learn to feel disgust toward certain things and fear toward other things because of the ways that certain responses promoted our ancient ancestors' survival. For example, it is much easier to develop a fear of snakes or spiders—which posed real threats to our forebears—than a fear of rocks or fish. To see why some emotional responses are thought to be prepared in this way, we will look more closely at fear and disgust responses and then briefly turn to other possible cases of prepared emotions.

Preparedness for Acquiring Certain Fears One kind of fearful reaction that is especially salient involves **phobias,** which are extreme, often irrational fears of specific things or situations. Some people have quite distressing and disruptive phobias of such things as going outdoors, flying in airplanes, or eating food cooked by others, but it is a mistake to think of all phobias as maladaptive. All humans and some other species may share fears of particular kinds of events and objects, and for good reason. This chapter does not consider the development of clearly irrational and maladaptive phobias, which are forms of psychopathology. The focus here is on the ways in which some fears are influenced by prepared learning.

An upsetting experience is much more likely to become associated with the fear of some objects than with the fear of others. A clinical observation of a 4-year-old girl who saw a snake in a park while she was on an outing with her family nicely illustrates this aspect of prepared learning of phobias (Marks, 1977). On seeing the snake, the girl had examined it with interest but no apparent fear. Then, a little later, she accidentally hurt her hand on the door of her family's car. If she was to develop any phobia following this outing, it seems likely that she would come to fear car doors or perhaps cars. Instead, she developed a lifelong fear of snakes. She strongly associated the experience of pain and trauma with the snake she had recently encountered, even though she had seen the snake *before* the car door accident. Learning to associate a painful or unpleasant experience with something encountered much earlier runs counter to the principles of classical conditioning, which predicts stronger learned associations between events that happen closer together in space and time. But a more evolutionary or ethological perspective easily explains the girl's experience and the resulting phobia. Instead of focusing on whether her experience with the snake and her injury happened very close together in time, these approaches emphasize the adaptive survival value of being highly sensitive to learning fears of natural dangers, such as snakes (Seligman, 1971).

If humans are indeed prepared to learn certain fears, it should be possible to show these biases in young children and perhaps even in infants. Just as infants have biases for more easily learning about human speech and human faces, infants may also have biases for quickly learning about evolutionarily threatening stimuli in the environment, such as snakes and spiders (LoBue et al., 2010; Rakison & Derringer, 2008). If humans are prepared to develop fears of snakes and spiders, it might make adaptive sense for these fears to emerge very early and to become easily associated with threatening stimuli (see Figure 7.8).

The most compelling argument that prepared fears have a strong genetic component (rather than developing mostly through experience) comes from studies in which the developing organism is afraid of particular "naturally" feared objects without having been previously exposed to them, either directly or culturally. Because such studies require subjects to be socially and culturally isolated, they are not ethical to do with humans, but they can be done with rhesus monkeys. In one study, researchers showed monkeys who had been raised in isolation videotapes of other rhesus monkeys exhibiting extreme fear to different sorts of stimuli (Cook & Mineka, 1989). Through clever editing of the tapes, some monkeys saw videos that seemed to depict model monkeys showing fearful reactions to harmless items, such as flowers or a toy rabbit, while other monkeys saw videos of model monkeys showing fear of a toy snake or a toy crocodile. Although the monkeys who watched the videos had not seen any of the feared objects before or had any opportunity to learn about them, they nonetheless developed a strong fear of snakes and crocodiles and no fear of rabbits or flowers. Thus, without any experience of the kinds of fearful events they watched, they developed fears in response to certain prepared stimuli simply by seeing others respond to them fearfully.

Like the rhesus monkeys, young children often show a strong prepared fear of snakes before they have had any negative experiences with them—or any experiences with them at all. In one set of studies, children between the ages of 3 and 5 years were asked either to find a picture of a snake among eight "distractor" pictures of harmless objects, such as flowers, or to find a flower picture among eight snake pictures (see Figure 7.9). Similar studies used pictures of frogs or caterpillars for distractors, both of which have some snakelike features. In all cases, even the 3-year-olds identified the snake picture among the distractors much faster than they could find another object among pictures of snakes (LoBue & DeLoache, 2008). Equally important, the children who had no prior experience with snakes were just as likely as those with substantial experience to detect snakes more quickly. Apparently, even without any direct experience with snakes, young children are much more vigilant for snakes than for other objects and notice them much more quickly (LoBue, 2013).

Further evidence shows that young children not only notice snakes especially quickly, but also are prepared to learn to fear them. In a second line of studies, researchers showed infants as young as 7 months a short video, either of snakes or some other exotic animal, while the infants listened to either a fearful voice or a happy voice (DeLoache & LoBue, 2009; see Figure 7.10). Even 7-month-olds looked longer at the snakes when the snakes were paired with the fearful voice, indicating that they were especially prepared to associate fear with snakes. Nonetheless, they did not look longer at the snakes when there was no sound accompanying the videos or when still pictures were used. Apparently, in young infants, one trigger for the fear of snakes involves associating the fear with an animated display. Infants also seem to show a similar prepared fear of spiders in the first 6 months of life. Infants as young as 5 months show a preference to visually track spider stimuli over other

FIGURE 7.8 Prepared fears. The preparedness model suggests that a toddler will be much more prone to develop a fear of snakes than to develop a fear of neutral objects.

DEVELOPMENT AND SOCIAL POLICY

The Causes and Consequences of Problems in Emotional Regulation

Some young children seem to lose control of their emotions whenever they get upset, spiraling into fits of despair, anger, or both. These children are not just touchy or easily distressed; instead, their emotions seem to run away from them.

Some children who have difficulty regulating their emotions seem to have problems in the domain of *emotional intelligence*. That is, they have difficulty inferring others' emotional states from their expressions and behavior, and they do not seem to understand how specific situations are likely to lead to certain emotions (Salovey & Sluyter, 1997; see also Chapter 11). These difficulties also seem to extend to their perceptions of themselves. They have difficulty recognizing and understanding their own emotions (Shields et al., 2001). As a result, they may have trouble keeping their feelings in check as a highly emotional situation starts to ramp up. A child with low emotional intelligence may fail to notice his own emotional response early enough to regulate it effectively.

Difficulties with emotional regulation can begin to cause other problems for these children quite early. Thus, young children who have trouble keeping their own emotions in check or understanding their own emotions and those of others tend to have more difficulty than their peers adjusting to the first year of preschool (Shields et al., 2001). Despite the challenge of precisely defining and measuring emotional regulation problems (Cole et al., 2004; Eisenberg & Spinrad, 2004), research suggests that toddlers and young children who have an unusually difficult time regulating their emotions seem to be more likely than other children to experience behavioral problems later in life, including having greater anxiety, depression, and difficulty interacting with peers.

Nonetheless, not all children with emotional regulation problems go on to have these difficulties. Rather, the level of stress in the child's environment seems to influence the outcome. We have seen this kind of interaction between a child's own tendencies and his environment in other domains of development as well; this is another instance in which a group of infants or children are not *predetermined* to have a particular kind of problem, but are at risk for doing so if they also have certain kinds of experiences. For example, one study compared two groups of children who were determined to be genetically at risk for emotional regulation problems but had experienced different kinds of parenting styles. One group of at-risk children who had a short form of a serotonin-related gene (see Chapter 6) grew up with parents who were not fully responsive and sensitive to their needs, and these children did indeed develop poor emotional regulation skills (Kochanska et al., 2009b). The other group of at-risk children had the same genetic allele associated with emotional regulation problems, but the children in this second group had more responsive parents. Interestingly, the children in this second group did not develop any more emotional problems than children who showed no genetic risks.

Much as in our discussion of parenting styles and attachment in Chapter 6, we should not assume that parenting styles directly

objects such as flowers, suggesting an early-emerging bias to monitor certain kinds of potential threats (Rakison & Derringer, 2008). Finally, at least one study suggests that female infants may be more predisposed than male infants to associate fear with snakes and spiders, a pattern that is also found in adults (Rakison, 2009) and that raises questions about origins of sex differences in some phobias.

The evolutionary roots of phobias serve to remind us that although the same situation can elicit different emotions in different people, the relation between situations and emotions is not arbitrary (Ohman & Mineka, 2001). We easily learn to fear potentially dangerous natural stimuli like snakes, and we find it hard to extinguish those fears. Moreover, we can even acquire those fears in cases where snakes are presented so briefly that we are not even aware of them (Mineka & Ohman, 2002b; Ohman & Mineka, 2003). These patterns of fear conditioning follow some of the usual laws of associative learning, but they also go beyond them in ways that reflect strong preparedness effects (Mineka & Ohman, 2002a). In short, many species seem to share evolutionarily ancient predispositions to develop fears of snakes, spiders, and even heights and other categories of stimuli (Barrett, 2005).

Preparedness and the Development of Disgust We have seen that some fears are rooted in prepared learning and do not depend purely on experience. Is the development of other emotions also influenced by adaptive prepared-caused emotional regulation problems in the first group of children, since many other genetic and environmental factors were also involved. But such a study does offer a plausible account of how one aspect of a child's environment (parenting style) potentially might interact with emotional regulation problems and influence the child's emotional development. Similarly, another study showed how insecurely attached children and coercive parents could get into vicious negative-feedback loops in which the parents' increased coercive behaviors seemed to exacerbate poor emotional regulation skills in their children, which in turn led to more coercive behaviors by the parents (Kochanska et al., 2009a). More generally, researchers may refer to "emotional availability" in parent-child relationships, where emotional availability includes effective emotional communication between parent and child, mutual emotional understanding, and emotional accessibility of each partner in an interaction. High levels of emotional availability in parent-child relationships are associated with good emotional regulation skills in infants (Bornstein et al., 2012).

One way that parental influence can work is by affecting the strategies that children develop for coping with emotional regulation. For example, infants of depressed mothers seem to cope with their distress differently than infants whose mothers are not depressed. Researchers examined the reactions of two groups of 5-month-olds—those whose mothers were depressed and those whose mothers were not—to the still-face procedure, in which the mother shows the infant a frozen, unresponsive, neutral expression. Infants whose mothers were clinically depressed were more likely to deal with the still face by using behaviors such as thumb-sucking to soothe themselves. In contrast, infants of nondepressed mothers were more likely to use attentional deployment strategies, such as looking away from the still face (Manian & Bornstein, 2009). One interpretation of these results is that infants of depressed mothers felt a stronger need to remain engaged with their mothers, who are often nonresponsive. Rather than looking away, even though the still face was upsetting, they kept looking at their mothers and tried to comfort themselves in other ways.

Children's emotional regulation problems raise a number of difficult questions. First and foremost, what can be done to help these children with their emotional struggles? One common therapeutic approach is to focus on specific behaviors, such as tantrums associated with excessive anger. In this case, a therapist might work with a child and his parents to develop strategies for modifying the child's tendency to throw tantrums (Kazdin, 1997). The therapist might teach the child an alternative behavior that more effectively regulates anger, such as deep breathing, and show him how it is more rewarding in the long run than throwing a tantrum.

A different approach attempts to expand on the child's ability to understand his own emotional states and those of others, assuming that such an increased awareness will lead to enhanced abilities to arrest an emotional surge before it gets out of control (Slaby et al., 1995). In addition, because parents of children with emotional regulation problems often discourage talk about emotions, developing strategies for having more extensive discussions between parent and child about emotional states may also be a way to give children some insight into how to manage their emotions (Suveg et al., 2005). With these approaches and a number of others, many children who have trouble regulating their emotions may be able to develop appropriate skills and see real, long-term improvements. Ideally, we would like to intervene earlier in infancy, when these problems may start to emerge, but the challenge is to design effective interventions for infants. Training parents to be more responsive and less coercive to their infants may well be the best strategy with younger infants.

ness? Disgust may well be another emotion that occurs in response to particular stimuli within the constraints of prepared learning. This idea dates back to Charles Darwin (1872/1975), who noted that disgust seems to consist of the specific emotion and facial expression that relate to potentially ingesting something offensive (see Figure 7.11). Emotional responses that are universal to humans are the ones most likely to have roots in evolutionarily prepared reactions. In the case of disgust, prepared reactions seem most likely in response to ingesting either living things or their by-products (hair, body excretions, and the like). In addition, there is a universal bias toward reactions of disgust to food that is physically connected with something offensive (for example, a long string connecting a plate of food to a disgusting substance), even when there is no way the physical connection could contaminate the food. Similarly, if an object has previously come into contact with offensive material, such as feces, people often react to that object with disgust, as if it has been contaminated, even if there is no rational way that any contamination could survive.

Although disgust, like some fears, shows evidence of preparedness, its development shows different patterns of change and cross-cultural variability than we saw with prepared fears. For example, disgust toward feces appears to be universal to adults in all cultures (Rozin et al., 1986, 2000, 2008), but it is not usually present in toddlers in any culture, at least not until the children are toilet trained. Instead, it typically develops sometime between 3 and

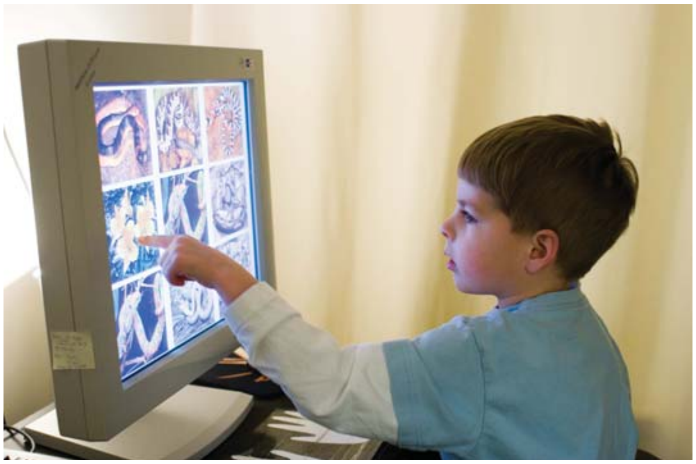

FIGURE 7.9 Threat detection. Preschool children tend to more quickly detect snakes than flowers. This may be because humans have evolved a bias to see snakes, but not flowers, as threatening. This boy is shown eight pictures of snakes and one picture of a flower on a computer monitor and asked to touch the flower. It takes him longer to identify the flower than it would to identify one snake in the midst of eight flowers. From LoBue & DeLoache (2008).

7 years of age (Rozin et al., 1986, 2000). Disgust seems to develop from a response to a very narrow range of stimuli, such as disgusting tastes (typically bitter ones early on), to a much broader range of stimuli. One view suggests that humans' earliest disgust reactions to bitter substances may be shared with many other species. As children grow older, however, the emotion of disgust becomes more general, as it is applied to items that could cause disease, such as animal body products. It then becomes further generalized to things and events that more broadly threaten the integrity of the body, such as death, wounds, bad hygiene, or sex. These extensions of disgust beyond taste seem to be unique to humans (Rozin et al., 1986, 2000, 2008).

Finally, all humans seem to develop culturally specific extensions of disgust to strange or undesirable people and to certain moral offenses, both of which pose potential threats to the social order. This ability to rely on culture for broadening the disgust category may have its roots in early infancy. Thus, while infants may not show stable disgust reactions to much beyond bitter tastes, by at least 11 months they do take note of adults' disgust reactions and avoid the objects of those responses (Hertenstein & Campos, 2004). Later in development, by at least 5 years of age, children are able to extend disgust reactions to immoral actions (Danovitch & Bloom, 2009).

Disgust therefore develops differently from fear in the sense that an early, specific disgust reaction becomes extended beyond a narrow range of stimuli to a much broader set of stimuli. Even in those extensions, however, humans show evidence of preparedness to associate disgust with particular types of things and situations, such as contaminants that threaten the integrity of the body or that potentially cause disease (Oaten et al., 2009). That notion of disgust may then become extended to certain sexual practices or moral transgressions that may contaminate the social system either by reducing reproductive success or by violating social norms (Tybur et al., 2009). Interestingly, even these broader extensions of disgust may be evolutionarily constrained, such that adults show disgust pertaining to three major domains: disease contamination from invisible things, such as microbes; certain

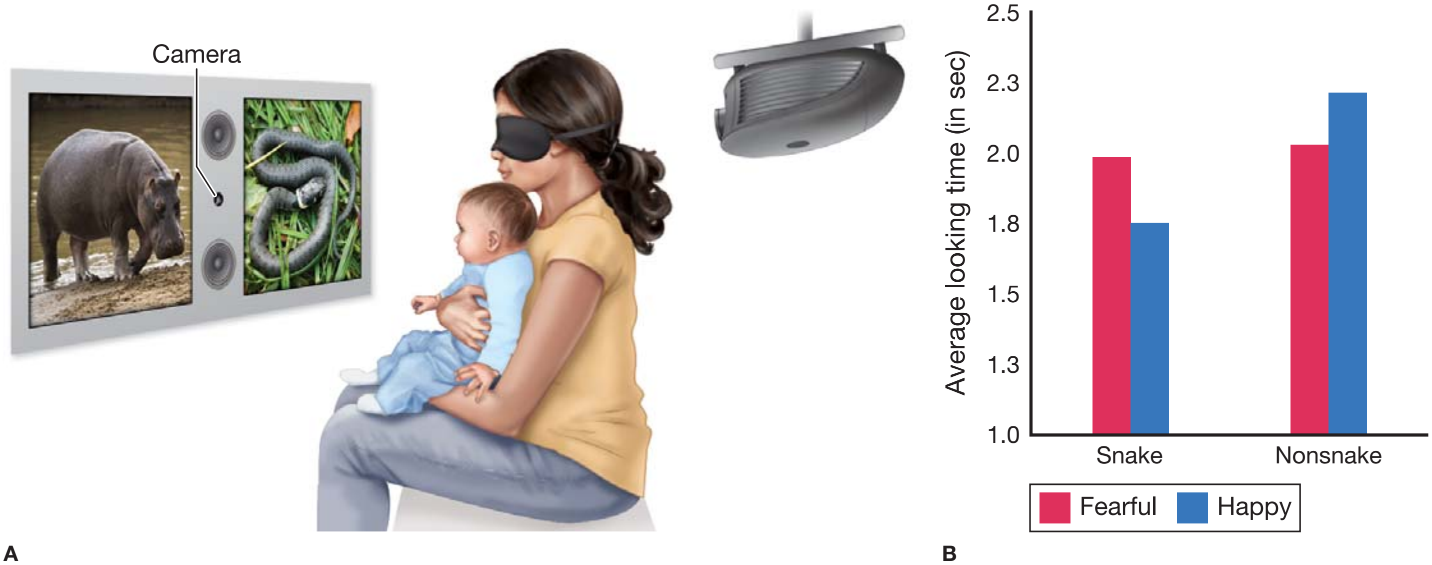

FIGURE 7.10 Learning to associate snakes with fear. (A) In this experiment, infants sit on their mother's lap and watch videos showing hippos and snakes accompanied by fearful or happy voices. **(B)** Infants as young as 7 months will look longer at a brief video of a snake when they hear a fearful voice, but not when they hear a happy voice. They look equally long at brief videos of hippos when they hear a happy voice as when they hear a fearful voice (the nonsnake differences shown are not statistically significant). Adapted from DeLoache & LoBue (2009).

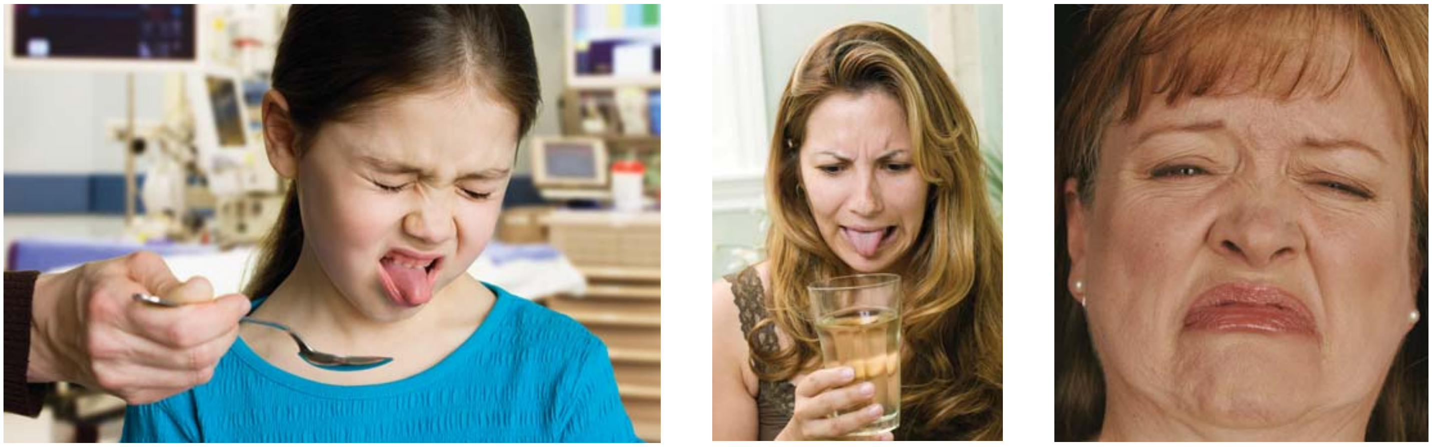

FIGURE 7.11 Preparedness for disgust. As these photos illustrate, disgust reactions are easy to observe in people of all ages. One component of the reaction seems to be a reflexive set of movements that serve to block any additional offending substances from entering the mouth.

types of immoral actions; and choice of sexual partners and behaviors. One major remaining challenge is to understand how and why people seem to develop a common emotional reaction to offenses within these particular diverse domains. Other questions that are still being investigated have to do with the reasons women tend to react more strongly than men to most disgust-provoking stimuli (Björklund & Hursti, 2004; Haidt et al., 1994; Marzillier & Davey, 2004, 2005).

Q: How might irrational thought related to disgust be evidence for disgust as a biologically prepared emotion?

Preparedness and the Development of Other Emotions The idea of preparedness may explain some aspects of the development of most emotions, but the details of these explanations await further work. For example, smiling may be a prepared response to a particular set of situations, which in turn helps give rise to feelings of joy. (The situation may give rise to joy itself, but the smiling response may enhance that feeling.) As mentioned earlier, the idea that emotions are rooted in prepared, adaptive responses to particular situations fits well with the view that emotions involve responding to situations in goal-directed ways. That is, certain emotions may be prepared to be associated with certain specific *combinations of goals and situations*. Thus, you are much more likely to be angry when a goal is blocked intentionally by others than when the obstacle is caused by natural events. Anger is surely more effective when it is expressed to another being who can respond to it than when it is displayed to something inanimate. For that reason, natural selection may have favored a prepared anger response to obstacles purposely raised by others.

We have seen that certain kinds of emotions seem to be linked, quite possibly through natural selection, to particular kinds of stimuli and to certain response routines. Over and above these deeply rooted linkages, emotional development involves constant refinement, fine-tuning, and extension of prepared emotions to broader classes of situations, resulting in more sophisticated and nuanced responses. Ultimately, our understanding of these prepared emotional systems needs to be integrated into broader accounts of how all emotions and our ways of regulating them develop. In addition, such an integration may bring new developmental insights into the close relationship between emotions and personality.

Temperament and the Origins of Personality

Any parent who has more than one child quickly realizes that different infants tend to react differently to similar situations. What frightens one infant might interest another. Some infants greet a challenge with anger, others respond with sadness, and still others show renewed effort. An infant's tendency toward particular emotional and behavioral responses to specific situations is known as **temperament**. An individual's temperament emerges early in life and remains relatively stable over time and can also involve individual differences in self-regulation (Goldsmith & Campos, 1982; Goldsmith et al., 2000; Rothbart & Bates, 2006; Zentner & Bates, 2008).

Temperament describes, roughly, an infant's personality. But most researchers use the term *temperament* when describing an infant's disposition because behavioral differences among infants are not the same as those that distinguish older children or adults. Because temperament describes infants' emotional tendencies, features of adult personality centering around emotions and moods seem to be among the most likely aspects of personality to have clear roots in infant temperament. But even in these domains, infants certainly do not show the richness or complexity of personality that older children and adults do. Moreover, personality includes many other aspects of human variation, such as intelligence, creativity, and self-monitoring ability, to name a few, that seem highly implausible—or at least unmeasurable—in infants. These considerations have led researchers to talk about temperament as a more biologically rooted and hence earlier-emerging part of personality (Allport, 1937; Buss & Plomin, 1984). Hence, the vast majority of research on the origins of personality in infancy has focused on studying infant temperament.

Q: What is the difference between temperament and personality? How are they related?

As we will see, a major challenge arises in trying to understand how differences in temperament among infants are part of the larger story of personality development. As part of that challenge, we will ask how differences in temperament that are present in infancy contribute to later patterns of personality and how certain types of social experiences and cultural practices influence this process.

Temperament-Based Components of Personality and Early Development

The notion that the richness and diversity of personality might develop from different combinations of a relatively few biologically based values actually dates back thousands of years. The ancient Greek physician Hippocrates was the first to offer a detailed version of this theory (Arikha, 2007; Smith, 1979). He believed that there are four different personality types, which reflect different balances of the body's four humors (derived from the Latin *umor*, meaning "fluid"): blood, phlegm, yellow bile, and black bile. For example, he thought that people who are social, outgoing, and optimistic show those traits because they have a relatively large amount of blood, whereas melancholic, introspective, and morose people have an abundance of black bile.

Although there is no physiological basis for Hippocrates's theory, it shares some important elements with the modern understanding of both temperament and personality. For example, many researchers hold that the vast variety of personality differences—over 10,000 terms in English refer to aspects of personality (Allport, 1937; Goldberg, 1982)—emerge from far fewer critical components, such as fearfulness and agreeableness. In this view, these few components interact with one another and with other aspects of a person and her experiences, yielding all the traits and types of personality (Cattell, 1978). Perhaps surprisingly, the four personality types that Hippocrates described resemble some of the categories presently described by researchers who study infant temperament and the development of personality.

Modern views of temperament integrate biological views with psychological processes. One influential line of work with a strong biological emphasis focused on the early emergence of temperament and its high degree of heritability—that is, how much genes contribute to individual variation—as its critical attributes (Buss & Plomin, 1984). These approaches are sometimes called *trait approaches* for their emphasis on behavior patterns as heritable traits. Over the years, this view evolved into an account that focused on three fundamental trait-like categories—emotionality, activity level, and sociability—which were thought to make important contributions to later personality traits. These three categories have become prominent for several interrelated reasons. First, each has been associated with significant heritabilities across a wide range of studies, suggesting important influences of genetic pathways. Second, several neural circuits and structures are associated with these categories. For example, amygdala activity is associated with both emotionality and sociability and more broadly with approach and withdrawal tendencies. The amygdala and its associations with temperament have also been linked to genetic variations. Thus, in young primates, a particular variation of the central amygdala gene *Ce* has been linked to anxious temperaments through a pathway that involves decreased receptor production and activity in the central amygdala (Fox et al., 2012). The same gene and its variants are present in humans. Other physiological correlates of emotionality, sociability, and activity level can involve variations in heart rate, cortisol levels, and the degree of involvement of the frontal lobes (Henderson & Wachs, 2007; Zentner & Shiner, 2012). Finally, there seem to be analogous temperamental variations in a variety of social species, including some primates and dogs, suggesting an adaptive role for these dimensions of temperament that occurs robustly across several species.

As always, the involvement of both genetic and biological influences should not be interpreted as genes and biology predetermining an infant's temperament. Instead, these factors interact with particular kinds of environments to create differences in temperament. These environmental influences include parent-child interaction patterns and the degree to which an infant's environment is predictable and nonthreatening.

Other researchers on temperament focus on individual differences in infants' tendencies to express and regulate basic emotions (Goldsmith & Campos, 1982, 1986, 1990). Consider basic emotions such as sadness, happiness, anger, surprise, and fear. Temperament would be interpreted here as tendencies to show either high or low levels of such emotions. We can see how differences in emotionality, activity level, and sociability could all lead to different tendencies to express basic emotions. Hence, even though these two approaches to temperament seem quite different, they may both be related to regulation of emotions. Indeed, if emotions are seen as having functional roles concerned with mobilizing oneself and eliciting reactions in others, emotional regulation can be seen as intrinsic to variations in the tendency to express emotions.

Determining Differences in Temperament

To identify different characteristics of infant temperament, researchers have used reports by caregivers, observations of infants in natural settings, and observations of infants in the laboratory. In the earliest studies on temperament, researchers used parents' reports about their infants and then coded the behaviors into a set of general characteristics. In all these approaches, stability of a temperamental classification over time and a range of situations was an important concern. Thus, a quick emotional reaction by an infant to a threatening situation is interesting to the extent that it appears repeatedly in similar contexts. Researchers also had to find ways to distill from thousands of highly specific observations of infant behaviors much broader characterizations of individual differences that enabled them to talk usefully about different temperamental types and dimensions. Moreover, the entire approach was also mindful of the long-term goal of ultimately connecting these broader factors to personality types in older children and adults.

The New York Longitudinal Study A major milestone in temperament research came in a large-scale longitudinal study conducted by Alexander Thomas and Stella Chess (Thomas et al., 1963, 1968; Thomas & Chess, 1984). Recall that a longitudinal study involves assessing each child repeatedly over an extended period of time to explore what remains constant and what changes in the child. The children in Thomas and Chess's New York Longitudinal Study were studied from infancy to middle age. As seen in Chapter 1, the central questions in this approach and in most other longitudinal studies on individual differences are whether what is measured at one age shows a similar value across all ages, observers, and situations (reliability) and whether the measure predicts the more naturalistic and intuitively compelling behaviors that are thought to underlie the temperamental measures (validity).

Among its most important contributions, the New York Longitudinal Study suggested some patterns in the development of temperament that became a basis for later research. Based on extensive interviews with the mothers at the beginning of the study in which each mother was asked to provide a detailed description of her infant's daily activities and routine rather than explicit information about the infant's personality or temperament, the researchers described nine dimensions of temperament: activity level, approach/withdrawal (from novel objects, people, or situations), adaptability (ease of changing responses to situational influences), mood (positive or negative feelings), threshold of responsiveness (when an infant starts to respond to a stimulus), intensity of reaction, distractibility, rhythmicity (regularity of biological functions), and attention span/persistence. Each baby was then scored and classified into one of three categories: (1) *Easy babies* (roughly 40 percent of the group) were happy and adaptable, generally showed a positive attitude, did not overreact to situations, and had regular daily routines. (2) *Difficult babies* (roughly 10 percent of the group) were often unhappy, did not adjust well to new situations, had irregular eating and sleeping patterns, and tended to show intense reactions. (3) *"Slow to warm up" babies* (roughly 15 percent of the group) were initially negative in mood, less active, reacted with relatively low intensity, and adapted slowly to new situations. The remaining 35 percent of the participants were called *average babies*, and they tended to have intermediate values on these scales.

Over the years, Thomas and Chess examined how these categories of infant temperament might relate to different patterns of behavior in later life, and they suggested some longer-term relationships. For example, they believed that a difficult baby who is also highly reactive to situations and shows a low attention span might be less likely to do well in highly structured elementary school settings and more likely to have hostile relations with peers (Rubin et al., 2003; Thomas et al., 1968). Moreover, children considered to be slow to warm up might tend to become more isolated from peers and would rarely become central members of social groups.

In several ways, the New York Longitudinal Study laid a crucial groundwork for later studies. First, it looked at infant behaviors in their own right rather than conceiving of them as infant versions of adult behaviors and qualities. Second, it suggested that infants' behaviors could be coded into temperament categories that might have some degree of developmental continuity, at least into the school years. Finally, it started to reveal how the specific circumstances of a child's development could strongly modify a child's temperamental disposition. Although the study has been criticized for failing to meet various criteria of reliability and validity, this frequently happens for studies that develop the first systematic measures in an area (Rothbart &

Bates, 2006). It usually takes time and considerable trial and error to work up optimal measures. Moreover, in longitudinal designs, it may be difficult to change a measure at later ages, even when its shortcomings are fully realized, as a changed measure might prevent direct comparisons with results at earlier ages.

Modern Approaches to Studying Temperament

Researchers have now developed more sensitive and accurate ways of measuring infants' temperament in terms of their behavior in particular settings. One especially promising measure, the Infant Behavior Questionnaire-Revised (IBQ-R) describes temperamental differences between infants in terms of three major dimensions: surgency/extroversion (such as exuberance, sociability, and approach, as well as impulsivity), negative affectivity (such as sadness, fearfulness, and irritability), and orienting/regulation or effortful control (such as effective shifting of attention, ability to focus on tasks, and behavioral inhibition). This questionnaire involves asking various caregivers specific, detailed questions about the infant's behavior. For example, where an older questionnaire might ask parents to rate their agreement with the statement "Child is very energetic" on a five-point scale (Buss & Plomin, 1984), the IBQ-R might ask, "When put in the bathwater, how often does the baby splash or kick?" and require caregivers to rate the frequency in the past week (Hwang & Rothbart, 2003). The second questionnaire leaves less room for different interpretations of what is being asked and over what time period. Questionnaires like this one, which ask about more focused, concrete behaviors, produce more reliable and valid results.

Thus, by focusing on specific behaviors and incorporating responses from several adults who regularly spend time with the infant, the IBQ-R helps reduce the influence of parents' subjective judgments. As a result, there is typically good agreement among an infant's different caregivers (Gartstein & Rothbart, 2003). In addition to questionnaires on temperament and the kinds of interviews with parents that Thomas and Chess used, researchers also observe children directly in their homes and in laboratory settings (Rothbart & Goldsmith, 1985; Rothbart et al., 2000). These converging methods help researchers focus on those aspects of temperament that are more consistently found across many situations (Goldsmith et al., 1999).

Researchers are also examining how the development of the brain's networks that regulate attention may relate to the emergence of individual differences in temperament (Posner & Rothbart, 1981; Rothbart et al., 1995, 2008). As the brain systems underlying attention (for example, the prefrontal cortex and anterior cingulate gyrus) mature, infants and young children develop the ability to focus and shift their attention, becoming increasingly able to direct their attention away from unpleasant aspects of a situation to focus on more pleasing ones. As a result, they become better able to inhibit and control their actions and perceptions (see Chapter 4; see Jackson, 1865/1958), which also significantly influences their ability to regulate their emotions and other aspects of their social development.

Because differences in attention play a role in early-emerging variations in temperament, researchers have started to ask whether variations in growth rates of the brain's attentional systems might help explain how some temperamental differences unfold over time. In fact, children appear to show different rates of maturation of these attentional systems, which may give rise to differences in temperament (Morales et al., 2005; Posner & Rothbart, 2009). A child who is less able to shift attention away from an unpleasant situation or thought might well develop a different kind of responsiveness to everyday situations (such as a crying younger sibling, an angry parent, or a frightening dog) and might sometimes develop more serious problems controlling attention that could lead to anxiety and depression (Racer & Dishion, 2012). Researchers are also finding that the development of the different neural networks that support specific attentional abilities—like purposefully shifting attention or ignoring distractions—seems to be influenced by different genetic pathways. Thus, one way that genes may contribute to variations in temperament is by fostering different developmental patterns in specific attentional capacities (Posner et al., 2010).

Q: How can studying the development of infants' attentional systems help us understand their individual differences in temperament?

Another approach to studying temperament focuses on the temperamental differences between infants who appear inhibited and those who seem uninhibited (Kagan, 1994, 2008). Inhibited infants and young children are more likely to be fearful and tentative in novel surroundings, such as a trip to a new store or meeting new neighbors, whereas uninhibited infants show more positive emotions and exploratory behavior in these settings and enjoy the novelty. Distinguishing between inhibited and uninhibited behavior might seem to describe a single dimension of behavior, related to how eagerly the infant engages with her world. But a leading researcher in this area, Jerome Kagan, believes that infants' inhibited behaviors actually have different biological bases than their uninhibited behaviors (Kagan, 2008). In addition, these two tendencies toward either wariness (inhibited behavior) or ready engagement (uninhibited behavior) can affect other aspects of temperament, because these tendencies interact with the degree to which certain kinds of emotions are expressed. In particular, uninhibited infants are more likely to express positive emotions, such as happiness, and inhibited infants are more likely to express negative emotions, such as fear.

Kagan suggests that the development of inhibited and uninhibited behaviors in infancy shows some significant patterns that seem to be human universals. For one, children throughout the world show increasingly inhibited behaviors in response to unexpected or unfamiliar events during the first two years of life. Kagan has argued that these kinds of inhibitions were important adaptive behaviors that promoted safety and survival by inducing the child to pay attention to stimulus discrepancies and not to approach or get involved in unfamiliar events (McCall & Kagan, 1970). If a child was not old enough to know how to interpret the world's real dangers, the best strategy might be to prefer what has been safe in the past and to be wary of novelty. Infants' tendency toward inhibition could also trigger distress sounds, like crying, that attracted caregivers' attention to potentially dangerous situations.

This wariness of novelty has also been documented in other species as an important behavioral strategy. For example, as some frustrated homeowners know, rats are notoriously "bait shy"; they have an enormous aversion to switching from a familiar diet to a substance with a new taste (Garcia et al., 1972). Similarly, one of the most powerful ways to contrast breeds of dogs is in terms of their different, genetically rooted levels of inhibition, or fearfulness (Mahut, 1953; see Figure 7.12). Although these differences might be influenced by the way owners interact with their dogs, different breeds' tendencies toward inhibited (fearful) or uninhibited (bold) behaviors are robust enough to demonstrate that these temperament-like differences can have a strong genetic component (Jones & Gosling, 2005; Saetre et al., 2006). More broadly, these comparative studies of genetic differences in animals' temperament-like traits can shed light on how we view the origins of human temperament. Because a wide range of organisms with quite modest cognitive and attentional skills show genetic variations in behaviors such as boldness, wariness, and fearfulness, some facets of human temperament may also not require the kinds of sophisticated cognitive appraisals and attentional processes that have been invoked elsewhere. Thus, some of the oldest evolutionary roots of human temperament may not depend on sophisticated information processing (Gosling, 2001).

Kagan argues that inhibition can have considerable value in protecting young children from the hazards of the world, but only in moderation. Excessive inhibition, which can give rise to inappropriate levels of shyness, can cause problems for children if it leads them to be overly fearful and avoidant of new people and situations. Kagan and his coworkers have found that children who were very inhibited at age 2 continued to show high levels of inhibition and shyness several years later, in elementary school (Kagan, 1994). Similarly, infants who showed notably uninhibited behavior remained more uninhibited and exuberant into elementary school. More recent studies of these same children are finding that these patterns continue into adolescence and adulthood (Kagan et al., 2007; Schwartz et al., 1999, 2003).

Q: What are some evolutionary arguments for inhibited behaviors across species?

More than most approaches to temperament, the research focusing on inhibition tries to tell a coherent story of how an early trait becomes manifested in later personality differences such as shyness. Indeed, this research has documented reliable correlations between early behaviors in infancy and behaviors that emerge over the course of later childhood and into young adulthood. Kagan developed

A

B

FIGURE 7.12 Temperaments in dog breeds. Different dog breeds, such as **(A)** the border collie and **(B)** the terrier, tend to have different temperaments. A shyness/boldness dimension is one of the strongest contrasts among breeds.

his approach from an evolutionary perspective, asking about the potential adaptive value of both inhibited and uninhibited behavior, and he has repeatedly emphasized the importance of cross-cultural data for showing that the developmental courses of both inhibited and uninhibited behavior patterns are universal. Finally, he has advocated a move away from describing children by using traditional emotion terms ("a fearful child") toward describing how they respond to specific situations ("a child who shows inhibited behavior when encountering a stranger in a store"). Studies of differences in inhibition therefore provide an excellent demonstration of how one facet of infant temperament projects forward through childhood and beyond. One major reason for the success of this approach may be that it focuses on an evolutionarily ancient and foundational aspect of temperament that has an important adaptive role throughout development. We now turn to other aspects of temperament that are more richly integrated with higher-level cognitive and attentional processes and in which the links between infant temperament and personality are more subtle and complex.

Linking Temperament to Personality Development

Ultimately, researchers who study infant temperament and those studying personality in older children and adults want one smooth, integrated account showing how temperament develops into personality from infancy to adulthood (Caspi, 1998). Though there is not yet a single account of this process, we can say, in broad terms, that initial aspects of temperament likely interact with each other, contributing in complex ways to the development of personality traits throughout childhood and adulthood (see Figure 7.13). For an example of how these interactions might work, consider the personality trait of conscientiousness, which can refer to being meticulous and careful or to acting in accord with one's conscience. Conscientiousness is not present in infancy, as it develops out of the interaction of specific components of early temperament. Thus, as Figure 7.13 illustrates, this trait slowly develops as a result of the interplay between activity level and persistence/attention span. A highly conscientious individual needs relatively high levels of both attentional monitoring and activity to remain vigilant as to her progress toward her goals and to be able to act quickly and efficiently. An excess of either vigilance or activity, however, could lead to distractibility and impulsivity, so the most conscientious people may be at the high, but not extreme, ends of these temperamental dimensions. These interactions between aspects of temperament are also influenced by culture and social experiences, so that infants with very similar temperaments can develop remarkably different personalities. In the next section, we will address how such environmental influences on temperament and personality take shape.

Child-Environment Interactions and Goodness of Fit

In thinking about the role of a child's environment and experiences in the development of personality, we need to keep in mind that different sorts of environments, cultures, and parents might "fit" much better with some sorts of infants than with others. Thomas and Chess, who conducted the New York Longitudinal Study discussed earlier, referred to

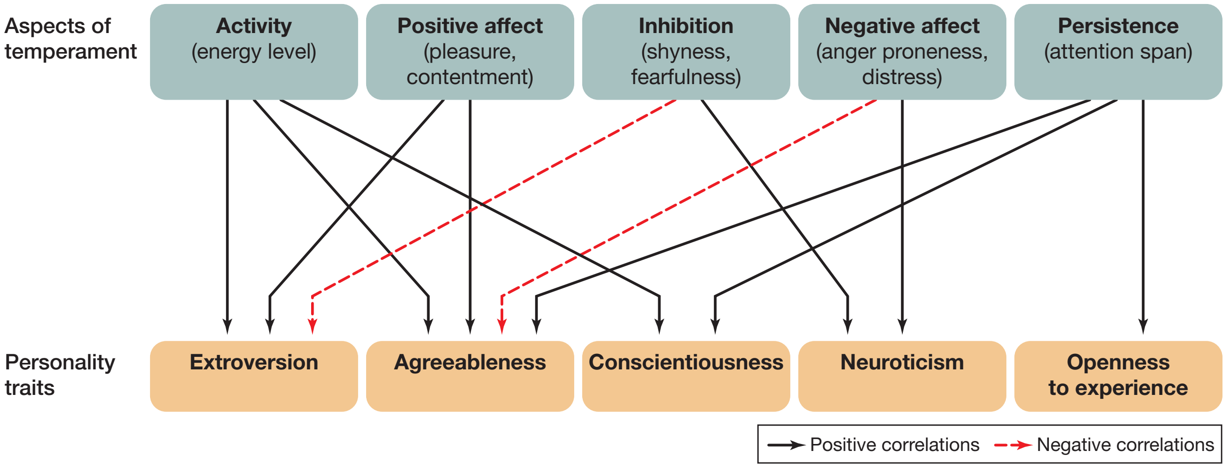

FIGURE 7.13 Linking infant temperament to personality. Linking measures of infant temperament to later personality measures is difficult. This figure illustrates one proposal about how such linkages might be organized, where black lines represent positive correlations and dashed red lines represent negative correlations. The multiple effects and possible negative and positive influences help illustrate why it is so difficult to translate infant measures into adult ones. Adapted from Caspi (1998).

this idea in terms of the **goodness of fit** between the child and the environment. In essence, the notion of goodness of fit maintains that the same environment is not optimal for all children and that an environment that could devastate some children might have little or no negative effects on others. This idea also implies that most children can flourish if they experience an environment well suited to their temperament.

The idea of goodness of fit helped launch a major shift in how we view infants and children, both within the study of development and at large. Many earlier views of development were based on the notion that children were passive recipients of whatever the environment threw at them. In contrast, the idea of goodness of fit stresses the ways in which children are active agents, whose interactions with caregivers and with their environment help to shape their development (Sameroff & Chandler 1975). The broad influence of goodness of fit has changed our ideas about the formation of personality, differences in children's learning styles in the classroom (Cronbach & Snow, 1977; Snow, 1989), and many other aspects of development. As a result, we now see children as actively seeking the best-fitting environment (for example, the environment best suited to their intellectual development; Scarr & McCartney, 1983) and parents and others (such as gifted teachers) as altering the environment to better fit each child. In the strongest terms, this concept also suggests that some environments might even have opposite effects on different types of children, helping some and hurting others. As we will see, there is now evidence to support these claims.

Q: How does the idea of goodness of fit relate to the notion of infants and children as active participants in their environment?

Environments for "Squeaky Wheels" A little reflection on the different aspects of temperament discussed so far suggests ways in which these features might enhance or diminish outcomes, depending on the infant's environment. For example, the saying "the squeaky wheel gets the grease" means that those who complain loudest fare better than others. This adage also suggests how some babies' temperaments might confer an advantage in environments involving competition for scarce resources.

In particular, we might expect "difficult" babies to show better developmental outcomes than "easy" babies in impoverished environments. A study of infants born in parts of East Africa during a drought confirmed that the "difficult" infants, although certainly not thriving, had better health outcomes and lower mortality rates than the "easy" infants (Devries & Sameroff, 1984). It is easy to imagine how a stressed, undernourished parent would find it difficult to monitor whether all of her children were receiving equal resources and instead might simply respond to the children who appeared most distressed.

Undoubtedly, difficult children also gain an advantage in other kinds of environments of scarcity. For example, we might predict that the worse the ratio of caregivers to children in a day care setting, the more likely that difficult children will get a greater share of attention, as overburdened caregivers are reduced to responding to the children who are most obviously upset. Similarly, children of impoverished families, especially larger families in which there is much competition among children for attention and resources, might fare better by being difficult (Garmezy, 1993). The outcomes associated with being a difficult infant or child also differ cross-culturally. One source of these differences has to do with how parents in a particular culture perceive the vulnerability of children and how those perceptions interact with their own child's temperament. Thus, parents who view infants as vulnerable to the influences of evil spirits and other negative forces are likely to be quite responsive to children who show high levels of distress because they are likely to perceive the distress as a sign of real danger. In contrast, parents from a culture that views young children as less vulnerable might see the same kind of behavior as whining and try to discourage it (Cervera & Mendez, 2006).

Q: Under what conditions might difficult and irritable temperaments in infants actually work to their advantage?

Parental Influences on Temperament In talking about interactions between a child's environment and her temperament, it is easy to overlook the ways that parents themselves affect a child's environment. In fact, even in identical settings, different parents can create very different experiences. For example, if a new mother is frequently distracted from what is going on around her because she is depressed, an "easy" baby might suffer from neglect because he would not call attention to his needs, whereas a more "difficult" baby who cried frequently for attention might receive adequate, if not cheerful, attention. In terms of goodness of fit, then, it seems unfortunate that children of depressed parents are often more inhibited than their peers (Kochanska, 1991). But as this example shows (and as we will continue to see), it is difficult to draw conclusions about causality based on these kinds of correlations between parents' and children's behaviors. A correlation that seems to show a parent's behavior affecting a child may really be more strongly influenced by the genes that the parent and child share, manifesting in different ways in children and adults. Thus, we can ask: To what extent is the child of a depressed parent more inhibited because of the kind of parenting she experienced? And to what extent are her inhibitions related to genetic factors that she has in common with her depressed parent?

Because birth parents and their infants share genes that might put them both at risk for certain behaviors and interaction patterns, adoption studies look at adoptive parents, who do not share any genes with their children, to find a way to ask about parental effects that are solely environmental and that do not also arise from shared genotypes. For example, one study of adopted infants and their adoptive parents asked how the adoptive parents' dispositions (in this case, their tendency to be anxious or depressed) affected infants with different temperaments, despite the fact that the infants and adoptive parents did not share any genes (Leve et al., 2010). In the study, 9-month-old infants were allowed to play with an attractive toy for a while and then were separated from the toy by a clear plexiglass barrier, which clearly induced frustration in the infants. The critical measure was how long the infants continued to stare at the barrier, the source of their frustration, rather than disengaging from the upsetting event. Infants considered at genetic risk for emotional regulation problems (because their biological parents had such problems) were more likely to stay fixated on the barrier when they also had adoptive mothers who showed high levels of anxiety and depression. This study illustrates two closely related points. First, it shows the importance of gene-environment interactions for developmental outcomes. At-risk infants do not invariably become fixated on frustrating barriers; they only do so when they experience specific kinds of parenting. Similarly, infants who are not genetically at risk for emotional regulation problems may not develop such problems, even when they experience parenting that might well promote these kinds of difficulties in at-risk infants. Second, this study shows how research designs that help to rule out particular influences can provide insight into development. Thus, the adoptive parents' behaviors influenced their children's temperament in ways independent of a shared genotype.

Q: How might a pair of monozygotic twins nonetheless develop different temperaments in infancy as a result of being reared by different adoptive parents?

As a result of their own personalities, particular caregivers mesh better with some sorts of infants than with others, and the best matches, or "fits," depend on both partners in the interaction. Recognizing that the development of early aspects of temperament are inherently interactive helps us understand why accurate measures of temperament are very difficult to develop. The interaction patterns between an infant and a caregiver form a dynamic system that is constantly changing based on the responses of both people involved. Consider a baby who, early on, is difficult—often fretful or crying and rarely content—perhaps because of an undetected earache. Some parents will find this difficult behavior extremely hard to handle, and they may begin to think about the baby in ways that reduce affection, leading to less patient behavior on the parents' part and, in turn, even more difficult behavior from the infant. The infant's increase in difficult behavior then causes more negative parental reactions, and the ensuing feedback loop can escalate negative behaviors on both sides, as shown in Figure 7.14.

Different parents might see the same early behaviors in a more positive light, interpreting them as an indication that their child is strong-willed. Or perhaps the parents would observe the infant's behavior in other situations before drawing conclusions. In such cases, the initial behavior might enter into a different feedback loop that channeled both parental and infant behavior in a much more pleasant direction, as shown in Figure 7.14. As we will see again in Chapter 16, clinicians may suggest that parents who are having difficulties with their children try to "reframe" how they construe the children's behavior (and likewise that the children reframe how they construe their parents' behavior). In some cases, such a change in interpretation can interrupt a dysfunctional feedback loop and lead to a cycle of interactions that gradually promotes more positive behaviors from both parents and children.

Several years ago, I came to know a family that used skillful reframing to deal with a challenging child. From birth onward, this boy had exhibited many "difficult" characteristics. He was extremely overreactive to change, flying into unpredictable rages even at minor problems. To most, these behaviors were enough to label the child as impossible, and he soon was setting records in his community for expulsions from preschools. One preschool director even went so far as to declare him a "juvenile delinquent" at the age of 3 (he lasted a very short time in that preschool)! These problem behaviors continued as he grew older, and by elementary school, he seemed to spend more time in the principal's office than in the classroom. Despite these negative behaviors, the boy's mother never framed his temperament purely in negative terms. She showed serious concern about her son's emotional problems and inappropriate behaviors, but rather than seeing him only as "unstable" or "impossible," she viewed these qualities as tradeoffs that come with a

FIGURE 7.14 Interaction patterns. Two different parents might have dramatically different interactions with an infant who has an earache. A parent who finds the infant's irritability aversive may withdraw and react negatively, exacerbating the subjective pain of the earache, which increases the infant's irritability, causing even more negative reactions from the parent in a downward spiral. A different parent might react in a manner that reduces (dotted red line) the infant's subjective pain and the level of irritability.

"fiery" and "spirited" disposition. In countless subtle but important ways, she helped to channel these aspects of her son's temperament into behaviors that were inspirational and exciting rather than antagonistic—and that boy is now a successful, charismatic adult. The kinds of behavior that caused such problems early on were turned into passion, enthusiasm, and, as his mother always saw it, "fiery" and "spirited" behavior.

Of course, not all behavior problems can be addressed by reframing, and there are many dangers in seeing one's children as incapable of wrongdoing. But when parents can strike a balance between taking behavior problems seriously and creating a "best-fit" environment for the child, the results can help to guide the child's temperament toward a very positive adult personality. To some extent, this influence undoubtedly involves helping the child to seek out environments and situations in which his best traits can flourish. The degree to which parents can influence or change a child's personality remains a controversial question, a topic to which we will return in Chapter 14. Even if the child's basic personality structure is not subject to much direct parental influence, however, parents may well influence the positive or negative ways in which that personality is seen.

Conclusions

While the focus on the early development of emotions and personalities may seem very different from the discussion in previous chapters of how we perceive and think about the world, strikingly similar themes emerge here as in earlier chapters. Research on the development of emotions, temperament, and personality is undergoing dramatic change. Infants are increasingly viewed as active seekers and creators, not only of their environments, but also of their own emotions, temperaments, and personalities. Rather than simply responding emotionally to a particular event or having features of temperament and personality impressed on them from the outside, they are constantly interpreting the world and using those interpretations to act on it. These interpretations and actions give rise to emotions and also contribute to aspects of temperament and personality.

Emotions also have an adaptive value that allows infants to regulate their own responses and their interactions with others. Along these lines, different personalities and temperaments have different advantages and drawbacks, depending on the environment. This has fostered the idea of goodness of fit—namely, that individual infants and children may flourish optimally in quite different environments. There is no such thing as a standard, ideal environment in which to raise children. The adaptive orientation has also led to a shift toward describing infants' behaviors, thoughts, and emotions in terms of their goals and how they perceive their ability to pursue those goals in specific situations, which is a key part of both the functional and evolutionary perspectives on emotions.

Emphasizing the adaptive value of early emotions and traits also leads developmental researchers to consider the extent to which emotions and temperamental styles might be targets of natural selection, preparing humans and other species to link specific emotions to certain kinds of stimuli or situations. Similarly, some dimensions of temperament, such as inhibition and wariness, may help infants learn the subtle tradeoffs between being cautious and exploring new opportunities.

There seem to be more and more suggestions that cognitive and attentional factors play a central role in evoking and possibly even forming many emotions as well as qualities of temperament and personality. Along these lines, developmental changes in cognition and attention may help to explain many aspects of the development of emotion, temperament, and personality. Exploring these cognitive and attentional contributions may bring insights into the distinctly human aspects of temperament and personality, as opposed to those shared across many species. They can also help us to understand how the more complex emotions might emerge from the basic ones present in early infancy. Moreover, cognitive and attentional factors can help to explain why many facets of an individual's early temperament do not translate directly into later personality traits but instead interact with many developing cognitive and attentional skills that affect the individual's developing personality.

Finally, an understanding of how emotions and temperament develop early in life offers the exciting possibility of uncovering relationships between various components of emotions and personality in adults. Developmental studies can demonstrate how cognitive and attentional strategies can powerfully influence emotions, and they may help us to understand how sophisticated processes of emotional regulation, such as reframing and reappraisal, work in adults. Similarly, developmental research that reveals the order in which particular emotions emerge can also suggest what kinds of situations elicit the later- versus earlier-emerging emotions in adults.

STUDY AND REVIEW

SUMMARY

Emotional Development

- Emotions are transient states that correspond to physiological and cognitive processes associated with distinct internal sensations, or feelings. They have been studied in terms of facial expressions and evolutionary signaling, physiological arousal, situational appraisal, and goals.
- We all share the same range of emotions, even as we vary dramatically in the extent to which we express particular types of emotions. Young infants, even newborns, also seem to show distinct emotions, as indicated by their varying facial expressions and behaviors in different contexts.
- Newborns initially experience positive and negative states that gradually differentiate into joy, surprise, and distress at 3 months, as well as anger at 4 months, and then fear at around 6 months.
- Infants do not show the full range of emotions that older children and adults do. One way of explaining this developmental change is to consider how cognitive interpretations of goals, situations, and their resolutions combine with basic emotions to create more sophisticated emotions.
- Complex emotions include shame, guilt, embarrassment, pride, jealousy, envy, and empathy, many of which are self-conscious emotions that require some degree of self-awareness. Social and cultural contexts play a role in differentiating and shaping emotions, including the moral emotions.
- A full account of the development of emotions will likely involve an integration of changes in cognitive development and how those changes influence the appraisals of situations and thereby create more nuanced emotional states.
- Even young infants seem sensitive to others' emotions and can distinguish basic emotions based on tone of voice. They are especially sensitive to negative emotions such as fear or anger, which helps them avoid danger.
- In some social situations, one individual's emotions can be readily transmitted to others. This phenomenon of emotional contagion seems to emerge very early in development as an intrinsic part of human social interactions.
- Through processes of emotional regulation, even infants can influence the emotions they experience and how they experience them. Emotions can be regulated through situation modification and selection, attentional deployment, and response modification. Initially, caregivers help infants regulate their emotions, but over time, infants begin to regulate their own emotions to a greater and greater extent.
- Some emotions, most notably phobias, seem evolutionarily prepared to be associated with certain stimuli. Fear of snakes is one such prepared association. Infants may have an early-emerging bias to track potential threats like snakes and spiders rather than flowers. Other emotions, such as disgust, may be similarly linked to special situations and kinds of stimuli with major adaptive significance, although cultural

factors may also play an important role in channeling and honing these prepared responses. This evolutionary perspective on the functional role of emotions may shed light on how emotions develop.

Temperament and the Origins of Personality

- Variations in emotions and other responses to stimuli contribute to differences in temperament among infants and young children.
- There is considerable evidence for temperamental differences among young infants, which gradually develop into personality differences. These developmental paths involve complex patterns of interactions between children and their physical and social environments, in concert with their biological predispositions.
- The New York Longitudinal Study classified infants into easy babies, difficult babies, and "slow to warm up" babies. Later studies measured infants' temperaments based on their behavior in particular settings and also found major dimensions on which they differed, including surgency/extroversion, negative affectivity, and orienting/regulation.
- Researchers have studied brain structures and neural circuits to understand differences in temperament. They have found that attentional structures and the ability to inhibit and direct attention may play a role in temperamental differences. Moreover, reactivity to novel situations may also play an important role in temperamental differences between inhibited and uninhibited infants.
- Different kinds of parents, environments, and cultures may "fit" better with some infants than with others. This idea of a goodness of fit between the child and the environment stresses that children are active agents who help shape their own development.

THOUGHT QUESTIONS

1. In some cultures, people may be more prone to feel the emotion of guilt, while in other cultures, they may be more prone to feel the emotion of shame. How might cultural practices influence a child to adopt a guilt versus a shame way of experiencing emotions? How might the cognitive components of these emotions differ?
2. How might a child's own actions make her a more active partner in the construction of her personality? Think of some specific actions and how they might influence particular aspects of her personality.
3. Would emotional contagion be more likely among those who are more like you—that is, members of your in-group? Would children and even infants also show such in-group effects?
4. How might certain forms of attentional training improve the emotional regulation skills of children? Design such a training program and consider the feasibility of actually implementing it.
5. The notion of goodness of fit argues that children with certain temperaments and personality traits may thrive in very specific environments and not in others. In what environment might a painfully shy child show an advantage over other children?

Language and Communication

Conclusions

Summary

A few years ago, I spent a long train ride sitting behind a young toddler and his mother in a nearly empty car, which made it quite easy to hear the mother and her son talking. In the course of those few hours, their communication revealed many of the patterns and tendencies that drive one of the most intricate and impressive developmental processes: language acquisition.

Even without attending closely to what the mother and child were saying, it was clear that a real conversation was occurring. The mother would say a sentence or two and then the child would respond, so that their exchanges maintained a tempo with active turn-taking on both sides. The child sometimes mislabeled things, such as calling a huge office building a house, and he often constructed statements in grammatically incorrect ways—for example, saying "I seed boat!" or "No take nap!" The mother, in turn, rarely pointed out these mistakes, although she sometimes responded to the child by using the corrected form, saying, for example, "I saw a boat, too." In addition, the mother spoke differently with the child than with the conductor, using shorter sentences, a higher-pitched voice, and slower, more careful pronunciation.

How did this child, at barely 2 years of age, become able to utter systematic, meaningful streams of words, when a year earlier he may have not been speaking at all? How can we explain the error patterns in this early speech, which are common and reliable, but are not the kinds of mistakes ever made by mature speakers? And what role do parents and other adults play as young children's guides to language learning?

Nearly all children proceed from showing no evidence of language use in the first year of life to producing and comprehending complex constructions in their third year. Few other patterns of developmental change are more clear and dramatic. Language acquisition is not an intentional intellectual achievement, like learning to play chess; language is acquired automatically, and apparently effortlessly, by almost all children in the first few years of life (see Figure 8.1). A language that emerges in this way is known as a **natural language**, which typically refers to any language spoken on a daily basis by a community. It is so uncommon for a child not to acquire any language (including sign languages, which are full-fledged languages like spoken languages) that most of us will never meet or hear of anyone who is completely language free. Acquiring language is an achievement that is so commonplace that it is easy to overlook the extraordinary complexity of language itself, which makes children's language development so impressive.

A

B

FIGURE 8.1 Learning language versus learning to play chess. The rules and computational complexities underlying the language of a preschooler far outstrip those of learning to play chess, and yet virtually all 3-year-olds seem to effortlessly learn language, while only a small handful of preschoolers learn to play chess, and only then with a large amount of explicit instruction and deliberate effort. Indeed, many would regard this chess photo **(A)** as implausible and probably staged, while seeing the chatting preschoolers **(B)** as perfectly natural.

One indication of the complexity of language acquisition is the great difficulty this process poses for computers. Even though computers far outperform humans at many other complex tasks, humans are unmatched in the ability to learn and use languages. For example, several chess-playing computer programs that run on a standard personal computer can beat all but a few thousand humans, but it is much more difficult for computers to learn the nuances of language. There are a great many ways that a chess game can unfold, and as with language processing, the chess-playing program has to analyze complex, novel structures and patterns and interpret them to compute a response. What makes chess so easy for computers, while language learning and processing is so difficult?

To begin to answer these questions, we will briefly consider some general properties of all languages before examining how children acquire language. We will consider the developmental changes in the kinds of things children say as their language develops, as well as changes in how others speak to children as they grow older. We will consider several theoretical models—behaviorist approaches, modern connectionist approaches, statistical learning approaches, and nativist approaches—each offering a different explanation of how language acquisition takes place.

We will then turn to how children decipher word meanings and how such meanings might change with development. We will discuss how children develop the ability to put together words in ways that follow the rules of a particular language, asking in what ways the ability to acquire a grammar might be constrained and whether children could create a new grammatical language largely on their own. Building on these discussions, we will ask about the extent to which linguistic abilities constitute a separate domain of cognitive development and whether these abilities seem to be uniquely human.

The relationships between language and thought also raise a host of fascinating developmental questions, such as whether specific languages guide thought in particular ways and whether language development amplifies the power of thought as the child matures. We will also ask how the child's cognitive development might, in turn, influence her language abilities. Finally, we will consider language as part of a broader social, communicative system that involves phenomena such as metaphor and irony. Our first step is to get a better sense of the workings of language itself.

The Structure and Complexity of Language

All languages allow us to constantly produce novel sentences that were never uttered before. Using a relatively small number of basic linguistic components and rules, we can create a boundless variety of unique expressions. This characteristic of language, known as its **generativity**, is surprisingly powerful. By one calculation, the number of possible English sentences of 20 words or less is 10^{20}—that's 100 billion billion sentences (Pinker, 1994)! If it takes roughly 5 seconds to hear a sentence, it would take 100 trillion years to hear all those sentences if you listened for 24 hours a day.

Using a finite system, our brain, we can comprehend and produce an infinite set of utterances. It is likely that no sentence in this paragraph has ever appeared in print before, and yet, as you read these novel sentences, you can easily and automatically judge whether they make sense and are well formed. Researchers in linguistics aim to specify the kind of human knowledge that allows us to make such judgments and to make them in distinctive ways for each of the world's languages. The related task for developmental psychologists is to explain how this mastery of language emerges in childhood.

Components of Language

To get a clear picture of language acquisition, we need to understand the main components that make up language's multilayered structure. The most common distinctions have been between *phonology*, *semantics*, *syntax* (a major component of grammar), and *pragmatics*.

Phonology is concerned with the sound patterns of a language and the rules for combining sounds into words. Thus, a phonological rule in a Boston dialect of English states that "r" in the final syllable position should be omitted; hence, "Harvard" is pronounced "Harvad." Similarly, in some dialects of African-American English, if a consonant is in an unstressed syllable, it cannot be followed by either an "r" or an "l"; hence, "protection" is pronounced "potection." Within a language, the smallest units of sound that create differences in meaning are called **phonemes**. For example, in the words "pin" and "thin," the differences are /p/ and /th/, and these sound units (or phonemes) change the meaning of the two words. In normal speech, more than 800 distinct phonemes are rushing by each minute. By age 3, most children can track almost all of these phonemes. Most 3-year-olds can also use phonetic rules to segment these sounds into words, allowing them to easily identify most of the words they hear in spontaneous speech. To understand the difficulty of this task, listen to a burst of speech in an unfamiliar language and try to determine the number of words. Then compare your guess with a native speaker's tally. To most adults the task seems impossible on first exposure to a new language; yet young children master it with apparent ease.

Semantics tells us not only the meanings of individual words but also how words combine to convey larger meanings. Thus, semantic analysis tells us why the sentence "Every arrow hit a target" has two potential meanings (*each arrow hit its own target* or *all the arrows hit the same target*). The set of words that a person knows is often called her **lexicon**. As children gain semantic knowledge, they develop more extensive and elaborate conceptual knowledge of categories (though it is also possible to understand some conceptual categories without having words for them).

In the context of language development, **syntax** traditionally refers to a set of rules concerning how words are combined into sentences. Knowledge of syntax is sometimes equated with knowledge of a language's **grammar**, but grammar also refers to knowledge of other rules beyond those governing relations between words, such as relations between elements inside words (for example, how words are constructed from roots). Because of the rules of English syntax, "Venetian blind" means something quite different from "blind Venetian," and saying that "surgeons are butchers" is different from saying "butchers are surgeons."

Finally, **pragmatics** is concerned with how we use language to convey our intended meaning within a particular social context and how we figure out others' intended meanings. Pragmatics, for example, helps us understand if an utterance is meant literally or sarcastically. Thus, pragmatics involves taking into account the inferred goals and motivations of a speaker, the status of those involved in the speech act, and other nonlinguistic cues to intended meaning, such as situational constraints, gestures, and tone of voice.

Each of these aspects of language has an extraordinary richness and complexity. Our ability to understand and use these components of language results in a single, unified language competency. Here we will focus primarily on syntax and semantics, largely because those are the two areas in which most of the experimental research has been conducted.

Q: What are some key components of language?

Universal Constraints on Language

One of the most interesting discoveries in the study of language in recent decades is that all languages show some of the same **universal constraints** on their structural patterns. These constraints take the form of consistent rule patterns across all languages, which result in specific structural features that all languages share (Bouma et al., 2001; Crain & Lillo-Martin, 1999; Maratsos, 1998; Richards, 2001). Consider one example. The sentence "Mary was amazed at how quickly she wrote the paper" has two possible meanings. "Mary" and "she" could refer to the same person (if Mary was surprised by her own speedy writing), or they could refer to different people (if Mary was surprised by another woman's quick work). Yet in the sentence "She was amazed at how quickly Mary wrote the paper," "she" and "Mary" cannot be the same person. This pattern of relating pronouns to noun phrases is not just a facet of English; it occurs in all known languages, and it arises from a quite abstract constraint on how pronouns are structurally embedded within sentences. A rich repertoire of similar constraints applies to all known languages, and the most fascinating thing about them is that *everyone honors them* without being told that they should. Universal constraints may play a pivotal role in guiding the acquisition of a first language. Thus, if a child already "knows" such constraints or somehow learns them very early on, she will be able to greatly narrow down the possible meanings of sentences that she hears. In addition, in her attempts to figure out the particular grammatical rules of her language, she can use the universal constraints to narrow down the possible rules quite dramatically, tacitly knowing that certain structures would never occur.

Acquiring a First Language

Language acquisition reflects a wide range of developmental changes, from the growth of a child's vocabulary to mastering intricate sentence structures. As we begin to explore language acquisition, it is useful to start with a broad overview of some of the major developmental patterns that shape the process. Later in this chapter, we will look more closely at how those patterns occur. Throughout this chapter, we will keep in mind that there is more than one way to measure and describe language abilities. In general, children tend to be able to comprehend what others say before they develop the ability to produce language themselves. Thus, while this chapter often describes the emergence of a particular language skill in terms of children's speech production, it is important to be aware that when this same skill is measured in terms of children's comprehension, it may appear earlier than their ability to display that skill in production.

Developmental Patterns

Although the age at which children show their first linguistic accomplishments varies considerably between individuals, there are some general patterns for the emergence of various aspects of language (see Brown, 1973; Clark, 2009; de Villiers & de Villers, 1978; Guasti, 2004; Pinker, 1995). Between the ages of 1 and 6, the average length of children's utterances (roughly the number of words), their vocabulary, the number of syntactic constructions (combinations of words to form primitive sentences), and their use of embedded sentences (relative clauses within sentences) all increase dramatically. But these different aspects of language often show their own distinct patterns of change. For example, the length of children's utterances starts to increase rapidly around age 3, long before they show a sharp rise in their use of embedded clauses, around age 5. In the following sections, we will see how these different patterns unfold over the course of acquiring a first language.

Prelinguistic Perception and Communication Long before children start to say intelligible words, they are paying attention to and producing aspects of language. As we saw in Chapter 3, very young infants actually perceive a larger number of distinct speech sounds than adults do. But with more exposure to their native language, infants stop perceiving phonemic differences that are not meaningful in their language. For example, the Japanese language does not require speakers to differentiate between “r” and “l” sounds. Consequently, Japanese infants can distinguish between those sounds more easily than Japanese adults. Long before they speak, infants learn which phonemes matter in their own language and which ones they can ignore. This process of learning to *categorically perceive* meaningful differences between sounds helps infants to begin making sense of the full range of speech sounds in their language. Clustering sounds into categories (such as all “ba” sounds or all “pa” sounds) allows many of the language’s nuanced, intermediate sounds to be treated as equivalent. As a result, these sound categories make it much easier to learn the language’s other rules for combining sounds. (Without categorical perception, every minor variation on a speech sound could seem to require its own rules.)

Although infants produce a variety of **prelinguistic vocalizations** in the first few months, ranging from lip smacking to cooing and squealing, consonant-like sounds do not normally appear until infants begin **babbling**, sometime after the fourth month of life. Babbling infants do not appear to be trying to express word meanings; rather, they are exploring the sounds in their language to get a feel for them (Pinker, 1994). Deaf infants babble aloud at a later age and with less frequency than do hearing babies, but if they are exposed to a sign language, they soon begin “babbling” with their hands, trying out the basic components of a sign language much as hearing babies do with sounds (Petitto & Marentette, 1991). Brain activity during babbling seems to occur largely in the left hemisphere, the region that typically supports language abilities, which suggests that babbling may be an important precursor of the brain’s language system (Holowka & Petitto, 2002).

Babbling is also a way to start mastering a language’s phonemes, which, as we have said, are the smallest units of sounds that cause contrasts in meanings (as in the initial sounds of “bin” and “thin”). As infants learn to combine phonemes in ways unique to each language, they begin to build up their language’s **morphemes**, which are its smallest units of meaning. Morphemes can be individual words or parts of words that carry distinct meanings, such as prefixes (for example, “anti-” or “re-”) or suffixes (like the “-s” that indicates a plural). Throughout the first year, infants are also mastering the rising and falling pitch patterns that are central to identifying and using words in all languages. For example, in English, a rising pitch at the end of a sentence can indicate a question. In tonal languages, such as Chinese, the meaning of a word may depend on whether the speaker’s tone rises or falls at the end. Well before they can say recognizable words, infants start to produce the pitch changes that characterize their language (Davis et al., 2000).

As children start acquiring language, they also increasingly show joint attention, the ability to interact with another person about an object of common interest (see Chapter 6). Thus, as children begin acquiring words, they already are able to establish a shared point of focus with another person and to know what a speaker is talking about. Joint attention may even be essential for normal language acquisition (Bruner, 1995; Tomasello, 1999).

One-Word Utterances At about age 1, most children utter one word at a time, typically referring to concrete objects (for example, “doggie,” “teddy,” “Mommy”) but also to actions (“up”) and properties (“hot”). The predominant one-word utterances are sometimes referred to as **holophrases**. A holophrase can stand for a whole sentence that the child has in mind as a linguistic entity but simply cannot produce (Bloom, 1970). By this account, a child who raises both arms toward a parent and says “up” doesn’t just mean the action but means for the word to stand for a sentence such as “I want you to pick me up” (see Figure 8.2).

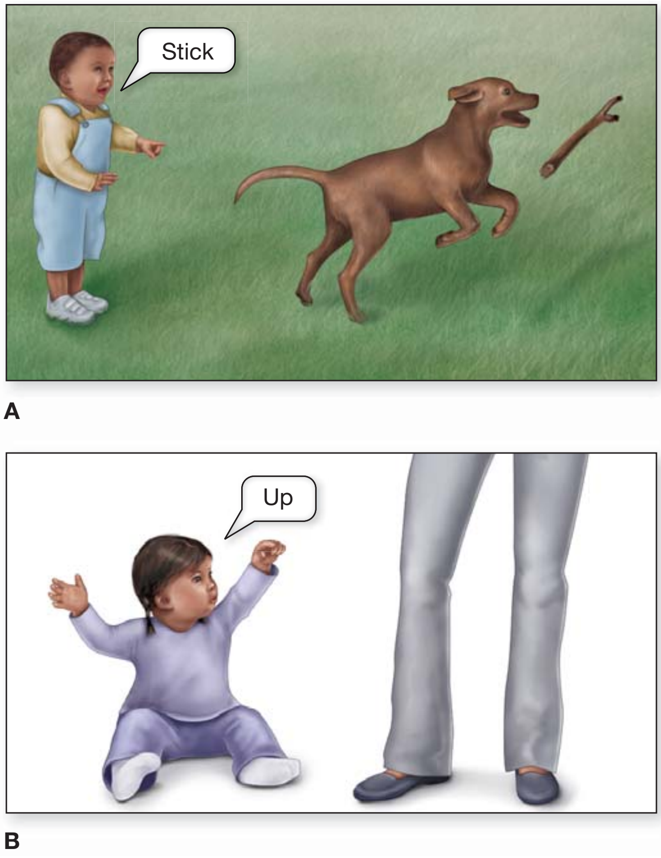

FIGURE 8.2 One-word utterances. Even in complicated situations in which a young child clearly seems to be trying to describe an entire event, such as **(A)** a dog chasing a stick or **(B)** wanting to be picked up by her mother, she may only be able to utter one-word sentences to describe what she means, such as saying “stick” or “up.”

Multiword Utterances At around 1½ years of age, many children start to put together strings of words in utterances of two or more words. Typically, these several-word sequences take the form of rote, inflexible phrases. For example, at around this age, our youngest son began saying "time to go now," but he didn't leave words out ("time to go") or insert new words ("time to go right now") until several months later. It is rare for children this young to combine words creatively.

At this point in the language acquisition process, children show dramatic individual differences. Some seem to hold off any attempts at multiword constructions until they have reached a high level of proficiency. Though the story is likely an exaggeration, the British historian and author Lord Macaulay supposedly spoke his rather surprising first words to a party guest of his mother's. After the guest apologized for spilling hot tea on him, the young Macaulay is said to have responded, "Thank you, Madam, the agony is sensibly abated" (Pinker & Bloom, 1990). Stories like this one help illustrate that children's ability to understand language can develop well before they begin using words in combination. The first words children speak may provide only a rough indication of their underlying linguistic abilities.

Q: Describe three different aspects of language that change during the first few years of life.

Children's initial multiword utterances are typically two words long, which is why children at this point are said to be in the "two-word stage." (This limit is not absolute, however; occasional three- and even four-word combinations are also possible.) In the two-word stage, children's utterances show highly consistent patterns. They tend to convey certain kinds of relationships, such as connecting an agent with the object of an action (agent-object) or linking a possessor with a possessed object (see Table 8.1). In addition, children at this stage very often express these relationships using the same word order that is most common in the language that they are trying to acquire (Braine, 1976; Brown, 1973). In English, for example, an agent who performs an action (agent-action) is typically named before the action.

After the two-word stage, children begin to vary their sentence length, up to about 10 words. These long sentences can appear as early as age 2, although there is usually a gradual lengthening of the average utterance length over several years. When children first start to combine words into phrases, they usually drop out words that are less important to convey meaning, such as articles and prepositions. Thus, instead of saying "The man picked up the brush," a child might say "Man pick brush," a speech pattern called **telegraphic speech**. Like the senders of telegrams, who had to pay by the word, children seem to face huge processing "expenses" associated with using many words in a single utterance—so they use only the words needed to communicate the gist of what they mean. In more modern-day parlance, we might refer to this as "texting speech."

Linguistic Rules Over the preschool years, children undergo extraordinary changes in grammatical competence as they master many more levels of language's complexity (Pinker, 1994; see also Crain & Lillo-Martin, 1999; Ingram, 1989). These changes suggest that even very young children's use of language involves rich, abstract mental rules. For example, many young children initially indicate questions by simply making a statement with a different tone of voice. Thus, a child might ask if he can ride a train by simply saying "I ride train?" with the rising intonation pattern of a question. Later, he might ask a question by putting a "wh-" word at the beginning of a sentence, as in "When I go home?" Only much later do children master the more subtle nuances involved in forming correct questions (Klima & Bellugi, 1966). During the preschool years, children also gradually master the ability to use a pronoun to refer to a proper name in a distant part of the same sentence (for example, "John knew it was important to wash

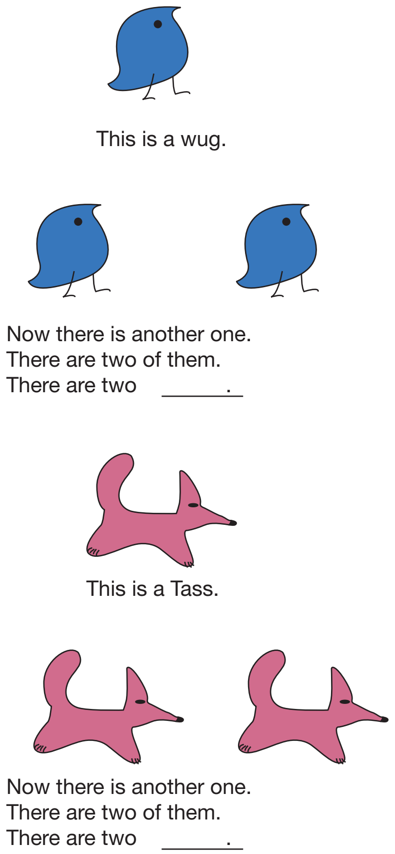
Conceptual Relationship	Word Orders Found	Word Orders Not Found
Agent-object	"Daddy book" "doggie sock"	"book Daddy" "sock doggie"
Agent-action	"Mommy read" "Daddy break"	"fall Mommy"
Action-object	"eat dessert" "bounce ball"	"dessert eat"
Possessor-possessed object	"dog tail" "Mommy tea"	"tea Mommy"
Object-location	"sweater chair" "man car"	"chair sweater" "car man"
Object-recurring	"more cookies" "more juice"	"milk more" "cookies more"

TABLE 8.1 Early two-word utterances. Even though young children may rarely produce utterances longer than two words, they still honor word orders that conform to those that adults normally use in their language.

himself before making dinner”) and to use complex sentence structures, such as one sentence embedded within another (for example, “Mary saw the dog that ran across the street after the cat”).

In short, children learn the rules of their language even though their understanding of those rules may be largely tacit and based on abstract principles that they are not aware of. This enables them to have reliable intuitions about novel constructions, an ability that was vividly demonstrated in a classic study by Jean Berko-Gleason (Berko-Gleason, 1958). Berko-Gleason examined three different English noun endings that make plurals: an “es”-sounding ending, as in “glasses,” “matches,” and “patches”; a “z”-sounding ending, as in “dogs,” “caves,” and “tubs”; and an “s” sound, as in “books,” “hats,” and “caps.” A rule is considered generative if it creates novel patterns never heard before but that still honor the rule based on familiar patterns. Berko-Gleason’s clever insight was to ask children to complete sentences that used novel, artificial words that nonetheless strongly obeyed the three plural patterns. A child would be shown a picture of two creatures (see Figure 8.3) and would be told, “This is a wug. Now there is another one. There are two of them.” Then the researcher would say, “Now we have two_____________” and look expectantly at the child. Most children immediately offered “wugs” as an answer. Like adults, they automatically inferred that the ending would be pronounced like a “z.”

This kind of generalization may seem obvious, but consider the minimal sort of knowledge a child would have to possess to be able to consistently make such judgments. Since the child has never heard any of the words before, she could not simply have memorized what plural endings went with what specific words. Instead, she might be using a more abstract principle concerning how certain consonants are combined with other consonants and vowels to make plurals. One such rule would be roughly of the form: All nouns ending in unvoiced stop consonants are pluralized by adding an “s” sound. If the rule were precisely of this form, the child would know an abstract rule that most adults are not consciously aware of. This rule would be immediately available to the young child to guide judgments in the wug task. Alternatively, a child might represent the regularities in a simpler way that only gives the appearance of having rules. For example, she might remember a large array of words in both singular and plural forms and create networks of associations between the word forms she has already encountered that allow her to generalize to novel cases without having an explicit rule (Zapf & Smith, 2007). Perhaps simply noting how often certain forms occur and co-occur in speech for familiar words would be enough to use as a basis for generalizing to novel words. Later in this chapter, we will look at different theoretical approaches that try to explain how young children are able to generalize word forms.



This is a wug.
Now there is another one.
There are two of them.
There are two ______.
This is a Tass.
Now there is another one.
There are two of them.
There are two ______.

FIGURE 8.3 Rules for plurals. In this classic Berko-Gleason task, young children seem to know a productive rule of pluralization, as they quickly and effortlessly know which of several possible plural forms go with novel words that they have never heard before. They know that the plural of *wug* is *wugs* and that the plural of *tas* is *tasses*. From Berko-Gleason (1958).

One other rule-related developmental phenomena is repeatedly encountered in language acquisition studies and is often called **overregularization**. Consider the ability to form the past tense for English verbs. Children often go through three distinct stages in their acquisition of this ability. Early on, they may make a number of mistakes but also frequently show some apparent mastery of the past tense forms of both regular and irregular verbs. Thus, a 2-year-old might be heard to say “kicked” and “liked” (regular past tenses) as well as “went” and “saw” (irregular past tenses). One might therefore conclude that the child is well on her way to mastering the subtle contrasts that adults use for past tense forms of verbs. Then, however, a curious thing happens: older children sometimes start to make more mistakes. They now take the regular form of the past tense (adding “-ed”) and use it for some irregular verbs. This incorrect use of the regular form leads to such utterances as “John goed home yesterday” or “I seed it.” These mistakes can persist for quite some time, even years, before the child once again starts to use the correct past tense of irregular verbs.

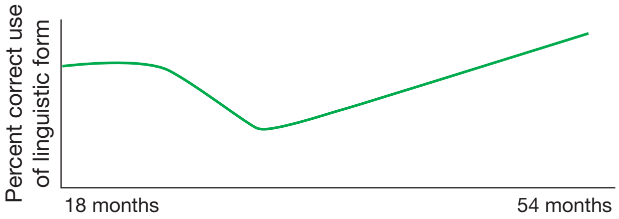


FIGURE 8.4 An idealized U-shaped developmental curve. These are some of the most intriguing patterns found in the developing child. They are often interpreted as reflecting the emergence of a new cognitive structure or a new rule that, in its initial stages, is used too crudely, and then becomes more carefully tuned. In the case of past tense forms, the emergence of a general "past = verb + ed" rule was thought to be initially overused with some irregular verbs and then gradually narrowed down to the right set. Later approaches tried to argue that U-shaped patterns could be modeled in distributed networks in which no specific rules were represented. Adapted from Marcus et al. (1992) and Marcus (1993).

Figure 8.4 shows an idealized version of this pattern, which holds true for other forms as well, such as regularizing irregular plurals (for example, "foots," "sheeps"; see Marcus, 1995). This kind of *U-shaped developmental curve* is one of the most intriguing and classic findings in developmental psychology (see Chapter 3). Such patterns have launched many debates about the underlying changes occurring in the child's mind (Strauss, 1982).

To understand this pattern, keep a few points in mind. First, the input does not change radically when children start to overregularize. Children of all ages are hearing essentially the same distributions of verbs and tenses. Second, irregular verbs are among the most frequently used in English, with the consequence that the majority of past tense verbs heard by children in normal speech are irregular ones with idiosyncratic past tense forms. When they start to overregularize the past tense "-ed" rule, they are therefore taking a pattern observed in a minority of instances and applying it to a broader range of cases. Third, parents rarely provide feedback to children about the correctness of such forms. They may laugh from time to time at the mistakes, but parents are generally unlikely to correct ungrammatical early utterances (Braine, 1971; Brown & Hanlon, 1970). Fourth, children usually have never heard these incorrect overregularizations in the speech of others, so they are producing novel, incorrect forms on their own.

Given these considerations, this particular U-shaped curve has been said to represent children's discovery of the past tense "-ed" rule. Younger children may only be remembering individual verbs and their different forms on a case-by-case basis. Children might hear verbs such as "go" and "went" and store them separately in their mental dictionary (Ullman, 1999; Ullman et al., 2005), perhaps even noting that "went" is used more in situations talking about the past. As they grow older, however, children discover the "-ed" rule, and even though it may occur in a minority of utterances, it is at least a clear rule. The discovery of this rule apparently suggests a broader pattern of use to the children than is seen in adult usage. Only with time and new insights into exceptions to the rule are the irregular forms once again mastered. The extent of the dip in this curve is often exaggerated, but even a small dip illustrates the classic developmental pattern.

When children as a group show a drop in performance, it is often taken as a strong sign of a developmental reorganization and the emergence of a new psychological system. We saw several clear cases in perceptual development; use of the past tense seems to be a case in language. This effect can occur in several other areas of language acquisition as well. The pattern is so compellingly explained by the notion of discovery and initial overuse of a rule that it is difficult to imagine that the children are not mentally representing abstract categories such as verb and past in a rule-like manner. As we will see later, however, this interpretation has been challenged by theories of learning that try to avoid any representations of abstract rules.

Q: What have U-shaped developmental patterns traditionally been assumed to represent?

Child-Directed Speech

Adults do not talk to young children in the same way they speak to older children or adults. This special type of speech, which was previously called **motherese** (Newport et al., 1977) and is now known as **child-directed speech** or infant-directed speech**,** differs from other speech in many ways. When talking to young children, parents tend to enunciate their words very clearly and to speak more slowly and at a higher pitch. These differences tend to accentuate the boundaries between individual words and between phrases. Child-directed speech also uses simpler words and fewer words per sentence, and it tends to be more grammatically correct (Snow & Ferguson, 1977; see also Golinkoff & Alioto, 1995). When speaking to children, parents more often repeat and expand on the child's previous utterance, or respond by **recasting**, in which they paraphrase what the child has said (Bohannon & Stanowicz, 1988). In recasting, adults are unlikely to directly correct a child's utterance by saying it is wrong, but will use the correct form of a verb or noun in their responses. In general, child-directed speech is modified in many ways that highlight critical elements in the language.

Infants in all cultures prefer to listen to speech that has the characteristics of child-directed speech (Fernald, 1985; Werker et al., 1994; see Chapter 3). Yet, there is no evidence that children who hear more child-directed speech than others learn any language faster or better. Cultures vary considerably in the extent to which parents modify their speech to young children, yet the course of language acquisition does not seem to vary in a corresponding fashion (Ingram, 1989). Child-directed speech probably helps attract the child's attention, and it may make some aspects of language processing, such as word segmentation, easier (Thiessen et al., 2005; see also Fernald & Hurtado, 2006; see Figure 8.5). Even accounting for these influences, however, many intriguing questions remain about how children learn their first language.

Q: How does child-directed speech differ from talk between adults?

Although differences in child-directed speech do not seem to affect how quickly children learn language, some other aspects of parent-child interactions may play a role. In one longitudinal study, mothers were videotaped while freely playing with their child. Researchers then examined the tapes to rate aspects of the mothers' responsiveness, such as their playfulness with their child or how often they imitated their child's utterances. Later, the children's milestones of language acquisition were tracked, including when each one spoke his first word, acquired his first 50 words, and first talked about the past. When the two types of measures were compared, the children of more responsive mothers tended to reach language development milestones at an earlier age (Tamis-LeMonda et al., 2001). Similarly, children whose mothers are more sensitive to their emotional states tend to achieve language milestones earlier (Nicely et al., 1999). Parents' interaction patterns may contribute to the considerable individual differences seen in the rate of language acquisition. As with the case of child-directed speech, however, these influences cannot fully explain children's basic ability to learn language. Using the right kinds of words can also have an apparent effect on vocabulary growth above and beyond simply using a lot of words. Even when controlling for socioeconomic levels and previous vocabulary levels, 3-year-old children who hear a more diverse and sophisticated vocabulary from their parents have larger vocabularies 1 year later (Rowe, 2012). Parental effects on language development may resemble the effects of fertilizer and water on plant growth; they are more helpful for explaining individual differences in growth rates than for describing the basic developmental pathway.

FIGURE 8.5 Child-directed speech. Parents adjust their speech in many ways when speaking to young children. These adjustments may help make some aspects of language structure more apparent to the child, but they do not explain how the child acquires language.

Theories of Language Acquisition

Over the years, there have been many competing models offering starkly different accounts of how children acquire language. Perhaps the most intuitively appealing model is that children simply imitate the language that they hear. As we saw in Chapter 4, even very young infants are capable of imitation. But there are two reasons why language is not simply learned through imitation. First, if what we mean by imitation is reproducing bits of what we hear, as a parrot does, then imitation clearly will not work as a model. Children are not at all like parrots or other animal mimics. If they were, they would not show the common problem of overregularization, and they would not be able to produce sentences they had not already heard. In fact, they would not be able to produce novel sentences at all if they simply stored parts of utterances and played back the most appropriate ones later.

Second, if we suggest that imitation is more flexible and that rather than imitating specific strings of words, infants imitate intentions, goals, and perhaps even rules, this explanation adds little to a model of language acquisition. If the infant is not imitating the speaker's actual spoken language but something much more abstract, such as underlying intentions or rules, then imitation only explains a general motivation. It leaves unexplained how a child discovers the rules or intentions that she imitates, since neither is directly observable. The question therefore remains how young children can learn linguistic rules from what they hear.

Moving beyond the superficially appealing but ultimately uninformative imitation account, we can consider several more detailed proposals about how language acquisition occurs. One major contrast between some of the most influential models concerns whether children acquire language through general learning mechanisms such as associations that work in essentially the same way as for acquiring many other forms of information (such as spatial or numerical knowledge) or whether children acquire important aspects of language through a learning mechanism specialized for linguistic information. This theme regarding general versus specific learning systems occurs in other areas of cognitive development, but it is especially salient in language acquisition. Here we will consider behaviorist models of language acquisition that favor the association-based general learning explanation and then related, more recent views known as connectionism and statistical learning. We will then turn to the nativist accounts, which tend to favor specialized learning systems, often those with specializations for abstract rules. As proposed earlier, young children may not be able to acquire language unless their language learning system "knows" some structural regularities of all natural languages from the start. Understanding the nature of what is already known, or what kinds of linguistic patterns are favored from the start, is the most central question of language acquisition. A child's ability to imitate may help him fine-tune some speech sounds or practice complex constructions (Speidel & Nelson, 1989), but it cannot explain the truly creative abilities that all children show as they master their mother tongue.

Behaviorist Approaches

Some theories about how children acquire language are based on broader accounts of learning that have been well known to psychologists for many years. As described in Chapters 1 and 4, these learning theories are meant to apply to all kinds of information. They are based on the idea that a few general principles, such as reinforcement to shape behaviors or the tendency to associate events that occur together frequently, are meant to explain all forms of knowledge and skill acquisition. Behaviorism, which stresses the ways that reinforcement shapes responses, dominated much of psychological research for the first half of the twentieth century. The prominent behaviorist B. F. Skinner believed that the same laws of learning that apply to rats and pigeons also apply to humans in their acquisition of language (Skinner, 1957). Skinner argued that parents and other caregivers gradually shape infants' linguistic response patterns, which gradually become more like adult language. For example, a child's babbling might initially appear random. Parents and others then respond more positively to babbles that resemble adult speech sounds and more negatively to those that do not, guiding and shaping the child's speech to become more like a mature speaker's. Moreover, it was thought that parents have the same effect on children's use of grammatical rules, reacting more positively as children utter strings of words that come closer and closer to adult grammatical patterns. To behaviorists, language acquisition seems to consist of learning the appropriate verbal "responses" in a variety of circumstances, making it a seemingly straightforward, easily measured object of study. Moreover, behaviorists never required any analysis of what goes on inside the mind of an infant or child; to them, all that mattered were environmental contingencies (see Chapters 1 and 4).

At first glance, the behaviorist account seems plausible. Children clearly learn the languages they hear spoken by those around them, and child-directed speech can influence patterns of acquisition. But a closer look at what is actually happening between adults and children during language acquisition reveals major problems with the behaviorist account. The most penetrating and influential criticisms of behaviorist models of language learning came from the linguist Noam Chomsky (Chomsky, 1959). Among his critiques, Chomsky pointed out that behaviorists assume that the learner needs direct, specific feedback, but he noted that parents rarely correct or compliment children's grammar in early utterances. Instead, parents devote most of their attention to the meaning that the child conveys (Brown & Hanlon, 1970). Consider a 2½-year-old who toddles up to her mother and says, "Mommy mostest pretty tonight." Virtually all parents would smile warmly—not explain to the child how her sentence was grammatically incorrect. Likewise, most parents would respond negatively to a rude, but grammatically perfect, statement by a child.

Behaviorist approaches would also predict that acquiring two or three languages at once should take a child much longer than learning just one language, since it would take more time for the child to experience enough positive and negative reinforcements for their speech in each language. In fact, bilingual and even trilingual children tend to acquire all their languages together at about the same rate as a monolingual child. They may experience minor early delays, but these seem to disappear just a few months into the learning process (Petitto et al., 2001).

Connectionist Approaches

Behaviorist approaches rely on simple learned associations between reinforced behaviors, but such simple associations have been insufficient to explain many aspects of language acquisition. In the 1980s, researchers introduced **connectionism**, a way of representing networks of associations based on computer simulations with multiple levels of associations. In at least some cases, the computer simulations can mimic what looks like the use of a rule even though the rule was never explicitly stated in the simulation. Connectionist approaches rely on associative mechanisms, but they are vastly more powerful than the early behaviorist explanations. Their power arises primarily from two innovative explanations of how language processing occurs. First, connectionist approaches propose that language acquisition depends on the brain's massive capacity for parallel processing—that is, handling many kinds of information simultaneously. Second, connectionism incorporates hidden layers of processing that go beyond overt associations learned through reinforcement. More broadly, connectionist approaches to language acquisition argue that the human brain operates like a computer. They emphasize that the brain can process vast amounts of information simultaneously and that it is made up of separate processing units that share information across networks of connections.

Most connectionist approaches fall within the empiricist tradition. They assume that cognition is built up from learned associations based on input from the environment and experience. But unlike the behaviorist approaches, which make this same assumption, connectionism also seeks to understand the mental processes, and even the neural structures, that underlie language acquisition. Thus, many connectionist theorists refer to brain anatomy and patterns of neural functioning to support their views (Rumelhart, 1989).

The computer models that are built by connectionist researchers test language acquisition theories by simulating the language learning process. When the two key ideas of parallel processing and hidden layers are supplemented with some general learning algorithms and rules, these software-based systems can often engage in surprising patterns of learning. They can, for example, represent several developmental patterns described earlier, including overregularization and the appearance of learning "rules." Thus, connectionist models have attempted to simulate the child's acquisition of past tense verb forms, including a pattern of learning that follows a U-shaped curve. Rumelhart and McClelland (1986) decomposed words into strings of phonemes and then presented them one at a time to a computer network. The computer was apparently able to learn the past tense, showing the same pattern of overregularizations typical of young children, without ever learning or explicitly representing the past tense "rule" anywhere in the system.

These results were criticized for several reasons, however, including concerns that the strings of phonemes input into the computer models were unrealistic (they differed from what a child hears) and that the computers were too powerful to provide a good model of children's language learning (Pinker & Prince, 1988). Later studies tried to rectify these concerns (Plunkett & Marchman, 1991) but had other shortcomings (Marcus et al., 1995). Currently, there is no consensus among language acquisition researchers about whether a connectionist model using a single associative process provides a better representation of the child's language development than a dual-process model consisting of both rules and associations (Bandi-Rao & Murphy, 2007; Marshall & van der Lely, 2006; Takac et al., 2012).

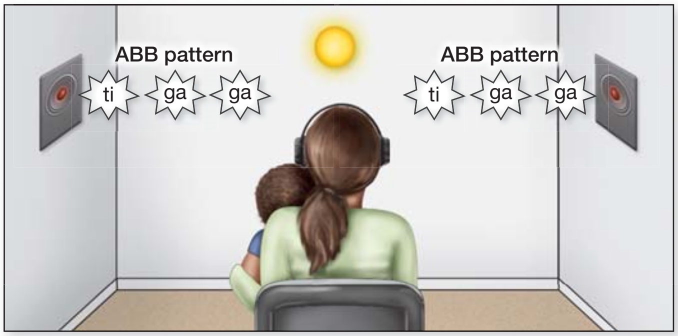
Q: What is the associative versus rule-based learning debate?

Statistical Learning Approaches

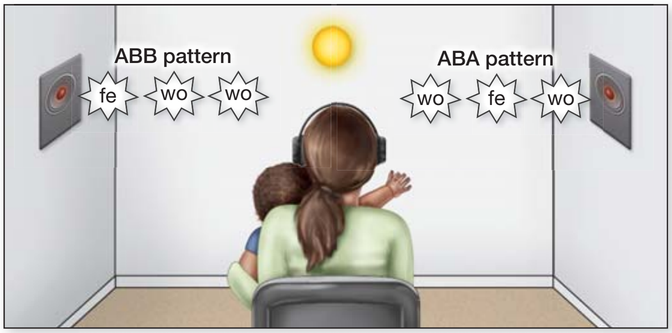
Language learning can also be examined in terms of **statistical learning**, which is learning based on the probability of events occurring both at the same time and in sequences over time. In recent years, researchers have given renewed attention to statistical learning to study the early roots of language development, using statistical learning to investigate the relative roles of linguistic rules and associations in language acquisition in infants. Statistical learning approaches are often allied with connectionist approaches, which are computational models that rely on statistical patterns of inputs. In statistical learning approaches, researchers have asked how infants can distinguish words out of streams of continuous sounds. They have examined whether infants can recognize the probability of sounds co-occurring within words (that is, the likelihood that one sound follows another within a word) or occurring at the end of one word and beginning of another. In one study, 8-month-olds listened to uninterrupted strings of phonemes in which particular sets of sound patterns were repeated, suggesting words. For example, the string "bidakupadotigolabubidak . . ." would continue for several minutes, during which time the sound sequences "bidaku" and "padoti" each occasionally repeated, interspersed with other phonemes. After listening for just a few minutes, infants seemed to learn which groups of sounds in this string reliably occurred together as "words." When the recording stopped and was replaced by either familiar sound sequences (“bidaku” and “padoti”) or unfamiliar ones (such as “dakupa”), the infants looked longer toward the speakers when the novel sequences played (Saffran et al., 1996). This result excited researchers because it seemed to show that infants have a rapid, powerful statistical learning ability for acquiring language and learning other nonlinguistic sounds (Bates & Elman, 1996).

Subsequent research found that young infants could also learn sequences of tones that recurred together within a stream of other tones but that did not sound like any language (Aslin et al., 1998; Saffran et al., 1999). In addition, after hearing particular sound sequences, such as “bidaku,” recur within a stream of phonemes, children are more likely to later learn word labels that use those same sound sequences than they are to learn sequences using other sounds, such as “dabiku” (Graf-Estes et al., 2007). Apparently, the brief exposure to recurring sound patterns helps prime young children to learn that such recurring sound sequences can represent meaningful words that are associated with objects and categories (Lany & Saffran, 2010; Shukla et al., 2011). Statistical learning theorists suggest that young infants’ ability to rapidly extract and use such complex recurring patterns from a continuous stream of sounds reflects not a language-specific system, but a much more general learning system that calculates conditional probabilities (that is, probabilities that a given event will occur given the occurrence of another event).

Can infants go beyond recognizing language’s recurring sound patterns to learning its rules? To explore this question, another research team (Marcus et al., 1999) presented infants with phoneme sequences much like those described in the previous study (Saffran et al., 1996), except that the sequences that the infants heard taught them a rule rather than a relation between specific groups of sounds (see Figure 8.6). Rather than simply repeating the same elements in the same three-syllable order, the researchers presented the infants with different elements that followed a similar rule-based pattern. For example, to teach an ABA rule, the recording would repeat the same element before and after an intervening one, so the infants might hear “ga ti ga” or “li na li” and the like for about 2 minutes. In another condition that taught an ABB rule, infants would hear sequences like “ti ga ga” or “na li li.” In the test phase, infants heard new sound sequences that either followed the old rule (for example, “wo fe wo” for ABA) or did not (for example, “fe wo wo”). In the test condition, the infants looked longer at the novel patterns that violated the rule, indicating their awareness of the rule and their surprise that the rule had not been followed. Moreover, infants who were only 7 months old (that is, 1 month younger than infants tested in the original study of phoneme sequences) recognized when a rule had been violated. A later rule-learning study showed the extra power gained when information is combined across sensory modalities. When 5-month-old infants were presented with visual patterns that were associated with each syllable they heard in a speech stream, the infants looked longer at the shapes on the screen when they were presented with new syllables that corresponded to a new rule as opposed to an old one (Frank et al., 2009). Thus, with adequate support, well before the first half year of life, infants can learn abstract rules that are distinct from any specific sound sequences (see also Frank & Tenenbaum, 2011).



A Training condition



B Test condition

FIGURE 8.6 Learning abstract rules. In the Marcus et al. study, 7-month-old infants learned to recognize abstract rules such that a sound pattern that they had never heard before but that corresponded to an old rule was seen as familiar. The infants sat in a booth on their parents’ laps (their parents wore headphones so that they could not influence their children) listening to sound patterns coming from side speakers. **(A)** During the training condition, after the center yellow light flashed, the infant was familiarized with the sound pattern (here ABB) coming from speakers behind red bulbs on both the right and left. **(B)** During the test condition, the infant was presented with different sound patterns coming from the speakers on the right and the left. A novel ABB sound pattern came out of one side speaker and a novel ABA pattern came out of the other side speaker. The researchers found that the infants looked longer at the speaker emitting the new ABA pattern that at the new ABB pattern that resembled the one they had heard during training, indicating their recognition of the rule and their surprise that it had been violated.

One challenge for statistical learning models concerns cases in which the syllable strings that infants hear vary in length from, say, one syllable to four. Can infants still learn to segment these syllable strings into words? One study found that neither 5- nor 8-month-olds could do so, even though they could do it easily when "word" lengths were the same (Johnson & Tyler, 2010). Even though the "words" of different lengths recurred predictably, the infants could not learn them. This finding is puzzling, because the real words that infants hear clearly vary in length (for example, "doggy," "ball," "banana"). It may be that infants need both to hear certain falling and rising pitch patterns associated with some word beginnings and endings and to see visual cues associated with objects to learn words of varying lengths. There may also be other statistical patterns, such as overall distributions of sound patterns, that are integrated together with conditional probabilities to help solve this learning problem (Thiessen et al., 2013).

Statistical learning approaches are becoming ever more diverse as researchers consider new patterns of frequencies, correlations, and contingencies in language learning, and formal ways of processing that information. One powerful technique is based on Bayes's rule, which provides a formal way of updating beliefs in light of new evidence. In terms of language learning, it is a way of confirming that certain rules hold. Based on new pieces of evidence, a child can become more or less certain of those rules, a process that is continuously repeated as the child encounters more and more evidence (Griffiths et al., 2012). Bayesian learning models provide ways of exploring how children of different ages, even when presented with the same evidence, might adjust the strength of a rule to differing degrees because younger and older children bring different kinds of prior knowledge to that learning event. In contrast to most connectionist models, in which rules are only tacitly present in a network, Bayesian learning models can apply statistical learning to the strength of explicit rules (Frank & Tenenbaum, 2011).

Before we close our discussion of behaviorist, connectionist, and statistical learning approaches to language acquisition, let's consider again the question of empiricism versus nativism. Empiricist systems are specialized to handle specific kinds of information *only* at the earliest parts of the learning process. As previously described, many statistical learning theorists view infants' ability to identify statistical patterns as evidence for a general learning system rather than a language-specific one. Connectionists have also noted that the basic features of a connectionist system—neural networks capable of parallel processing—make up almost all animals' brains. Thus, connectionists argue that humans acquire language and other species do not mostly because humans have a bigger, more powerful brain—not because the human brain is somehow tailored for the complexities of language. To understand this view, consider that relatively simple computers cannot run the complex software that runs easily on a more powerful computer. But if you look inside both computers, you will not necessarily find anything about the more sophisticated one that is tailored for that software. More likely, it just has sufficient memory and a fast enough processing speed to execute the intricacies of the program without crashing.

A different analogy is also possible, however. The two computers might differ not only in size and power, but also in their specific components. If the more powerful computer is able to run the software because it has a set of chips dedicated to processing graphics, while the other computer lacks such a device, then the first computer gains its unique capabilities from a specialized system. This second case is more like the nativist view of language acquisition, which we will turn to now.

It is important to acknowledge, however, that statistical learning approaches need not be squarely in the empiricist tradition. For example, a Bayesian learning model might grant that certain types of rules are so improbable that they can virtually never be favored based on new evidence, while other types of rules are so probable as to virtually never be discounted based on new evidence. If those rules and their probabilities are relevant only to language, then they can be seen as language-specific learning constraints.

Nativist Approaches

Nativist approaches emphasize the idea that humans are endowed with a specific brain system specialized for acquiring any natural language. That system would not work well for learning about spatial layout, number, or moral principles. But it must be able to acquire all natural languages, even though those languages vary widely at the surface level in terms of their grammatical rules and many other features. The nativists do not claim that the system specifies details, such as particular grammatical rules. Instead, they say that it includes abstract principles that guide learning about the structural patterns common to all languages. This specialized system, which is often called the **language acquisition device** (Chomsky, 1965), is thought to embody a great deal of implicit linguistic knowledge about all languages. Thus, it must be specialized for learning the kinds of abstract grammatical patterns all languages share, while remaining flexible enough to learn any particular language.

Over the years, Noam Chomsky has made a number of proposals about the nature of the language acquisition device. For example, he pointed out that the linguistic information that young children receive from other speakers is full of false starts, interruptions, and unfinished sentences. (Listen to any casual conversation, and you'll see how frequently sentences are interrupted or ill formed.) Because young children hear imperfect speech, Chomsky argued that what they hear is not a sufficient basis for learning language. This view, known as the **poverty of the stimulus argument**, holds that since children couldn't possibly learn language only by listening to others talk, they must already have some knowledge of the language's structure. (Even though adults often address young children with simplified, child-directed speech, the amount of this kind of speech that a child hears does not seem to predict how easily he acquires language.)

Nativists point out that in behaviorist theories of learning, the learner's incorrect responses must be corrected in order for the learner to make progress. But children receive only very rare, minimal feedback about their many early errors. This small amount of negative feedback seems insufficient to shape their many ungrammatical sentences into the correct, mature use of the language. Nonetheless, while children make many mistakes early on (such as "goed" instead of "went"), they still manage to correct themselves as they get older.

More generally, nativist approaches about the nature of the language acquisition device attempt to figure out how such a system might learn language effectively from only a few relatively simple, minimal inputs. Along these lines, they embrace the idea that the language acquisition device can use a few key bits of information, such as differences in intonation, as richly meaningful cues to linguistic structures.

Discovering the Meanings of Words

The speaking toddler seems like an utterly different creature from the preverbal infant. As the child labels objects and events, asks questions, and comments on situations, we gain new insights into his mental life. How do children learn word meanings as they transition out of a preverbal state to become more fluent users of language? How do children's language development and other emerging cognitive capacities influence each other? How do children learn to use language to communicate in ways that go beyond the literal, as in the use of metaphor or irony? Many researchers believe that in trying to answer these questions, we can come closer to understanding what makes us human. To begin to address these issues, we examine how children begin to learn word meanings.

Linking Words to Concepts

When a child learns a new word, she doesn't simply link that word onto a single object in the world. Instead, she links the word onto a concept, which then enables her to apply the new word to various objects that correspond to the concept at hand. For example, a child who learns the word "doggy" doesn't just learn that a particular sound sequence is associated with the dog she has just encountered. Instead, she learns that "doggy" names a concept or class of things—roughly, furry, four-legged creatures that bark. This process of linking sounds that form words onto concepts is known as mapping. **Semantic development**, or the emerging understanding of word meanings and their interrelationships, requires linking words to concepts, which in turn often correspond to real-world phenomena. (There is not always a correspondence of words to real-world concepts, however, as we can learn words such as "unicorn" or "kryptonite" even though neither is real.) First, we will consider a few basic patterns concerning the growth of the child's lexicon, or the set of words he knows.

During the first year of life, many children speak no words at all and probably understand just a few. After about age 1, words start to enter the child's productive vocabulary (that is, the words that the child can produce or say) at the gradually increasing rate shown in Figure 8.7. The child initially starts acquiring words at a slow rate, but then that rate increases continuously over the next few years, hitting a peak rate somewhere around 4 years of age. By age 5, many children have vocabularies as large as 10,000 words (Anglin, 1993; Bloom, 2000).

The contents of words also change with increasing age. Many children's first words refer to concrete objects, although this pattern is subject to large individual differences. Early

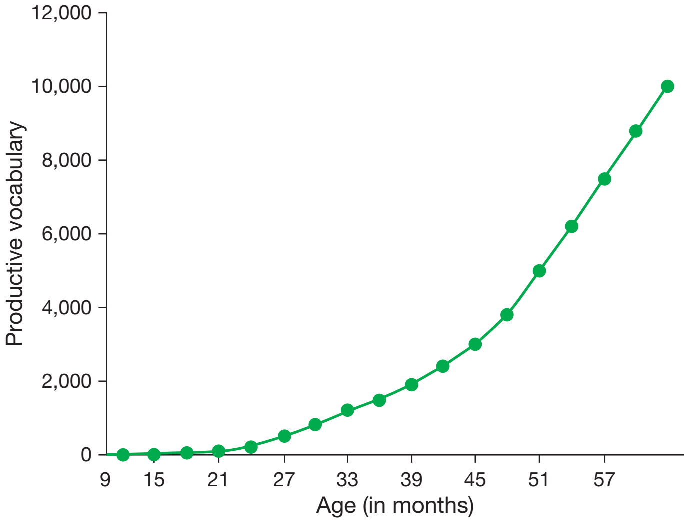


FIGURE 8.7 Vocabulary growth. The child's vocabulary initially grows at a slow rate, but then rapidly accelerates in later years. The actual vocabulary size can vary considerably across children. This example would be for a fairly precocious child. For most children, the rate gradually increases with age with no sharp spurts. Adapted from Bloom (2000) and Ganger & Brent (2004).

words for actions, such as "up" (for being lifted up) or "open" are also common. A child's first words also tend to be at an intermediate level of generality. Thus, a child is much more likely to first learn "dog" than either "collie" or "mammal." Levels of generality are predicted from the frequencies with which terms at the different levels are used by adults, and young children tend to linguistically encode the world at the level most often used by adults (Anglin, 1977; Brown, 1958a, 1958b; Horton & Markman, 1980; Mervis & Crisafi, 1982; Rosch et al., 1976).

Children do not require explicit training to increase their vocabularies. Sometimes parents do correct a child's mistaken word usage or point to a novel object or event and label it. But parents rarely provide children with full definitions, such as "A dog is a mammal that has four legs, a tail, and makes a barking noise. It is a social animal and has litters of roughly six puppies." For many words, such a complete definition would involve words that are beyond the young child's comprehension. The extraordinary speed with which young children seem to map words onto the correct concepts, sometimes as fast as 500 new words a month, is often called **fast mapping** (Carey & Bartlett, 1978). Fast mapping is thought to be possible because out of the universe of possible word meanings, children are somehow biased to infer only a relatively small subset, making the learning problem much easier, given the child's cognitive abilities.

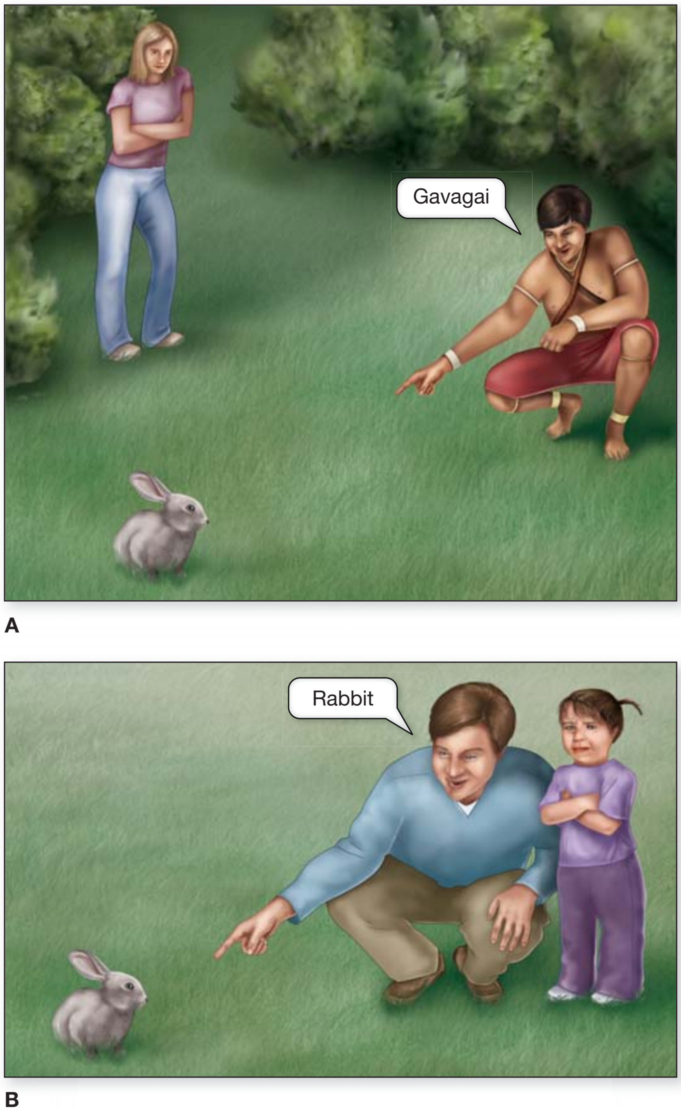

FIGURE 8.8 Riddle of reference. (A) Quine's example of a person from a radically different culture uttering "gavagai" while pointing to a rabbit illustrates the riddle of reference. There is no way to know for sure whether the person means rabbit, rabbit parts, or any number of other meanings that cannot be distinguished by merely pointing. **(B)** The young child also seems to face this problem every time she encounters a new word (here "rabbit" as spoken by her father) and yet narrows down the set of possible meanings to a much smaller set that makes the learning of word meanings feasible.

Q: What sorts of words are more common in the early stages of word learning?

These developmental patterns are fascinating because they reveal an extraordinary ability to learn words without any apparent explicit instruction. How is such a rapid and seemingly effortless process explained at the psychological level? To better understand this process, it is useful to first consider the nature of the challenge in more conceptual terms.

To a large extent, all the patterns in the growth of vocabulary revolve around the most central question: How is it possible to acquire word meanings at all? The philosopher Willard Quine (1960) posed a dilemma that can help illuminate the difficulty of the task children face as they learn to associate words with meanings. He described the following scenario: Suppose you were transported to a completely unfamiliar culture in an unexplored rain forest. You have been dropped off by helicopter and are standing alone in a clearing when a native of this culture comes along. At the same time, a rabbit hops into the clearing and the native gestures toward it and says "gavagai" (see Figure 8.8). How can you tell what the native is talking about—that is, how can you translate the word correctly?

We will refer to this dilemma as the **riddle of reference**. It is impossible to tell whether "gavagai" applies to rabbits, the set of connected rabbit parts, or a rabbit-related event or action. Quine argues that we assume that "gavagai" means rabbit (and not rabbit event or parts) just because we share with the other speaker a common way of carving up the world into meaningful units. The scenario Quine describes is especially dramatic because no amount of experience could ever make you certain that you had understood what "gavagai" means. The information available from both the environment and experience is too ambiguous to ever distinguish between "set of connected rabbit parts" and "whole rabbit." Moreover, the learning process is complex even when the environment does enable you to clearly distinguish between meanings. If "gavagai" means "rabbit head," it would take a specific set of highly unusual events with incomplete rabbits to figure this out. Similarly, recognizing the meaning of the words for "rabbit fur" or "hopping rabbit" would require quite particular encounters.

The "gavagai" example bears directly on the challenge facing a young child as she begins to connect words with meanings. The child resembles the traveler in the clearing, except that in some ways the child's dilemma is more difficult. The traveler arrives with one language, which can be used to attempt to translate the unfamiliar terms. In contrast, the young child has no other language, so her task involves both translating the sounds into concepts and building new concepts to correspond with speakers' meanings.

Q: How do theoretical problems with language translation lead to questions about the acquisition of word meaning?

Constraints on Word Meanings

The only solution to the riddle of reference is to assume that the child's choices among possible word meanings are limited somehow. Many types of **constraints on word meanings**, or ways of limiting the number of possible meanings that could be assigned to a given word, have been proposed. Researchers suggest that infants and young children have certain biases that guide them in determining what a word is referring to (Markman, 1989, 1992). Our purpose here is to consider how these different types of constraints help to solve the problem of connecting words with meanings. As Quine's dilemma illustrates, if a child entertained all possible meanings every time she encountered a new word, she would never be able to begin building a vocabulary. If, on the other hand, most possible meanings are ruled out from the start, word learning becomes feasible. In this way, constraints on word meanings do not really constrain the child; they liberate her by reducing the number of possible meanings (Keil, 1979). We will consider three types of constraints on word meaning: *perceptual*, *conceptual*, and *pragmatic* constraints. For this system of constraints to help the child learn the meanings intended by others, the child must share the same sets of constraints with the speakers around her.

Q: Why are constraints on word meanings considered essential to explanations of word learning?

Perceptual Constraints The first kinds of constraints on word meanings are perceptual constraints, which are biases toward certain interpretations of words that arise from the way our perceptual system naturally carves up the world into distinct objects and events. This process can involve all the senses, but most researchers have focused on vision. One example of a perceptual tendency that constrains word meanings is the **shape bias**, according to which objects of roughly the same shape are assumed to have the same name (and objects with different shapes are assumed to have different names). Toddlers show this bias in the lab when, having learned the name of a novel object, they are asked to pick something else with that same name from a pair of unfamiliar objects. Children as young as 18 months will choose the object with the same shape as the first object, rather than choosing an object that shares its same colors or textures. This attention to shape over the object's other properties suggests a bias to think that things with the same shape will have the same label (Landau et al., 1988).

Q: How might an object's shape help word learning?

Conceptual Constraints Our perceptual biases are not the only influence on our choices of which things to name. We are also guided by conceptual constraints that make some kinds of categories or relationships seem more "natural" to label. Thus, even when there may be equally compelling perceptual features, some conceptual slices of the world are more easily mapped onto words (Arunachalam & Waxman, 2010a). For example, the **whole-object bias** describes our preference for labeling whole, bounded objects—rather than objects' parts or their relationships to other things (Macnamara, 1982; see Figure 8.9). For example, if 3-year-olds are presented with several unfamiliar tools, and each has one very noticeable part, they will still assume that the labels associated with these tools apply to the whole tool, not just to the part. More broadly, when

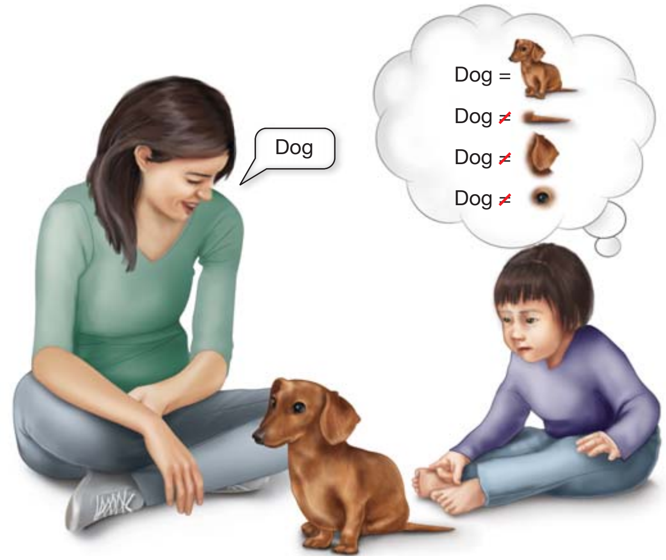

FIGURE 8.9 The whole-object bias. This bias assumes that novel words refer to whole bounded individuals and not to their parts, colors, textures, or other component attributes.

young children encounter a label for an unfamiliar object, they tend to assume that it applies to the object as a whole (Markman, 1989; Markman & Wachtel, 1988). This has the potential to greatly simplify first guesses about the referents of novel terms. Infants also assume that a novel word refers to a whole object as opposed to a property such as color or texture.

Infants also appear to make taxonomic assumptions, such that they prefer to attach labels to objects of the same kind (for example, five dogs or five balls) and not to relationships between objects (for example, five dogs chasing balls) (Markman & Wachtel, 1988). Moreover, children may also use Bayesian inference to acquire word meanings. Thus, it has been argued that when a child hears an individual label three dogs with the same label, she may infer that it is very unlikely that the speaker meant "animal" with the label and not "dog" because it is implausible that the speaker would have repeatedly picked just dogs and no other animals with a label meaning "animal" (Xu & Tenenbaum, 2007).

SCIENTIFIC METHOD: Early Use of Syntax to Guide Learning New Words

Hypothesis:

Even very early in syntactic development, children are able to use syntactic information to infer word meanings.

Method:

1. Seventy-two 19-month-olds were given practice watching videos with background narrations and choosing videos in response to questions.
2. In a test condition, children saw side-by-side videos in which an actor performed a novel action while another person stood by (intransitive action) or in which an actor performed some action on another actor (transitive action).
3. While looking at the videos, children heard either a two-noun sentence ("She is gorping her"), a one-noun sentence ("She is gorping"), or a neutral sentence ("Look here").
4. Experimenters scored the proportion of looking time for the two-participant event (transitive action).

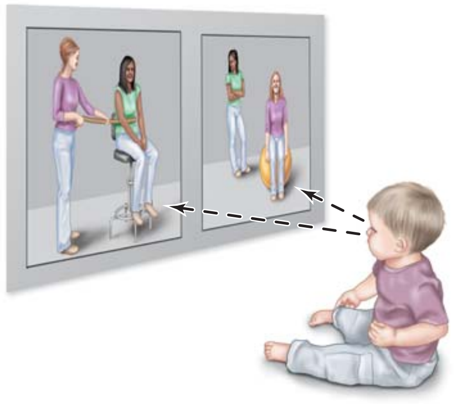
Results:

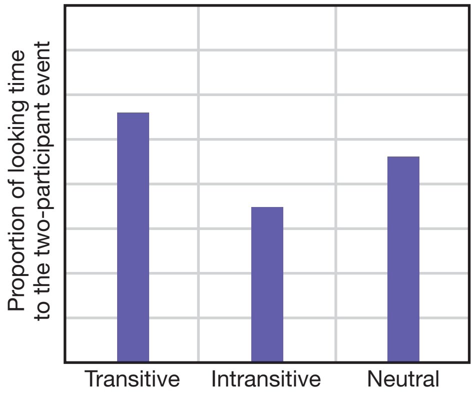
Infants looked longer at the transitive video after hearing a sentence with two nouns. They had no strong bias to prefer either video in the neutral condition without nouns.

Conclusion:

Well before 2 years of age, infants will use the presence of one versus two syntactic categories (nouns) in a sentence to infer the meanings of novel verbs.

Source study: Yuan et al. (2012).





Proportion of looking time to the two-participant event
Transitive
Intransitive
Neutral

Finally, the surrounding sentence frame can give conceptual clues to new word meanings. Thus, if a speaker says "John flugged that Bill lives next door," we can constrain the meaning of "flug" to a class of verbs involving beliefs and attitudes (for example, "thought," "believed"), which generally are not understood until relatively late in development (Lidz et al., 2001). This is known as "syntactic bootstrapping" (Chierchia, 1994), early versions of which may be present when the infant is as young as 19 months (Yuan et al., 2012; see Scientific Methods box), but which is clearly evident by the time infants are 24 months (Arunachalam & Waxman, 2010b).

Pragmatic Constraints Along with perceptual and conceptual constraints, the goals and beliefs attributed to a speaker may guide a child's understanding of what a word means. Such pragmatic constraints on word meaning come into play when the child infers what the speaker is referring to, thereby limiting where the child directs his attention (Tomasello, 2000). One pragmatic constraint, known as **mutual exclusivity**, refers to the assumption that each object in a language has only one label (Clark, 1988; Markman, 1989; Markman & Hutchinson, 1984; Markman & Wachtel, 1988; Merriman & Bowman, 1989). That is, if something is called a "hammer," then it is unlikely to be called by another name as well. To study how children use this constraint, researchers presented children with two objects—one that they were already able to name and one that they could not yet label (see Figure 8.10). While looking at both objects, the experimenter asked the child for an object by using an unfamiliar label. In this scenario, children as young as 2 years old tended to choose the object whose name they did not already know. They apparently assumed that each object had only one label, so that the new label did not refer to an object whose name they already knew.

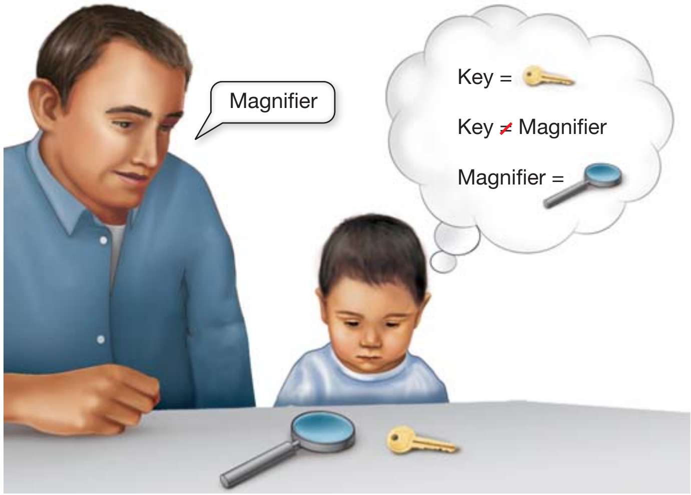


FIGURE 8.10 Mutual exclusivity. This bias associates new words with objects that do not already have labels. If the child is confronted with two objects and knows the name of only one ("key"), she will assume that a new name ("magnifier") applies to the other object.

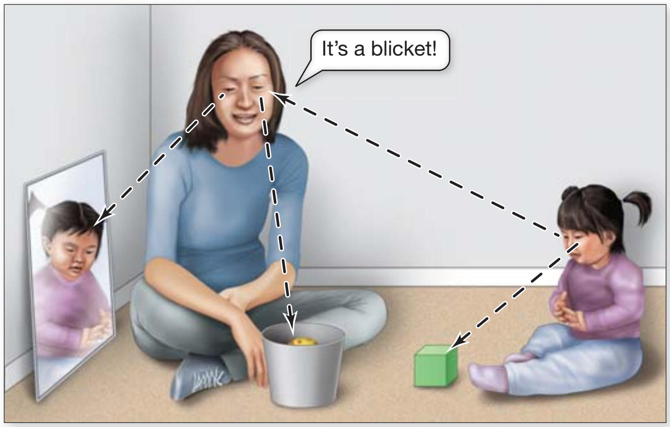

It's a blicket!

FIGURE 8.11 Using the speaker's gaze. Children younger than 18 months old know that the direction in which a speaker is looking provides information about what she is speaking about. In this study, the experimenter used a mirror to covertly watch where the child was looking while the experimenter looked into a bucket and declared "It's a blicket." Even though the child did not know she was being observed, she checked the direction of the speaker's gaze to decide what the person was calling a "blicket."

Other kinds of pragmatic cues also help children narrow down possible word meanings. For example, where parents look and the emotions they show influence how children interpret the things parents say (see Chapters 6 and 7). A series of elegant experiments examined how children as young as 1 year use the direction of an adult's gaze to help them understand what is being talked about (Baldwin, 1991, 1993). In one setup, at the same time that the child was looking at a toy, the experimenter would look into a bucket and utter "It's a blicket" (see Figure 8.11). The child would often look away from the toy to focus on the adult to see where his gaze was directed. Later, when the child was shown both the toy she had been looking at and the object that was in the bucket and asked to "point to the blicket," she would point to the object that had been in the bucket. These results argue strongly against the notion that children merely associate the words they hear with whatever they are looking at. Instead, even the youngest children took into account where the adult was looking. Children also rely on a speaker's mental and emotional state. Thus, if a speaker says, "Let's find the blicket" and frowns while looking at and touching two objects, but smiles while looking at and touching a third object, a 2-year-old will assume that the third object is the "blicket" (Tomasello & Barton, 1994).

Q: What are three examples of constraints on word meaning that seem to operate early on?

The Nature of Constraints on Word Meanings We have seen several examples of constraints on word meanings. Although the nature of these constraints remains controversial, it appears that they may reflect broad cognitive biases that extend beyond the process of word learning (Bloom, 2000). Consider the whole-object bias, for example—children's strong preference to attach new words to whole objects rather than to objects' parts or properties (Woodward & Markman, 1998). This same bias is also involved in tasks that have nothing to do with word learning (Bloom, 2000). In counting, for example, children show a strong bias to count whole objects as opposed to objects' properties (Dehaene, 1997). Like words, numbers are typically associated with whole objects.

The mutual exclusivity bias may also have a much broader basis. We do tend to think that if one object already has a label, then a new label must apply to something else. But more broadly, when we are engaged in conversation, we assume that the speaker will indicate shifts in topic. Thus, if the speaker introduces a new label rather than using a familiar one, we tend to assume that the label must apply to an object not yet named and that the new label is serving as a topic-shifting device (Clark, 1995).

Children could not learn word meanings without powerful ways of limiting the number of possible meanings. Several different combinations of constraints provide these limiting guidelines, and they appear to apply not just to words but to many aspects of cognition and communication. If there is a language acquisition device, it does not seem to be specialized for learning most word meanings. Instead, children usually acquire specific word meanings through using more general learning strategies (Bloom, 2000).

Q: What is the evidence against the proposal that constraints on word meanings are active only in the context of word learning?

Developmental Changes in Word Meanings

Beyond the constraints that enable children to narrow down the vast number of possible word meanings, children's understanding of word meanings seems to change in fundamental ways over the course of development. Researchers have investigated this process for more than a century, exploring whether the changes in children's mental representations of words occur gradually or in distinct, qualitatively different stages.

Overextensions and Underextensions The studies of developmental changes in children's understanding of word meanings have focused on two common patterns that children show as they acquire new words. The first of these tendencies, called **overextension**, involves applying a word too broadly. For example, a toddler who calls any large, four-legged animal a "cow" has extended this label far beyond its true boundaries. A child might happily use this label for horses, pigs, and large dogs, and on a trip to the zoo might call zebras, elephants, and antelopes "cows" as well. This pattern is especially apparent in observational studies in which caregivers or other observers write down children's notable utterances each day. Those records often document overextensions because they are obvious and often amusing—as when a toddler starts calling all men "Daddy." On the other hand, the related pattern of **underextension**, in which a child incorrectly applies a word too narrowly, is much less noticeable, though also very common (Anglin, 1970). A child who underextends the word "doggie" by applying it only to dogs that look like the family pet might say "doggie!" when he sees a Labrador retriever or another kind of large dog but might say nothing in the presence of small dogs (see Figure 8.12). This underextension would probably go undetected by his parents and others.

Q: Why might it seem that children mostly overextend word meanings when in fact they also underextend them?

Linking Features with Meanings One way to think about semantic development focuses on the features associated with word meanings. In particular, most researchers assume that people use certain perceptual and conceptual features of objects and events to help link words to relevant objects and events. For example, the meaning of "dog" is typically said to rely on both perceptual features of dogs, such as certain sizes, textures, and shapes, as well as conceptual features of dogs, such as being an animal, a living thing, and a physical object. Researchers who are studying semantic development have investigated how these semantic links between features and words develop, and they have asked: Are the developmental changes in children's understanding of word meanings linked to changes in the way they think about semantic features?

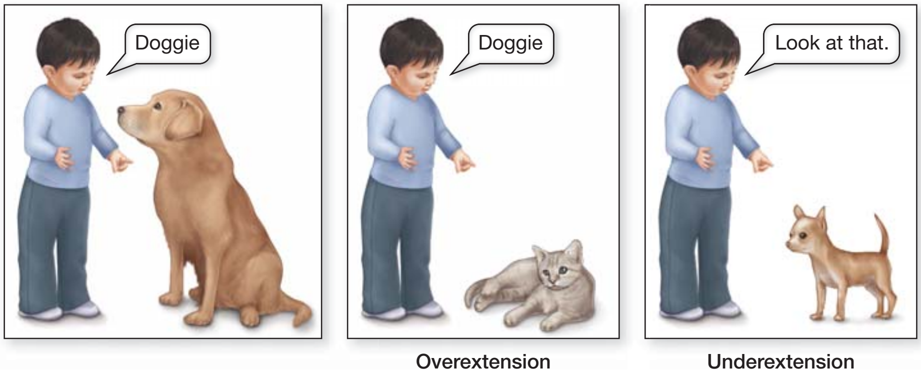

FIGURE 8.12 Overextensions and underextensions. While overextensions of word meaning are often easier to notice (and were more commonly recorded in early diary studies of children), underextensions also occur. The child might comment on something without realizing that a familiar name applies to it, or the child might say nothing at all.

One proposal suggests that the types of features children use to represent word meanings change with development. For example, younger children may focus on perceptual features, such as color, size, and surface texture, rather than functional or conceptual features, such as an object's use or whether it is dangerous. This view assumes that younger children are either unable to use some kinds of features or, at the least, have a strong bias against using them (Gentner & Rattermann, 1991; Landau et al., 1998; Nelson, 1973).

A second view suggests that the ways that children internally represent semantic features change. For example, younger children might take note of as many features of an object as possible to determine what its name means, whereas older children weigh only the few features they have determined are central to the meaning. To see how these theoretical approaches are translated into experimental studies, we will take a closer look at an example of this second type of proposal.

One way of envisioning how mental representations of word meanings develop is based on the idea that word meanings are made up of two kinds of features (Smith et al., 1974). **Characteristic features** are the properties most typically associated with members of a category. For example, characteristic features of jails include that they have bars on the windows and are highly secure. **Defining features** are the properties that pertain to what the word really means and how adults would tell whether it applies in a particular case. Thus, a defining feature of jails is that they are places where criminals are held. Not all words' characteristic and defining features can be easily distinguished, but for those that can, a possible developmental model emerges (Keil, 1989; Keil & Batterman, 1984). Perhaps younger children initially rely on characteristic features as the basis for word meanings, and then, as they get older, they shift to understanding word meanings in terms of defining features. Thus, they may undergo a shift from relying on characteristic features to emphasizing defining features for learning word meanings. This characteristic-to-defining shift could also help explain younger children's greater use of over- and underextensions of word meanings. If a younger child puts a greater emphasis on the characteristic features of the most typical jails, she might call a well-fortified bank a "jail" (overextension), while not recognizing a more upscale jail as such (underextension).

In an experiment designed to discover whether children considered characteristic or defining features more important to various word meanings, researchers told preschoolers and elementary school children several pairs of descriptive stories created to pit an object's characteristic features against its defining features. For example, in one story, the children were told:

> There is a beautiful building with columns. Mr. Johnson lives there, but he has a big problem. There are these cracks in his floors and walls. So, he covers them with paintings and statues, and he never lets anyone see them. Could that be a museum?

This building has several characteristic features of a museum (it is beautiful, has columns, and is filled with art), but it lacks an important defining feature: no one is allowed to see the art inside. In contrast, the second story in this pair describes a building with the defining features of a museum, but not its characteristic features:

> There is this small wooden shack in the countryside. People come from all over and pay 50 cents to get inside and see the interesting display of dirty shirts with rings around the collar and spots and stains. Could that be a museum?

If younger children understand word meanings only in terms of characteristic features, they should identify the first example as a museum, but not the second. And if older children and adults base word meanings on defining features, they should do the opposite.

The results suggested that preschoolers more often base their notions of word meanings on characteristic features, and elementary school children more often use defining features. Nonetheless, this characteristic-to-defining shift does not occur for all words at the same time. Rather, depending on the words involved, it can extend from the preschool years on into adulthood. Words in some domains, such as terms for moral actions (lying, stealing, cheating) shift in the preschool years, while words in other domains, such as terms for kinship (uncle, aunt, grandmother) shift much later (Keil, 1989). Interestingly, the shift does not occur for each word separately; instead, clusters of closely related words shift at the same time, probably because the words have closely interconnected meanings. It is very hard, for example, to know the defining features of a husband without knowing those of a wife.

In short, children initially use characteristic features to understand word meanings, and over the course of development, they increasingly focus on defining features. Adults, too, show this pattern of semantic development as they progress from novice to expert in a particular area (Chi et al., 1981).

Q: Give an example of a characteristic-to-defining shift in the development of word meaning.

The Growth of Grammar

We have seen that as children acquire word meanings, they seem to draw on general learning strategies and constraints that extend far beyond the domain of language. Learning grammar, however, may depend on much more specific mechanisms and constraints that are unique to language. The grammar of a language principally contains the syntactic rules for combining words, prefixes, and suffixes into well-structured sentences. In the first few years of life, the child's syntactic abilities develop rapidly, which has drawn many researchers to explore how these impressive changes unfold.

One theory that aims to explain how children come to use and understand syntax, known as the **principles and parameters approach,** was advanced by Noam Chomsky (Chomsky, 1975, 1981). This approach suggests that a common set of principles governs the internal structure of all languages—for example, the principle that all sentences must have a verb. In addition, because specific languages also vary in many ways, this view also holds that early in life, the child's mind contains a large number of possible linguistic forms or alternative parameters that become fixed, or set, according to the specific language the child learns—for example, whether the language requires that a sentence explicitly includes a subject or if it can be dropped and represented implicitly. Thus, while all languages share certain kinds of grammatical categories—for example, subject, verb, object—individual languages differ in terms of other factors that have to be set for each language—for example, how clauses are embedded within sentences or word order.

By analogy, consider the process of installing a new scanner. All scanners share basic features and use similar methods for transferring data, but they differ in the details of their resolution settings, error-checking routines, and the like. To set up a new scanner, you have to make a number of choices to make it compatible with your computer, printer, and perhaps other devices. Similarly, researchers following Chomsky hypothesized that the young child does not have to "start from scratch" to figure out most aspects of language structure. Instead, she has to figure out a relatively small number of "settings" appropriate to her own language.

One example of a language parameter is its **branching direction**, which refers to the order in which ideas typically occur in a sentence. English is a right-branching language, which is evident in the sentence "I saw the man who taught the child who had a broken arm." The embedded clauses in this sentence ("who taught the child" and "who had a broken arm") branch out after, or to the right of, the main verb ("saw"). Japanese, by contrast, is a left-branching language, so the ideas in this same sentence would typically occur in a different sequence, "Had a broken arm child taught man I saw," with clauses branching out before, or to the left of, the main verb. Children seem to learn very early whether their language is right or left branching and then "set" that parameter, which then guides additional learning about syntax.

Interestingly, the early-acquired parameter of branching direction has close connections with the rhythm ingrained in the sentences spoken to a child. Left- and right-branching languages are each associated with particular intonation patterns. As very young children listen to their native language being spoken, they may use these patterns to "set" the parameter for right or left branching even before understanding much of the syntax (Mazuka, 1996, 1998). Thus, children may get their earliest clues about grammatical forms from the **prosody** of the speech they hear—that is, its acoustic properties, such as intonation, rhythm, and pitch (Hirsh-Pasek & Golinkoff, 1996).

The branching direction of a language is just one of many possible parameters on which languages differ and that need to be "set" by the young language learner (Valian, 1994, 2009). In fact, one drawback of the principles and parameters approach is the difficulty of determining how many parameters are involved in the world's languages and how many "settings" or variations are possible for each language. This approach also leaves researchers with the significant challenge of understanding precisely *how* parameters become set in the mind of a young language learner. Nonetheless, the principles and parameters approach to syntactic development is appealing in many ways. It describes how languages' universals might occur in conjunction with their many differences. It offers a theory about how children might learn syntactic structures and patterns that are specific to their own language by setting a parameter, rather than having to start from scratch.

In short, learning syntax and grammar seems to require rich mental capacities to support children's ability to master the specific, elaborate rules of their native language using only the relatively simple cues that they hear. When it comes to finding clues to their language's complex underlying structures, children are good detectives, even if their detective work occurs largely outside of awareness.

Q: What is parameter setting and how is it relevant to language acquisition?

Effects of Age on Language Acquisition

In addition to the overall constraints on syntactic structures that we have discussed, there are limitations on the periods during which syntax and phonology are acquired with ease. We can understand these limits by considering several kinds of evidence for such *critical periods*, including what happens when language acquisition occurs after such periods. Many of us have noticed that young children seem able to learn languages much more easily than adults. Such a pattern suggests a critical period for language acquisition—although, as we have seen, references to critical periods do not usually imply that learning becomes impossible after a certain point. Instead, critical-period effects usually refer to the way that certain behaviors or types of information, such as fusing visual information from the two eyes, singing a species-specific birdsong, or following one's parent rather than another moving object, become more difficult to learn after a certain point in development.

Some of the strongest evidence for critical periods for language acquisition concern our ability to learn a second language. Adults who move to a community where a language that is new to them is spoken will often speak the new language with an accent, even after speaking only that language for decades. Yet, young children who grow up in bilingual communities become fluent (and accent-free) in both languages. This change in language learning ability typically occurs during the onset of puberty. These critical-period effects on language acquisition can show up clearly in siblings who emigrate to a new country at the same time—for example, at the ages of 8 and 16—and must learn its language. Even 40 years later, when the siblings are 48 and 56, the older one will probably still show traces of an accent, while the younger one will likely sound like a native speaker. Although some especially talented or hardworking individuals learn to speak new languages without an accent into adulthood, this is rare.

The language abilities of non-native speakers also differ in more subtle ways that reflect critical-period effects. Much like the issue of accents, our ability to learn the more complex aspects of a second language's grammar partly depends on the age at which we learn the new language. Researchers had bilingual adults listen to sentences recorded in English (their second language), then tested their ability to detect subtle grammatical errors in these sentences. These studies showed a gradual, continuous drop in the adults' English grammatical skills, depending on the age at which they began learning the language (Newport, 1990; Figure 8.13). Adults who had been introduced to English when they were under 5 showed grammatical abilities equivalent to native speakers, whereas those who learned English as older children or as adults did not perform as well. Thus, someone exposed to English for 30 years, between the ages of 20 and 50, might well show poorer command of subtle grammatical forms than someone exposed to the language for only 10 years, from age 8 to 18.

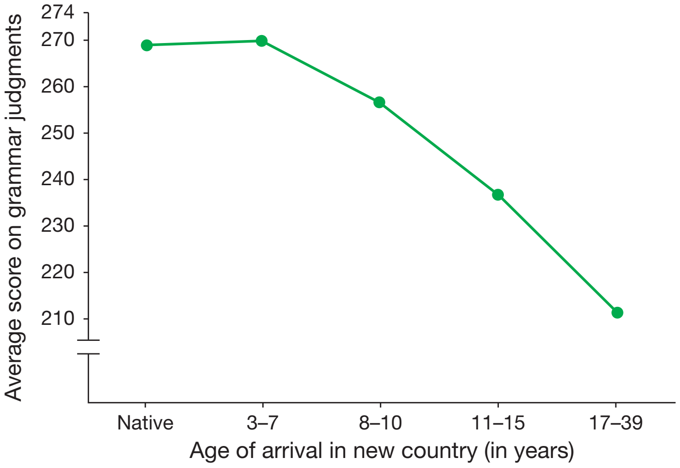

FIGURE 8.13 The critical-period effect for grammatical ability. When an average score is constructed for each person on a set of subtle grammar judgments in that person's second language, there is a clear decline in scores as the age of first arrival in the country of their second language increases. Adapted from Newport (1990).

Q: What aspects of language are likely to be subject to critical-period effects?

Acquiring Language after the Critical Period

The most striking demonstration of a critical-period effect on language development would involve complete deprivation of exposure to any language until the critical period was over. This would enable researchers to find out whether language learning would still be possible beyond the critical period. Of course, deliberately depriving a human child of language would be immoral, but over the years, some relevant cases have emerged from the enormous variety of human childhood experiences.

For centuries, there have been reports of **feral children**—that is, "wild" children who spent infancy and childhood out of contact with other humans. The first well-documented case occurred in 1800, when a French doctor, Jean Marc Gaspard Itard, began studying Victor, "the wild child of Aveyron," who apparently had spent much of his youth roaming the forests of southern France without any human contact (see Figure 8.14). When Victor was discovered at the age of 12, he was reported to possess no language.

Itard attempted to carefully document the child's psychological development and particularly his abilities to learn new linguistic, cognitive, and social skills. Despite Victor's early promise, however, he never developed much language ability, and Itard eventually grew discouraged (Itard, 1932/1962; Lane, 1976). It seemed as if there was a critical period for language and that by the time he was discovered in early adolescence, Victor had missed it.

FIGURE 8.14 Feral child and language. Jean Marc Gaspard Itard studied Victor, "the wild child of Aveyron," a child who had lived in the woods without human contact until he was about 12 years old. When he was found, Victor could not communicate in words. Despite progress in understanding language, Victor never acquired more than a rudimentary ability to speak.

More recently, another tragic case of a "wild" child occurred in the United States, which yielded more specific information about a possible critical period for language development. In 1957, Genie was born to parents who grossly maltreated her, at least partly because they regarded her as defective. She was born with a dislocated hip that required a cast (which her father prematurely removed), and she was improperly diagnosed as retarded because of her slow performance in an early pediatric examination—while ill with a high fever. Genie spent most of her childhood strapped to a potty or in a crib within an isolated room in a large house. During those years, she never heard another human utter a word (her parents only grunted and growled at her), and she was beaten for vocalizing any sounds (Curtiss, 1977; Rymer, 1992). When Genie was 13, her condition was discovered, and she was immediately moved to a foster home, and psychologists, social workers, and linguists worked to help her overcome her massive cognitive, social, and linguistic deficits (see Figure 8.15A). Finally, it was decided that the benefits of a more private life outweighed those of continued instruction and assessment, so her treatment was gradually discontinued.

Reports of Genie's language skills, compared with her cognitive and social skills, revealed a specific language learning difficulty. Even after 4 years of instruction and care (Curtiss, 1977), Genie differed most from other children with respect to language. While her nonlinguistic cognitive abilities had reached or surpassed the levels expected for an 8-year-old, showing that she had gone through rapid cognitive changes, her language skills lagged far behind.

With respect to language, Genie readily acquired new words, at least those for concrete objects, and her vocabulary continued to expand throughout the time she was studied. Genie also could perform adequately when she could rely on pragmatic cues to understand a speaker's intentions. For example, if someone in a room with her looked toward the open window and asked, "Genie, would you please close the window?" she would nod and go close it. (It is tempting to conclude that she understood the request. But if the person had instead looked toward the window and said, "Window" or "Don't close the window," Genie would likely have responded in the same way, simply assuming that the other person wanted the window to be changed somehow.)

Genie had much more trouble, however, when the task required her to understand linguistic structure. She entered the two-word stage rather easily, but then her progress slowed enormously. Although she did quite well at developing her vocabulary and in other areas of cogni-

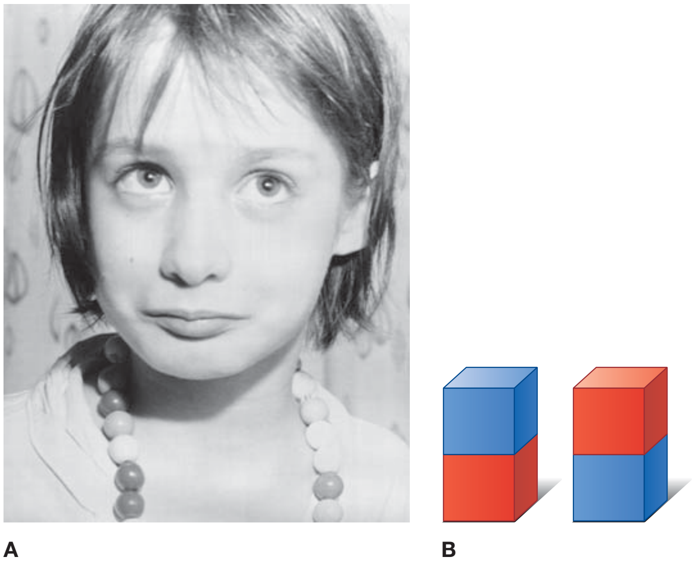

FIGURE 8.15 Genie and language acquisition. (A) A photo of Genie, who had been abused and not exposed to language until she was 13 years old. **(B)** After Genie was finally exposed to language, she rapidly learned many words but was never able to master syntax. For example, when she was shown two sets of colored blocks like the ones shown here and asked to either "give me the one that blue is on" or "give me the one that is on blue," she had great difficulty choosing correctly. This sort of task, which requires careful attention to syntax, was easy for much younger typically developing children.

tive development, Genie had considerable difficulty mastering aspects of syntax. For example, as a teenager, Genie did not perform as well as a typical 4-year-old at answering questions about the spatial relationships between two pairs of colored blocks, despite having had much more explicit instruction by that time than most 4-year-olds would have experienced (see Figure 8.15B). She also had not mastered the structures of negations, questions, or embedded sentences. Her grammatical development seemed far more impaired by her early experiences than other aspects of her cognition.

It therefore seems that, in those few well-documented cases, children who grow up without the benefit of human communication struggle to learn the grammatical structure of a first language at a later age. Domain specificity is implicated because in many other areas of knowledge acquisition they seem to progress rapidly and often become indistinguishable from other children of the same age.

Acquiring American Sign Language after the Critical Period

A different line of work on learning a language after the critical period has passed has looked at a group of people who experience relatively normal early cognitive and social environments in all other respects: congenitally deaf children acquiring American Sign Language (ASL). About 90 percent of deaf children are born to hearing parents, and the time of these children's first exposure to ASL varies widely, usually occurring when the children enter a residential school that teaches ASL as the main language. Being exposed to ASL at an earlier age results in clear advantages at mastering some aspects of its structure (Newport, 1990). Even decades of immersion in ASL among congenitally deaf adults was not enough to make up for starting to acquire it a few years later than one's peers (see Emmorey et al., 1995; Mayberry, 2010). Many health agencies require regular screenings for deafness starting at birth, and the evidence for critical-period effects suggests that it is most beneficial to start ASL instruction as soon as the child is identified as being deaf.

The most common explanation of such critical-period effects is that an underlying capacity specific to language learning declines with age (Borer & Wexler, 1987; Lenneberg, 1967). We saw in Chapter 4 that some critical-period effects in other species, such as songbirds and barn owls, are rooted in the changes that take place in the brain as it matures. Similarly, in humans, there is evidence that critical-period effects on language learning are associated with brain maturation. People who learn another language later in life seem to rely on different brain regions for their second-language grammatical processing than do people who learn the additional language early on (Bloom, 2000; Kuhl, 2010; Mayberry et al., 2011; Wartenburger et al., 2003)—and comparable brain differences have been found for learners of ASL as a second language (Newman et al., 2002). Other explanations of the critical-period effects on language development have not been fully ruled out, however. For example, rather than causing a decline of a language-specific ability, maturation may cause a more general learning capacity to diminish, affecting language acquisition as well as other abilities (Greenfield, 1991). Although some controversies remain about critical periods for language (Birdsong & Molis, 2001; Hakuta et al., 2003), the effects have been found often enough to suggest that they are real, even though they are not yet fully understood (Clahsen & Felser, 2006).

Inventing a New Language

Perhaps the strongest test of whether the child comes into the world with a bias for a rich array of highly structured abstract linguistic patterns would involve demonstrations that children could invent languages on their own that honored the universal patterns of all languages. We have seen that this will not occur in cases where children are reared in total isolation, but perhaps the results would be different in settings where communicative partners are available.

One dramatic case of language creation involves deaf children. In some cultures that considered spoken language intrinsically superior to signed language, deaf children were never exposed to signs; they were only spoken to, with the assumption that they eventually would acquire spoken language through lip reading or other means (Neisser, 1990). Tragically, very few of these children could easily use even a dozen spoken words. Fewer still had much success with lip reading, a medium in which many of language's meaningful distinctions (for example, the difference between the sounds "pa" and "ba") remain ambiguous. In these situations, deaf children have sometimes developed their own unique signed languages, either with their speaking family members or covertly with other deaf children if the surrounding culture discouraged signing. These invented sign languages clearly show the essential core features shared by all the world's other languages (Feldman et al., 1978). When these children created a new language, they seemed to be implicitly guided by a set of universal principles shared with all other known languages. They may have arbitrarily chosen certain parameters to set because there were no clues from a surrounding language, but they were still guided by a skeletal set of universal constraints on syntactic forms.

Nicaraguan Sign Language is a recent, more detailed example of a language created virtually from scratch by deaf children (Kegl, 2002; Kegl et al., 1999; Senghas, 2010). Because deafness was stigmatized in Nicaragua, most deaf people there spent their time largely in their homes or those of relatives. They had few opportunities to meet other deaf people, and they rarely married or had children. Thus, over many generations, deaf children typically had hearing parents and grew up with no exposure to sign language and no peer group within which to develop it.

Groups of deaf children were brought together for the first time in Nicaragua when the government set up new schools for the deaf in 1979. Initially, the children had no common language, just their own individualized signs. But they soon started to share their signs and adapt them into shared ones (see Figure 8.16). Together, they invented new signs, and their language developed a richer, more elaborate structure. Researchers observed that younger children had more complex and more fluent forms of the new language than the older children (Kegl, 1994, 2002, 2008; Kegl et al., 1999), suggesting a possible critical-period effect in which the ability to create a new language from scratch is more powerful in younger children. The language, which is now called Idioma de Signos Nicaraguense (Nicaraguan Sign Language), was created entirely out of the minds of the first deaf children in Nicaragua to be educated together.

As amazing as the story of Nicaraguan Sign Language is, it is not unique. Deaf children have repeatedly been shown to spontaneously create full-fledged languages of signs (Brentari & Coppola, 2013; Goldin-Meadow & Mylander, 1998; Meir & Sandler, 2008; Senghas & Coppola, 2001). In addition, when parents of deaf children make a concerted effort to use a standard sign language such as ASL, the richness and complexity of the children's ASL quickly surpass that of their parents. Again, because children deprived of all language input are able to create languages from scratch when they grow up with peers, we see support for the idea that hearing children bring to the task of learning their native tongue a tacit knowledge of those aspects of their language that are universally shared with all other languages. It is presumably the same tacit knowledge that guides deaf children to create new languages despite not having any external input.

FIGURE 8.16 The creation of a new sign language. These children in Nicaragua are signing fluently in a language that deaf children created on their own. A social group seems necessary to trigger the language system, but not input from others who already know a language.

Q: Why is sign language repeatedly used as evidence for the creation of new languages?

The Domain Specificity of Language

To what extent do young children start language learning already endowed with cognitive capacities that are tailored specifically for learning language? If those capacities are truly used only for the acquisition of language and nothing else, then they would constitute strong evidence for the domain specificity of a language acquisition device. As we saw in Chapter 1 and in our discussion of perceptual development (Chapter 3), these questions about domain specificity are closely linked to debates between empiricists and nativists. In addition, the debates often focus on whether domain specificity occurs only at the initial stages of language processing or whether some higher-level thought processes are also language specific. Thus, many empiricists might argue that some aspects of humans' sensory or perceptual abilities are especially sensitive to speech-like stimuli (domain specific), but that more abstract representations, like a language's meaning or structure, depend on cognitive abilities that also contribute to other, nonlinguistic skills (domain general). Nativists endorse domain-specific specializations at those more abstract levels as well. The most passionate debates about language focus on whether humans use a language-specific ability to learn some aspects of grammatical rules or whether they can fully learn grammatical rules through a more general set of cognitive skills that enable them to also learn other patterns beyond grammar.

In this section, we will take two different approaches to these questions. One strategy for assessing whether language is a domain-specific skill is to ask whether it can be dissociated, or distinguished as separate, from other cognitive functions. This approach involves looking closely at neural dissociations between brain functions that support language and those involved in other areas of cognition. If brain damage or congenital disorders can selectively affect aspects of language while sparing other functions (and vice versa), then those particular linguistic skills may be domain specific. We then ask whether other species can acquire human-like languages and what such findings suggest about domain specificity. In particular, if other species that have never shown any use of human-like languages in the wild can nonetheless learn such languages with a reasonable level of competence in captivity, it would seem that they must be using learning systems that are not specialized for language. It would, after all, be quite mysterious for them to have a language-specific learning system if they had never had to learn such languages in their evolutionary history.

Neural Dissociations

To examine whether language learning is domain specific, we will discuss neural dissociations in which language and other cognitive skills are affected differently by strokes or other damage to specific brain regions and neural circuits. We will discuss a kind of brain damage in which language is affected but other cognitive skills are not. We will also look at genetic disorders in which language skills are preserved but other cognitive skills are not. Finally, we will examine specific language impairment in which there are specific inherited syntactic deficits in language but not in other cognitive abilities.

Aphasias In adults, the dissociation between language and other cognitive capacities has most often been studied in **aphasia**, a type of neurological deficit in which localized damage to the brain causes language impairments. In some cases, often in a region in the left inferior frontal gyrus known as Broca's area, syntactic abilities are damaged while semantic skills remain more intact, often leading to especially salient deficiencies in producing language and labored speech. In other cases, often in a region in the posterior part of the temporal lobe known as Wernicke's area, semantic abilities are impaired and syntax seems to remain largely intact, often resulting in problems understanding speech while still being able to produce rapid speech (even though it is now made up of combinations of words that do not make sense). Moreover, other patterns of brain damage, such as those that severely impair spatial skills, often have little impact on language skills (Goodglass, 1993; Swinney, 1999). These patterns of deficits in adults may provide evidence for built-in language-processing regions and circuits in the brain. But it is also possible that areas of neural tissue with no specializations for language in young infants could nonetheless end up becoming specialized for language in older children and adults because they become organized in that way over the course of learning.

Williams Syndrome A new wave of developmental studies with populations of children who, because of genetic anomalies, either have intact language with impaired cognition or impaired cognition with intact language are of great interest to researchers studying whether language is domain general or domain specific. If these children show evidence for a dissociation of language from other cognitive skills at the earliest stages of language learning, this would provide compelling evidence for domain-specific language specialization within the brain. Thus, researchers ask if certain unusual alleles enable some children to learn language relatively well even if they are more generally learning disabled and if other alleles enable different children to learn nonlinguistic information well, but not language.

The genetic disorder known as **Williams syndrome** may provide one example of the "compartmentalization" of language relative to other cognitive abilities (Pinker, 1994). Although Williams syndrome is rare, it affects approximately 1 out of 10,000 children. It is caused by the deletion of a series of 26 genes from chromosome 7 and is characterized by an unusual set of physical and behavioral traits (Bellugi & Wang, 1998; Martens et al., 2008; Mervis & Velleman, 2011). Physically, these children are said to have similar facial features, including small upturned noses, long upper lip lengths, full lips, and small chins (see Figure 8.17). They are generally cheerful and extremely sociable. Overall, they score below normal on intelligence tests and especially on tests of visual-spatial and mathematical skills. Children

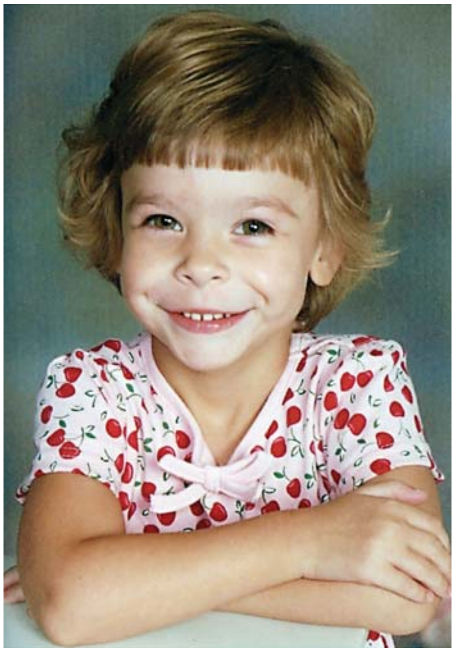

FIGURE 8.17 Williams syndrome and language. Children with Williams syndrome share a genetic disorder that seems to largely spare language abilities while impairing other areas of cognition. The defect also results in a facial expression, as shown here, in which the child has a small upturned nose, a long upper lip length, full lips, and a small chin.

with Williams syndrome may lag behind other children in the earliest stages of language acquisition (Bates, 2004). But by age 3, their expressive language skills seem relatively intact (Bellugi et al., 1993; Marini et al., 2010), and they chatter away rapidly in relatively fluent sentences. As adults, they still speak quickly, using many idiomatic phrases and an advanced vocabulary, but their speech often involves little meaningful content.

Many questions remain about the abilities and deficits of people with Williams syndrome. For example, those with Williams syndrome have often been reported as being quite musical. Perhaps there is a specific ability that is preserved in Williams syndrome, but it may not be as specific as language. It could be a somewhat broader cognitive ability based on differences in the volumes of particular brain regions and on dendritic connections (Eckert et al., 2006). As research in this area intensifies, it will likely provide a clearer account of the links between Williams syndrome and models of domain specificity. At present, however, the dissociation seems likely and points toward a separate language acquisition skill. In particular, the evidence suggests that children may have a special brain-based ability to acquire aspects of language that can work relatively independently of other cognitive skills, such that a child with obvious deficits in general cognitive skills can still reach relatively high levels of linguistic proficiency with little evident effort.

Q: Which cognitive capacities seem most affected in Williams syndrome and which ones seem to be spared?

Specific Language Impairment (SLI) The best evidence for dissociation of cognitive abilities comes in the form of *double dissociations*. Establishing a double dissociation between two cognitive abilities requires showing that either ability can be impaired while the other one remains intact. To show a double dissociation between language and other kinds of cognition would require two types of evidence. In addition to people who have broad cognitive problems and relatively intact language abilities (like those with Williams syndrome), you would also need to show the reverse—people with largely intact cognition and impaired language. Researchers seem to have discovered this second pattern in cases of specific language impairment.

Specific language impairment (SLI) first came to light in a single family. Members of this family were generally bright and successful. Over several generations, however, they showed highly specific problems using particular syntactic structures, including noun-verb agreement, verb tenses, and the proper use of articles (such as "a" and "the") and prepositions (Gopnik, 1990a, 1990b, 1994; Gopnik & Crago, 1991; van der Lely & Christian, 2000). Within members of the family, these language problems showed a distinct pattern of inheritance that suggested that the deficits were genetic. Moreover, the problems seemed to be linked to a specific rare mutation of an allele on a gene that was associated with these particular aspects of linguistic performance; the rest of their cognitive skills seemed completely unaffected.

Later studies have examined whether SLI is truly specific to these narrow linguistic deficits or whether it might reflect broader cognitive problems, such as difficulty perceiving rapid sequences of stimuli (Bates, 2004; Thomas & Karmiloff-Smith, 2005; Ullman & Pierpoint, 2005). Thus far, SLI does seem to involve some language-specific deficits. Although individuals with SLI struggle to process rapid speech sounds, they do not have this problem with rapid visual stimuli (Archibald & Gathercole, 2006). It also now appears that several genetic defects may contribute to SLI, including some that are language specific and others that have broader, more domain-general effects (Bishop, 2006; Graham & Fisher, 2013; Newbury et al., 2011).

Studies of language skills and deficits in special populations—such as in people with aphasia, Williams syndrome, or SLI—are still in their early stages, but they promise exciting insights into whether, or to what extent, language skills are domain specific. Current evidence suggests that a

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

A Language Gene?

For some time, researchers have suspected that certain locations on the human genome might be closely and specifically related to language abilities. In fact, many spoken and written language abilities seem to have genetic components. And different aspects of language, such as lexical versus syntactic abilities (that is, knowledge of words versus understanding of how to put words together into meaningful sentences), seem to be associated with distinct genetic loci (Stromswold, 2001). The most powerful evidence for genes related to language abilities comes from studies designed to pinpoint specific genes associated with language deficits. The findings point to a gene known as *FOXP2*, which is located on chromosome 7 and produces a protein that affects the formation of brain regions and circuits associated with motor control. In humans, it also affects brain regions associated with planning and ordering in speech and language.

This finding emerged during a study of three generations of the KE family in England (Fisher et al., 1998; Fisher & Scharff, 2009; Lai et al., 2001, 2003; Vernes & Fisher, 2011). Roughly half the family members showed significant spoken language difficulties, while the other half were unaffected. The affected relatives had severe articulation problems, so that their speech seemed extremely effortful. They also had enormous difficulty producing ordered speech sounds and could barely be understood. Overall, these individuals seemed to show severe disruptions of the planning processes and movements necessary for clear speech. A closer look revealed that the affected members also had difficulties interpreting some grammatical aspects of language.

It was clear that there was a genetic component to the KE family's language disorder, so the researchers started to look for a mutation that may have led to the disorder (Lai et al., 2000). Because relatives share more of their genes than strangers do, it was not easy to isolate the relevant gene that might have led to the mutation by comparing the family members' genetic sequences. A major advance occurred when researchers discovered a boy with highly similar language problems who was unrelated to the KE family (Lai et al., 2001). When his genetic sequence was compared with that of the KEs, it corresponded to the genetic sequence in every one of the affected family members—but not in the unaffected members—in a crucial way. Like the genes of the affected KEs, his genes showed a distortion of 1 amino acid out of the 715 produced at the site of the *FOXP2* gene. Other studies have since found that other abnormalities in the *FOXP2* gene are also associated with language deficits (Fisher & Scharff, 2009; MacDermot et al., 2005; Peter et al., 2011; Zhao et al., 2010) and with abnormal patterns of functioning in language-related brain areas (Liegeois et al., 2003; Vernes & Fisher, 2011).

Do these findings provide evidence for a "language gene"? One critical question concerns whether the gene's effects are language specific or whether its mutations actually affect a broader range of cognitive functions. The affected members of the KE family scored below normal on intelligence tests, but so did the unaffected members. This pattern suggests that the affected relatives' genetic difference at the *FOXP2* site was not necessarily a factor in their low scores. Even so, testing all the family members to compare their performance on more linguistic and nonlinguistic tasks would help clarify whether their deficit really is restricted to language-related learning and skills.

A second finding also relates to the question of whether *FOXP2* specifically affects language. This same gene is found in many species as a regulatory gene that activates other genes involved in the formation of brain structures and circuits during the embryonic period and in learning to sequence movements. The chimpanzee *FOXP2* gene differs from the human version in only 2 of the 715 amino acids it produces. The version in mice differs by 3. Moreover, the best estimates of when in evolution humans and chimpanzees diverged—that is, when the uniquely human gene emerged—point to between 120,000 and 200,000 years ago (Enard et al., 2002). Thus, around 10,000 generations ago, a very small mutation in *FOXP2* may have spread quickly and conferred a strong selective advantage on a human-like species, possibly leading to the ability to rapidly articulate strings of speech-like sounds.

Even if the *FOXP2* gene in humans turns out to be involved only in language abilities (and deficits), the mechanism underlying its effects still remains unclear, and the current evidence in no way suggests a single "language gene" or even a single gene for a particular component of language (Marcus & Fisher, 2003; Vargha-Khadem et al., 2005). It remains to be seen whether *FOXP2* is necessary for language, but it is clearly not sufficient. A full account of how humans are able to acquire a natural language with all its astonishing complexity will depend on the interaction of many genes with an elaborate set of environmental inputs.

domain-specific language acquisition system is present from the start, but more research will be needed before we can say that there is definitely such a system. More broadly, it is becoming clear that different aspects of language may yield different answers to questions about domain specificity. These answers in turn will inform questions about what sorts of cognitive abilities all normal children use to learn language and will help explain how such a complex body of knowledge and skills emerges so quickly in the first few years of life.

Q: What aspects of language seem to be affected in the disorder known as specific language impairment?

FIGURE 8.18 Comparing language acquisition abilities. The chimpanzee Gua and the human child Donald were raised together as if they were sister and brother in one of the first naturalistic studies comparing language acquisition in a human and a chimpanzee.

Species Specificity

Humans appear to be unique in their ability to acquire and use language, and yet researchers have wondered whether other animals, especially our closest primate relatives, might learn language more successfully under carefully tailored circumstances. If other species could acquire language, this would have important implications for understanding how young children's linguistic abilities develop. For example, if chimpanzees were able to learn and use language, despite never having shown such a rich communication system of their own, they would presumably have to rely on learning mechanisms that were not innately tailored for language. If this achievement were possible, it would show that the capacity for language does not require language-specific brain areas or cognitive abilities. Rather, it would suggest that more general systems, tailored for learning and using a broader variety of information, could be sufficient to acquire language.

Chimp as Child In the 1930s, psychologist Winthrop Kellogg and his wife Luella attempted to raise a 7½-month-old chimpanzee named Gua along with their own 10-month-old infant son, Donald, treating the two very similarly in order to compare their development (Kellogg & Kellogg, 1933/1967; see Figure 8.18). The Kelloggs called Gua by name and regularly encouraged her to talk but did not try to tutor her. Instead, Gua experienced the same sort of environment in which human children acquire language. Although Gua and the Kelloggs bonded and did communicate in some ways, Gua soon lagged behind Donald in the ability to speak. When the study ended, after about 9 months, Donald was already outpacing Gua at acquiring language. Interestingly, when the Kelloggs compared Gua and Donald's other cognitive abilities, Gua often outperformed Donald. She could skillfully manipulate objects, such as a door latch or a spoon, at an earlier age, and she could solve more complex spatial problems. Thus, Donald's much greater success with language suggested a bias for language learning that was specific to humans, given that he was not merely a better learner than Gua in all respects. Because the Kelloggs' study supported the notion that language is a specifically human ability, it also lent support to the possibility that linguistic abilities show domain specificity. If primates perform well in nonlinguistic cognitive tasks, then domain-general cognitive abilities are apparently not sufficient for learning language. Instead, some other cognitive component is needed that may be tuned to process and learn linguistic information.

Nonhuman Primates and Sign Language Several decades later, researchers tried a different approach to teaching apes human language. Around this time, a new, landmark account of the evolution of linguistic abilities argued that humans' unique specializations for language included not only mental capacities but also the structure of the anatomy that allows humans to articulate a wide variety of nuanced sounds (Lenneberg, 1967). Although the structure of the mouth, throat, vocal cords, and voice box in nonhuman primates prevents them from speaking, researchers wondered if chimps and great apes might be able to acquire a nonspoken sign language. This idea that nonhuman primates might be able to learn language using their hands converged with an increasing awareness that human sign languages were as natural and complex as spoken languages (Klima & Bellugi, 1979; Neisser, 1990).

Initial studies in which researchers attempted to teach chimpanzees to use American Sign Language (ASL) seemed to show some success (Gardner & Gardner, 1969, 1980).

The chimps appeared to master using signs to refer to specific classes of things, as well as combining signs in ways that suggested an understanding of syntax. These findings were met with tremendous interest and raised many questions. If the chimpanzees could learn signs, why didn't they ever invent them on their own? Did the chimps' "language," which they mostly used to request things, really resemble human language? And critically, how different were the chimps' conditions of language instruction from the experience of a young child learning a language?

If the chimps' manner of learning is quite different, we must be cautious in deciding whether the skill they have learned (and the cognitive capacities it involves) truly resembles that of humans. Consider the old observation that although a dog can learn to walk on its hind legs, dogs, unlike humans, do not have a predisposition to do so. The dog requires continued, intentional instruction to maintain the behavior, whereas the child simply develops the skill without guidance or reinforcement. If other species can only acquire language in a manner that resembles the dog learning to walk on its hind legs, this shows a profound difference between other species' language capacities and those of humans. For nonhumans, the only path to learning and maintaining language seems to be through intensive effort and continuous reinforcement.

Aside from the way they learned language, a closer look at other primates' rudimentary language abilities is also revealing (Seidenberg & Pettito, 1979; Terrace et al., 1979). Under scrutiny, the chimps trained to use ASL mostly seemed to be imitating signs that humans modeled for them, rather than spontaneously producing new phrases. More broadly, other primates, whether gorillas or chimpanzees, did not appear to have the capacity to use language in a flexible, generative way to form new, spontaneous expressions. There is, after all, a large difference between memorizing symbol sequences and being able to generate an indefinitely large number of new, meaningful, and well-formed sequences.

Q: In what ways are chimpanzees most similar and most dissimilar to the young child with respect to the ability to acquire a first language?

Bonobos and Joint Attention Criticisms of the early ASL studies with chimps bolstered the view that nonhuman primates' linguistic abilities fell far short of those of humans. But as the study of primate communication continued, researchers started to ask whether some primates might show partial language abilities—and which specific skills might be involved. As described in Chapter 5, one essential component of learning language is the ability to use joint attention to focus, along with a communication partner, on the same thing in the environment (Tomasello, 2005; Tomasello & Call, 1997). Primatologist Sue Savage-Rumbaugh and her colleagues (1998) sought to investigate whether bonobos, a rare species of primates that seems relatively more capable of joint attention than other nonhuman primates, would also do better than other primates at learning language. An opportunity arose when, in the course of teaching a language system to an adult bonobo, the researchers noticed that her adopted son, Kanzi, seemed to be picking up the language by observing her lessons—and without direct training (see Figure 8.19).

Kanzi's spontaneous learning was impressive, and the group quickly directed its efforts to him. He was paired with a 2-year-old child, and both were exposed to spontaneous speech and simple geometric shapes called *lexigrams* that were used to represent words. Kanzi's ability to understand syntax appeared to far surpass primates in earlier studies, but his ability to produce language lagged considerably behind the ability of a human child. More generally, bonobos seem to be capable of learning some relations between categories. But it is difficult to know whether their learning is truly based on understanding how syntax works (like the relation between a subject and a verb) or whether they are relying on a more concrete, conceptual understanding (such as the relationship between an agent and an action). Based on her studies, Savage-Rumbaugh concluded that it may be more accurate to think in terms of a continuum when comparing humans' language acquisition skills with those of other primates, rather than a sharp distinction (Savage-Rumbaugh et al., 1998).

FIGURE 8.19 Communicating with nonhuman primates. Kanzi, a male bonobo, learned language using lexigram symbols and appeared to be able to produce genuinely novel structures.

Indeed, it seems likely that the most sophisticated and social primates may have some abilities that are important to learning language and that these abilities may form the foundation on which our own abilities to acquire languages evolved. Evolutionary debates continue on the extent to which humans evolved broad, cognitive abilities that supported changes in many domains, including language (Hauser et al., 2002)—or whether the evolution of a capacity for language was more domain specific (Bickerton, 2007; Fitch, 2011; Pinker & Jackendoff, 2005; Stromswold, 2010).

Language and Thought

As language emerges in children, the question arises as to how it interacts with other aspects of thought. Does language come to structure thought and knowledge in ways that would otherwise be impossible without language? Does language make possible different kinds of cognitions? And do the particular properties of the specific language a child learns come to exert any unique guiding influences on the way she thinks about the world? Conversely, do changes in the child's cognitive development influence the way she uses language? Many strong claims, running in both directions, have been made about powerful influences between thought and language. We will start with the question of how language might structure thought.

Linguistic Relativity and Linguistic Determinism

Are our ways of seeing and understanding the world framed by the language we speak? This idea, that thoughts and perceptions are influenced by our native language, is termed **linguistic relativity**. The stronger version of this notion, **linguistic determinism**, holds that the language we speak actually determines the nature of our thoughts. Counter to both of these views, some argue that differences in communication merely reflect cultural differences between groups and that they can still exist even if the groups speak the same first language but have radically different cultures. These issues have interested developmental researchers, who have sought to understand whether these linguistic influences exist and how they might take shape as children come to master their native tongue.

The Sapir-Whorf Hypothesis The idea that specific languages powerfully mold thought is known as the **Sapir-Whorf hypothesis** after the anthropologist and linguist Edward Sapir and his student Benjamin Lee Whorf. In this view, all speakers of a language acquire a way of perceiving and understanding the world that is unique to that language and a direct consequence of special aspects of that language (Whorf, 1956). Thus, the words of a language can influence the categories that the speaker uses for objects and ideas, and the grammar of a language can affect how the speaker perceives events. In this view, all prelinguistic children might think in terms of similar conceptual schemes, but as each child acquires a specific language, their conceptions of the same events would increasingly diverge (see Figure 8.20).

The Whorfian view is generally in line with empiricist traditions. It assumes that prelinguistic children have essentially no strong predispositions in how their minds "carve up" the world—or that if they do have predispositions, such biases are easily overridden by the specifics of each language. Yet, such an assumption seems increasingly questionable, given all that we have learned about the highly structured ways in which infants perceive and understand their world. It is still possible, however, that language exerts many new cognitive influences beyond those present in infancy.

Some of the most famous claims for language structuring our thoughts involve different levels of nuanced meaning across languages. You may well have heard the claim that children growing up in the Arctic learn far more words for snow than other children do and that this rich vocabulary allows them to perceive subtle differences between types of snow that other speakers cannot see. Although this example has become a classic, it is fraught with problems. First, it illustrates the problem of disentangling experience and language. If people living in the Arctic can discriminate between more kinds of snow, perhaps it is simply because they have a great deal of experience with it and more opportunities to see different types. Language would then simply mirror these conceptual distinctions rather than creating them. Second, speakers of other languages might well be able to make all the same distinctions by describing them with compound nouns and phrases rather than single words. Third, the analyses of Eskimo-Aleut languages that gave rise to the initial claim may have been inaccurate. Many languages' grammar includes rules for adding chains of prefixes and suffixes to a single root word, such that a whole complex sentence might appear to an outsider as one long word (Baker, 1996). Thus, the many "words" for snow may really be descriptive phrases, much like those that speakers of many other languages would use (Woodbury, 1991). In fact, the snow example itself may be little more than an urban myth that was never actually proposed by a serious scholar (Pullum, 1991).

In short, children who grow up in the Arctic are undoubtedly familiar with more types of snow than those in the tropics, but this difference may be completely inde-

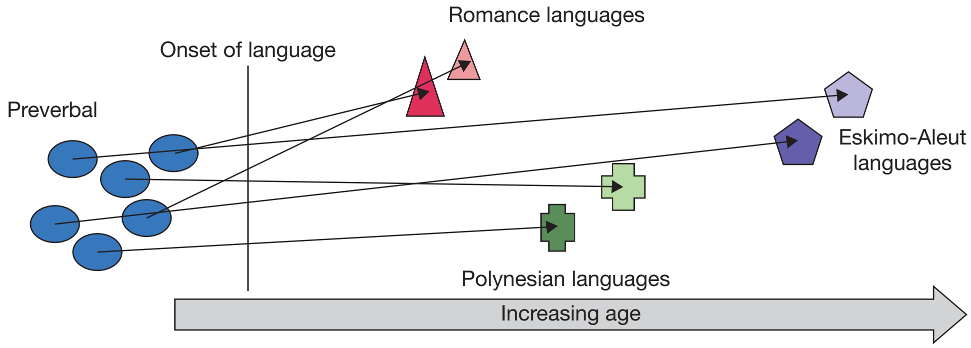

FIGURE 8.20 Linguistic relativity. According to Whorf, prior to the onset of language (indicated at the vertical line), children from different cultures have very similar conceptual schemes (indicated by same-shaped ovals), but after they become immersed in specific language families, their conceptual schemes diverge (indicated by different geometric shapes and different locations in conceptual space).

pendent of the languages they speak, resulting instead from varying experiences. It is clear that irrefutable support for the Sapir-Whorf hypothesis will require more powerful and carefully collected evidence. More recent research examining linguistic influences on thought has focused on more subtle effects that are often only evident in carefully controlled experimental settings. We now turn to a few such cases.

Color and Number If two languages' color words divide the spectrum of light differently, perhaps speakers of those languages actually perceive different sets of color categories. Because infants show categorical perception of color many months before any language skills (see Chapter 3), we know that language is not necessary for categorical perception effects. Nonetheless, color words might subtly tune color perceptions in ways that resemble the effects of spoken language on categorical perception of speech sounds. Some linguistic influences have indeed been found in languages that require two different color words for a category that has only one color word in English. For example, Russian speakers use different words for dark blue and light blue, while English speakers can simply use "blue" for both. Native Russian speakers do seem to show a subtle advantage over English speakers in the ability to discriminate between blues that take different labels in Russian (Winawer et al., 2007). Apparently, their need to constantly monitor different hues of blue to know which label to use may sharpen perceptual processes related to the discrimination of those colors.

Language development may also affect where in the brain categorical perception of color is processed (Kay & Regier, 2006; Regier & Kay, 2009). Preverbal infants are better at discriminating between color categories when the colors are presented to the left visual field, and therefore processed primarily in the brain's right hemisphere. In contrast, children and adults show better color discrimination when the colors are presented to the right visual field, and processed primarily in the left hemisphere. Moreover, toddlers who are just beginning to learn color words seem to process color category names in the right hemisphere, whereas those who show more mastery of the same color terms do so in the left hemisphere (Franklin et al., 2008).

Even in adults, learning new terms for unfamiliar color categories can quickly redirect which parts of the brain are dedicated to color processing, shifting the processing of the new categories from the right to the left hemisphere (Clifford et al., 2010; Zhou et al., 2010), but it is not yet understood how this change happens. Researchers are also exploring whether learning the names of objects might exert comparable effects on the way the brain processes objects. Along these lines, one study found that when 1-year-olds view objects for which they have learned labels, they show increased levels of visual object processing than they do while viewing equally familiar objects for which they do not have labels (Gliga et al., 2010). Certainly, not all cross-language labeling differences directly affect object perception and cognition (Barner et al., 2010), but there are some indications that language can modulate and redirect the way children process some aspects of colors and perhaps objects.

Specific languages also appear to affect mathematical thought, as demonstrated in one remarkable study of bilingual children who spoke both Welsh and English fluently (Ellis & Hennelly, 1980; see also Baddeley et al., 1975). The researchers utilized the fact that there is a difference in the length of the words that each language uses for numbers. Welsh number words are longer, and as a result, they make greater demands on memory and cause more difficulty in timed calculations like those on intelligence tests. Thus, the researchers found that the same child who was fluent in both languages took longer to do some mathematical calculations in Welsh than in English. Similar effects have been found when comparing mathematical calculations done in other languages with those done in English (Chan & Elliott, 2011; Pixner et al., 2011). Thus, a child's specific language may modestly influence the development of her mathematical thought. These effects may also be quite specific. For example, if Russian-English bilinguals learn to do a particular calculation in one language, they will later be able to do that calculation more quickly in that language than in the other language in which they are equally fluent (Spelke & Tsivkin, 2001b).

Q: How did Whorf and Sapir think language related to thought? What are some problems with their account?

Other Influences of Language on Thought Another possible influence of language on thought involves subtle differences in how categories are understood. For example, when a term is masculine in one language and feminine in another, subtle differences may arise in how other properties are associated with the object that the term refers to (Boroditsky et al., 2003). Thus, "key" is masculine in German and feminine in Spanish. German speakers tend to use more stereotypically masculine terms to describe keys (for example, jagged, hard, awkward), while Spanish speakers tend to use more stereotypically feminine terms (for example, shiny, intricate, yellow). Another study suggests that a child's native language may also affect how early the child learns his or her own gender. When a language requires speakers to specify the gender of others extensively—as Hebrew does, requiring gendered words for "you"—its young speakers seem to learn their own gender almost a year earlier than children learning a language such as Finnish, which has very sparse gender markings. Children learning English, which is in between Hebrew and Finnish in its gender markings, learn their own gender about 6 months earlier than the Finnish speakers (as described in Boroditsky, 2011). Thus, constantly marking a particular contrast in words may accelerate children's learning about it.

Some of the most intriguing claims about linguistic relativity arise from studies of how languages encode orientation (Levinson, 1997; Majid et al., 2004). Some languages guide their users to encode directions in terms of an external set of reference points (for example, north, south, east, or west) or particular geographical points ("It is in the down-mountain direction"). Other languages, including English, guide their users to encode directions relative to the speaker ("It is to the right of me"). Thus, Canadians and Europeans tend to say, "The boy is to the right of me," but speakers of Australian languages of the Pama-Nyungan group say, "The boy is north of the table" or "The boy is up-island from the table." Similarly, the Tzeltal language in Mexico uses both absolute terms of reference ("down mountain" or "across mountain") and intrinsic terms ("at the front side of an object"), but it has no words for terms relative to the self, such as "left," "right," and "behind."

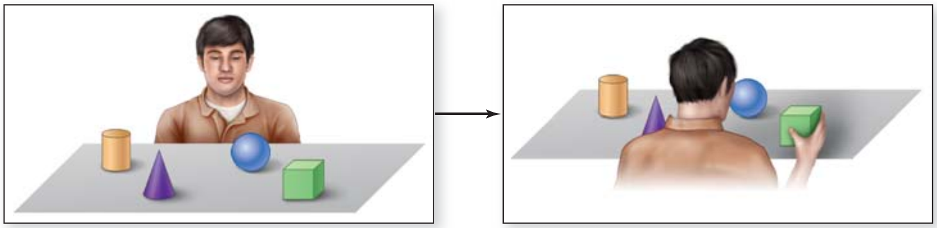
These linguistic differences seem to affect cognitive schemas and performance on spatial reasoning tasks. Consider, for example, the two tasks shown in Figure 8.21. Adults are shown several objects arranged on a table. The adults are then rotated 180 degrees, taken to another table, and asked to reproduce the arrangement using a new, duplicate set of objects. Tzeltal speakers will set up the objects in the same orientation as the first set relative to external points of reference (for example, placing the same object in the northernmost part of the display). By contrast, Dutch speakers will arrange the objects in the same orientation relative to themselves (for example, placing the same object in the part of the display closest to themselves). These and many other spatial tasks illustrate that the spatial terms a speaker uses seem to cause different ways of representing spatial information (Levinson, 1997).

Developmentally, these influences of language on spatial representations can occur quite early. For example, when children who are around age 8 in the Netherlands (where self-referential terms are primarily used) and in Namibia (where external referential terms are generally used) perform a wide range of spatial reconstruction tasks, they show differences very much like those found in adults (Haun et al., 2011). Their languages seem to have already set up strong default modes of spatial thought. Moreover, when the experimenters prompted the children to switch to the other type of spatial reasoning, the children found it very difficult, suggesting that by age 8, if not earlier, these modes of spatial thought are quite entrenched.

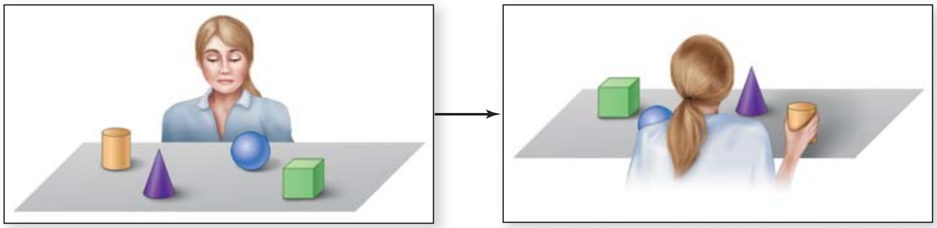
With the current revival of more subtle versions of the Sapir-Whorf hypothesis, we cannot yet know the extent to which language variations might influence cognitive development, but any such differences that have been documented in adults have strong developmental implications. In any areas where language exerts an influence on cognition, children can be expected to take different cognitive developmental paths from the time they begin learning a language, branching off in subtle ways from a common, preverbal path.

Language as an Amplifier of Thought

Even as controversies continue about whether differences in language cause differences in thought, there is another way in which language might shape thought that is independent of the differences between languages. This view focuses on the universal properties that all languages share as formal systems of symbols. The key question is whether language acquisition in general, regardless of the particular language acquired, might have a dramatic influence on the nature of thought, making thought in the presence of language profoundly different from thought in the absence of language. In fact, many suppose that human thought differs profoundly from thought in other animals precisely because of the way language amplifies and structures thought. In this view, as children acquire language, their thoughts are dramatically restructured through the common properties shared by all languages.



Tzeltal (Facing South) Tzeltal (Facing North)



Dutch (Facing South) Dutch (Facing North)

FIGURE 8.21 Spatial relative versus spatial absolute languages. Speakers of spatial relative languages (Dutch and English) and spatial absolute languages (Tzeltal) seem to perform nonlinguistic spatial tasks in different ways, re-creating displays in sharply contrasting formats that correspond to underlying spatial schemes. Adapted from Levinson (1997).

One of the most eloquent and forceful proposals about how the emergence of language reshapes thought came from the Russian developmental psychologist Lev Semyonovich Vygotsky (Vygotsky, 1934/1962, 1978). Vygotsky's approach to development was wide-reaching and influential, and we will consider other aspects of his approach later in the book (see Chapters 9 and 11). In this chapter, we will discuss his view of the influence of language on thought. Vygotsky believed that over the course of early development, the child internalizes his own language, making it a true vehicle or tool for thinking about the world. He held that before language is internalized, the child's thoughts are entirely concrete and tied to the here and now. Language, Vygotsky claimed, liberates the child's thoughts by making them more abstract and therefore a more powerful, principled way of understanding meanings and categories. Vygotsky described phenomena very much like the characteristic-to-defining shift that we discussed earlier in the chapter, and he assumed that such shifts are a consequence of internalizing language. He believed that language enables the child to formulate mental definitions instead of mere associationistic impressions. Others have since argued that when children begin talking themselves through difficult tasks, this is evidence that they have internalized their language as a vehicle of thought (Sokolov, 1972).

In Vygotsky's view, language may facilitate thought in both children and adults. It can provide additional memory and attentional support for complex tasks and can sometimes foster more analytical problem solving. Sometimes the effects of language may result from the ways in which grammatical structures and interpretations of words focus thought in particular domains like number (Carey, 2009) and theory of mind (Astington & Baird, 2005; de Villiers & de Villiers, 2009). Other times language may help integrate domains of thought. These general influences of language on thought may be analogous to the influences of gesture on thought, where nonverbal gestures often provide critical additional support to children to focus their memory and attention in complex tasks, boosting cognitive performance above levels found with language alone (Goldin-Meadow, 2011).

Several scholars have converged on the idea that the emergence of language allows the child to bring together different domains of thought and to combine them in novel ways (Carey, 2009; Carruthers, 2002, 2004; Gentner, 2003; Inagaki & Hatano, 2003; Mithen, 1996; Spelke, 2003; Spelke & Tsivkin, 2001a). They argue that preverbal children might understand concepts in separate domains but might need language to bring them together. Some examples include using language to unite knowledge of an environment's geometric features with its landmarks, to unite number estimations with more precise numerical knowledge, and to unite the domains of plants and animals into a common domain of living things. Language is considered a domain-general common ground within which to combine elements from separate domains. A key challenge for this proposal is to demonstrate that language is the dominant vehicle for these integrations, rather than just one of many ways of uniting elements of thought (Atran, 2002; Hampton, 2002). To resolve this question, researchers are increasingly conducting experiments to carefully contrast linguistic influences with those of other kinds of representations, such as symbols and pictures.

In the end, some effect of emerging language use on thought seems inevitable, if only because speaking our thoughts aloud so often brings new insights. But even after years of intensive research on how verbalizing while thinking relates to basic cognitive skills, many aspects of the relationship are still not understood (Bloom & Keil, 2001). At present, we simply do not know how much of an effect language has on developing thought. It most likely does not cause a global, stage-like shift, but it may well have interesting effects on more focused aspects of thought and knowledge.

Q: What is some recent evidence that language may facilitate specific aspects of thought?

Influences of Cognitive Development on Language

We have considered ways in which acquiring particular languages, as well as language in general, might influence the way a child thinks. We can also turn the tables and ask if changes in a child's cognitive development can influence his language. There is surprisingly little evidence that differences in cognitive development have a strong influence on the development of grammar (Snedeker et al., 2012), but cognition may have more of an influence on how language is effectively used. Jean Piaget, whose theories of infant cognition were described in Chapter 5, was especially influential in this area. Recall that Piaget was a proponent of developmental stages; he claimed that children experience distinct, qualitative changes in their ways of thinking and understanding. In his view, language is just one part of a much larger system of thought, and a child's progress through the stages of cognitive development has profound effects on his use of language (Piaget, 1926/1959).

Piaget observed, for example, that in experimental studies, young children had trouble understanding the full range of possible perspectives on a situation. More specifically, he concluded that children younger than about 7 years old were unable to take more than one perspective on a scene or to free themselves from their own viewpoint. He assumed that this **egocentrism** represented a general cognitive deficit that would also be manifested in young children's language. To examine how children's egocentrism affected their ability to communicate with others, Piaget set up an experiment in which children were told a story, then asked to repeat it to someone else. Here is one of the stories, followed by a typical repetition by an 8-year-old child:

> Original version: Once upon a time, there was a lady who was called Niobe, and who had 12 sons and 12 daughters. She met a fairy who had only one son and no daughter. Then the lady laughed at the fairy because the fairy only had one boy. Then the fairy was very angry and fastened the lady to a rock. The lady cried for 10 years. In the end she turned into a rock, and her tears made a stream which still runs today. (Piaget, 1926/1959, p. 83)
>
> An 8-year-old's version: Once upon a time, there was a lady who had 12 boys and 12 girls, and then a fairy a boy and a girl. And then Niobe wanted to have some more sons. Then she was angry. She fastened her to a stone. He turned into a rock, and then his tears made a stream which is still running today. (Piaget, 1926/1959, pp. 102–103)

Clearly something was lost in the repetition! Younger children seemed to neglect whether the people they were addressing would be able to make sense of their retelling. By using personal references and unclear pronouns, they thoroughly confused listeners who did not already know the story. Rather than providing listeners with the relevant background and details, it was as if the children were recounting the story to themselves or to someone else who knew as much as they did. Their problems in retelling the story are especially interesting because the children knew perfectly well what had happened. They could answer Piaget's specific, detailed questions about what took place, but they apparently did not know how to communicate their understanding.

In a similar study by Piaget and his colleagues, a researcher told young children how a device worked, then asked them to explain it to others. The researchers did their best to ensure that the children understood how the device—perhaps a syringe or steam engine—worked. Nonetheless, even children who seemed to fully understand the mechanism still regularly failed to explain it to someone else because they did not take the other person's viewpoint into account.

One of the most dramatic demonstrations of children's egocentric speech uses a **referential communications task** (Krauss & Glucksberg, 1969), in which two children (or a child and an adult) sit on opposite sides of a table, separated by a large vertical panel (see Figure 8.22). One child, designated the "communicator," is charged with telling the other child, "the listener," how to stack a sequence of patterned blocks. As the communicator takes each block out of a dispenser on his side of the panel, he instructs the listener to select the same block from her set, then put it on a stacking peg.

There are two reasons why children younger than roughly 6 years of age often fail spectacularly as communicators in these tasks: (1) Their descriptions are often too vague. They might say, for example, "Take the red one" when there is more than one red block. (2) Their descriptions often are too idiosyncratic and personal to be helpful to the listener. They might say, "Get the one that looks like Mommy's favorite hat" or "Take the one that looks like the tree in our yard" without understanding that these references are unfamiliar to their partner.

But is the egocentric use of language really a developmental stage, as Piaget supposed? Figuring this out requires addressing two questions: (1) Are there similar tasks at which adults also fail? If so, the cognitive ability in question may change in a slower, more incremental way over time, rather than showing a distinct shift into a new stage. (2) Are there similar tasks at which much younger children succeed? If there are, this raises the possibility that children may fail at particular versions of these tasks because they require more advanced abilities for completing the particular tasks—perhaps in terms of memory or conceptual understanding—that are separate from the overall cognitive ability being studied. In the case of the egocentric use of language, the evidence suggests that the answer to both questions is yes. Rather than a general stage of cognitive development, egocentrism seems to be a view that people revert to in the midst of difficult communicative tasks.

Adults often communicate egocentrically in unfamiliar settings, such as while traveling abroad. In especially blatant instances, tourists assume that everyone living in the foreign place they are visiting knows the tourist's own language. In slightly more subtle cases, someone in the host country makes a polite, tentative attempt to speak the tourist's native language—and the tourist replies with a rapid barrage of speech, forgetting that this is clearly a second language for the host. Egocentrism is therefore a factor in communication even in adult life (Keysar, 2008). But at the other end of the continuum, even very young children are not always egocentric communicators. Interestingly, very young children make the same adjustments to their vocabulary and speech patterns as adults do when they are talking to even younger children (Shatz & Gelman, 1973). Moreover, the specific ways that they change their language suggests that they are not just imitating what adults do. They seem to recognize that the younger child needs to have things made simpler. One way of understanding developmental change is to see children getting better and better at overcoming egocentrism as their executive functioning gradually increases and they become more skilled at inhibiting their own point of view so they can more easily take into account other perspectives. Thus, there is evidence that increasing executive skills are related to increasing performance in referential communication tasks (Nilsen & Graham, 2009).

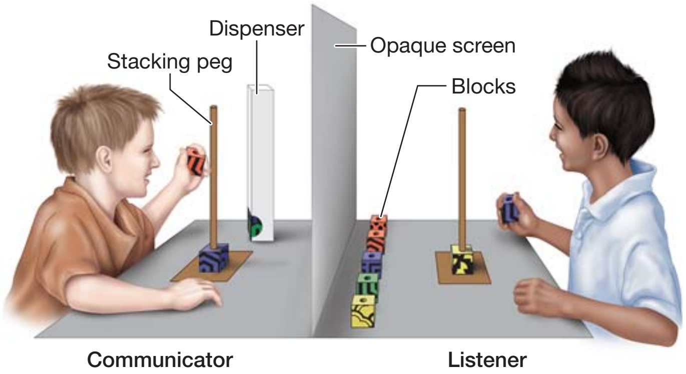


FIGURE 8.22 The referential communication task. Children fail to realize what the communicative common ground is and make highly idiosyncratic references to the blocks in front of them. These references make it difficult or impossible for the listener to know which block the communicator is referring to. As a result, the listener is unable to pick out the blocks described by the communicator to stack them on the peg. Adapted from Krauss & Glucksberg (1969).

Q: What is egocentrism, and how does it relate to language development?

This kind of debate, about whether particular developmental changes are stage-like or more continuous, is a classic one in developmental psychology. When evaluating claims that there are stages of development characterized by qualitative changes to a cognitive or social ability, consider the alternative. The ability may be manifested along a continuum, in which even the youngest children can succeed at the easiest levels and even mature adults might fail at the hardest levels. If this kind of pattern emerges among adults and children, and if all the different levels of the task are indeed tapping into the same basic ability, then the existence of developmental stages becomes less likely.

Language and Communication

As our discussion of egocentrism in communication shows, the development of language skills goes beyond semantics and grammar. Another important aspect of language development involves the ability to convey and interpret additional layers of meaning in an utterance, depending on its context. That context can include the surrounding sentences, the physical situation, and the listener's inferences about the speaker's (and other listeners') mental state. Adults can use and understand metaphors, irony, and sarcasm (Gibbs, 1994, 1999). They can decide when to discount a speaker's credibility, and they can understand the unstated norms of conversation. These *pragmatic* aspects of language—ways of using language to relay and infer meanings within a particular context and to understand and use indirect language—have roots early in the preschool years, but they can take many years to fully master.

DEVELOPMENT AND SOCIAL POLICY

The Cognitive Effects of Bilingualism

Early views of bilingualism seemed to suggest that children who faced the "chore" of learning two or more languages would certainly fare worse—in both linguistic and cognitive skills—than their peers who learned just one language (Haugen, 1956). But these early studies almost always confounded the effects of bilingualism with the effects of specific social disadvantages. They frequently involved the bilingual children of poor, immigrant families who were often enrolled in inferior schools. Within a few decades, however, a series of landmark studies led to a major turning point in our understanding of the effects of bilingualism on cognitive development.

Consider the situation in Montreal, Canada. Montreal is in the province of Quebec, which is officially French speaking, but where many people are bilingual. For the first half of the twentieth century, the city's wealth and power were largely concentrated in certain English-speaking groups, such that those who only spoke English often had an economic advantage over bilingual speakers of both French and English. Not surprisingly, the children from economically disadvantaged backgrounds, many of whom were bilingual, often performed worse than monolingual children on a variety of cognitive tasks. The breakthrough on the effects of bilingualism occurred when Wallace Lambert and his colleagues conducted much more careful studies of children from Montreal, balancing the socioeconomic status of the monolinguals and bilinguals (Lambert, 1975, 1985; Lambert & Tucker, 1972).

Lambert's results were striking. The bilingual children performed at least as well on intelligence tests and in academic settings as the monolingual children, and in several cases they performed better. Being immersed in two languages seemed to help the bilingual children become more aware of language itself as a system of arbitrary symbols. They developed this awareness earlier than the children who spoke just one language, and it seemed to also make them more aware of their other cognitive skills, such as their memory abilities. Since Lambert's studies, hundreds of other studies worldwide have documented a similar pattern: speaking more than one language is associated with several possible cognitive advantages and no known deficits (Bialystok & Barac, 2012; Diaz, 1983, 1985; Hakuta, 1986).

Bilingual and multilingual individuals consistently show advantages in tasks that require a more objective understanding of language and its structures. In one group of studies, monolingual and bilingual children were shown drawings of objects with word labels below them. Although the children could not yet read, some of them had a sense that words carried meaning. And when the labels were moved to accompany different pictures, these children also knew that the words retained their meanings, despite being placed under different objects. The bilingual children understood at much earlier ages than the monolingual children that words have fixed meanings and that words' physical characteristics are not linked directly to objects—that is, that bigger words do not necessarily correspond to bigger objects (Bialystok, 1997). Moreover, the awareness of language as a

Some forms of indirect language (language that is not literal, such as complicated metaphors, sarcastic or ironic comments, or double entendres) may hinge critically on cognitive capacities that develop during the school years, such as the child's understanding of the intricacies of others' mental states. (We will look more closely at these abilities in the next few chapters.) For our purposes here, the key point is that preschool children may have difficulty going beyond a literal understanding of utterances that depend on a rich interpretation of the speaker's beliefs and desires. Younger children might not have a sufficiently developed model of other people's mental states and how they interact with situations to be able to go beyond the literal. Moreover, even adults who are, for example, oblivious to the underlying hostility in a situation may not notice sarcasm or irony that would be obvious to people familiar with the circumstances. Examples like this make it clear that some aspects of indirect speech take years to understand and require that children become more knowledgeable about social situations and the mental states that specific situations elicit in the people involved. Thus, while a young child may easily understand metaphors such as "The car is hungry" (for a car that needs gas) or "The dog is talking" (for a barking dog) or "The house needs a new hat" (for a house that needs a new roof), that same child may have great difficulty understanding a wry comment about someone's mental abilities when phrased as "not the sharpest tack in the box." Understanding this metaphor requires knowing what it means to be a "sharp tack in a box" as well as inferences about relative mental states in others. Children are able to understand metaphors when they link domains system in itself (and not just as a means of communication), which bilingualism seems to foster, may also be critical to learning how to read. In comparisons of carefully matched groups of bilingual and monolingual children, the bilingual children often seem to master initial literacy skills earlier than the monolingual children (Bialystok, 1997). By fostering a more developed awareness of how language works, bilingualism may indirectly promote earlier literacy.

We began with the question of how learning more than one language early on might affect other cognitive abilities; it appears that there are only benefits. But these issues are quite different from the more often politicized questions about whether public schools should offer bilingual education for children whose first language is different from the region's official language. When bilingual education initiatives were first introduced across the United States in the 1960s, they were hailed as a major advance in educational opportunities for children who were not native English speakers. Although such initiatives came in several versions, one of the most common proposals in the United States was to offer instruction in both Spanish and English, especially to children for whom only Spanish was spoken in the home. Advocates argued that failing to provide bilingual education amounted to discrimination against immigrants. They held that children should learn to read and develop a knowledge base in their native tongue before learning English—so that they would not have to face learning to read in an unknown language. It also seemed that giving immigrant children the chance to initially learn in their native language would boost their self-esteem, whereas having to learn in an unknown language could cause a string of initial academic failures. Supported by this reasoning, bilingual education became a major program in school districts across the country. The need for these programs quickly increased as the percentage of new students who spoke little or no English rose rapidly in the 1990s and in the first decade of the twenty-first century.

Despite the broad reach of bilingual education programs, several reports comparing them with English-immersion programs have shown little or no advantage of bilingual programs (Glenn, 1997; Gersten et al., 1992; Rossell & Baker, 1996). By the late 1990s, these problems led California businessman Ron Unz to campaign for a new law to make English-only immersion programs the default for California's public schools and to offer bilingual public education only in specific districts where parents requested it. Interestingly, many members of California's Hispanic and Latino communities supported the proposal, which was approved in 1998. Since that time, a series of studies have argued that when we take a longer-term perspective, there may well be benefits from bilingual education because it enables children to achieve more rapid mastery of language and general-knowledge skills by initially exposing them to instruction in their native tongue (Christian, 2011; Collier & Thomas, 2007; Oades-Sese et al., 2011). But others ask if there may be delays in second-language development and whether those delays offset gains in other areas (Conger, 2010; Tong et al., 2008). The debate continues with great passion and emotion on both sides. We can only hope that the next decade will resolve the debate as more long-term and comprehensive studies on English-immersion and bilingual programs are compared. Nonetheless, the cognitive benefits of bilingualism still hold regardless of the way a second language is learned.

that they understand (for example, linking vehicles with eating), but they don't understand metaphors in which they don't understand one of the domains (Keil, 1986).

We also learn when to doubt what others say. We are, for example, often cynical about politicians' seemingly self-serving statements. More broadly, we are inclined to doubt a statement when it seems that the speaker is making it merely for personal gain. Although this cynicism seems like a fairly sophisticated interpretive skill, young elementary school children actually seem to know when to take a statement with a grain of salt. In one study, children were told about a race in which two runners finished so close to each other that it was hard to tell who won. When children as young as 7 years old were told that one of the runners said he had won the race, they thought he was less likely to be telling the truth than a runner who said that he had lost (Mills & Keil, 2005). Apparently, children take people's intentions and motivations into account when they are quite young as a way of judging their truthfulness.

Q: What are some reasons why indirect speech might take longer to learn to understand than direct speech?

A different aspect of the social uses of language involves learning how to be a conversational partner—how to create a clear narrative and how to use and interpret the pragmatic devices that enhance communication. Research suggests two broad patterns in the development of these skills. First, even the youngest speakers usually have some sensitivity to pragmatic devices and other conversational practices. Second, full mastery of such devices and skills takes many years, and young children often miss the more subtle nuances of communicative practices (Thompson, 1997). We will consider a few examples to illustrate children's early but incomplete awareness of these conventions: turn-taking skills, collaborative repair, politeness mechanisms, and narrative skills.

Turn-taking is a key aspect of learning to converse with others. Each speaker must be able to sense when the other has reached the end of a thought or a reasonable pause point. Almost all children sometimes interrupt inappropriately, but these turn-taking failures, while very noticeable, seem to be fairly uncommon. Even the youngest children rarely engage in simultaneous speech when someone is speaking to them (Garvey, 1984; Garvey & Berninger, 1981). In addition, young children are sensitive to pragmatic cues, such as the length of a speaker's pause, that serve as signals for turn-taking (Miura, 1993).

In the course of speaking to conversational partners, miscommunications may sometimes arise, necessitating collaborative repairs. The repair is completed when the speaker who was misunderstood realizes what was missing from the unclear utterance and repairs it by providing the necessary details to her communicative partner. Even very young children show some rudimentary forms of collaborative repair in their play. In one observational study, a group of 2- and 3-year-olds talking among themselves at nap time worked together to resolve miscommunications in very much the same way that adults do (Aviezer, 2003). Moreover, bilingual children as young as 2½ engaged in repairs while talking to someone who spoke only one of their languages. In these cases, if the listener asked the child to clarify a miscommunication, the child would switch to the listener's language (Comeau et al., 2007). On the other hand, despite their early, basic understanding of collaborative repairs, younger children show a limited ability to monitor the context of a conversation and understand when clarifications are needed (Loukusa et al., 2007).

Finally, it is important to keep in mind that conversational norms vary significantly across cultures—and even among supposedly similar peoples. Thus, even though the Swedes are considered quite reserved by international standards, a cross-cultural comparison of mealtime conversations revealed that they are chatterboxes compared with the Finns (Tryggvason, 2006). Every mealtime was an opportunity to instill in children this very noticeable difference in conversational style. Thus, the tempo of conversational exchanges, the time intervals that are perceived as "uncomfortable silences," and the amount of time that any one speaker talks before relinquishing control of the conversation are not simply reflections of general cognitive styles of information processing constraints. Instead, they can evolve over the years to have their own form in each culture and then be passed down from generation to generation.

Politeness mechanisms also vary considerably between languages and cultures; some languages, such as Japanese, have subtle conventions of politeness that may take until adulthood to master (Brown & Levinson, 1987; Holtgraves, 2002; Watts, 2003). Politeness serves complex social functions, including acknowledging differences in status or power, or softening the impact of a request (Clark & Schunk, 1980). Thus, when adults want someone else to do something, whether it is as simple as passing the salt or as onerous as jump-starting a car, they do not just issue directives. Instead, they embed the request in a frame of politeness. They also tend to be more polite with strangers than with close friends or family. Learning all these subtleties of politeness takes children several years. Early on, they often use simple direct commands like "Pass the salt!" (Bates, 1976). Not until age 7 or 8 do they begin to frequently make the kind of indirect requests that are culturally considered polite ("Could you pass the salt, please?"). By around age 9 or 10, children can easily recognize the inappropriateness of direct requests made by others (Axia & Baroni, 1985; Baroni & Axia, 1989).

Narrative skills involve the ability to describe an event in a coherent, organized way that conveys its key themes. Fully developed narrative skills normally consist of devices that convey the story's structure, including a brief summary or "title" telling the listener what the story is about, an introduction that is often quite conventional (such as "once upon a time . . ."), descriptions of the story's time and place, its characters, and the problem or challenge they face, the resolution, and an ending that, like the introduction, is often stylized. In addition, narrative skills include a kind of interpretation of the story's events, such as signaling the speaker's point of view through emphasis (Uchikoshi, 2005, see also Chang, 2004). Finally, narratives should order a sequence of events clearly in time, leaving out unimportant details.

Although children as young as 3 years old have a sense that events should be described in temporal order, children do not develop most narrative skills until they are about 6 years old. Younger children often omit key events from their narratives, giving incomplete accounts in which the events are not connected. Even 5-year-olds often end their stories at the high point rather than continuing through to the resolution (Peterson & McCabe, 1983). Thus, narrative skills develop and grow increasingly elaborate from the early preschool years into the first grade and beyond. In addition, there may be some gender differences, with girls starting to use context and make evaluative comments earlier than boys (Haden et al., 1997).

Narrative skills do not develop in the same way the world over. Their structure depends in important ways on the child's culture, including, for example, the extent to which the child experiences bedtime stories (Fivush et al., 2006; Heath, 1986). In one study, when 5- and 6-year-olds engaged in reading experiences that encouraged dialogues about the content of a storybook, they showed a substantial increase in narrative skills compared with children who received phoneme-awareness training, a common technique for early literacy teaching (Lever & Sénéchal, 2011). Given that the development of narrative skills enhances some forms of memory and may help to foster some reading skills (Fivush et al., 2006), it is impressive that narrative skills can even be imparted by mass media in relatively simple ways. For example, in one study, kindergarten children watched one of two television shows regularly for 1 year: either a program with a strong narrative structure or one that focused on verbal skills and vocabulary. By the end of the year, the group that had watched the show with a strong narrative structure showed markedly better narrative skills than the other group (Uchikoshi, 2005). Even though certain ways of describing events may seem obvious and automatic, it is clear that children's narrative skills improve when they are exposed to certain approaches to storytelling modeled in the broader culture.

This survey of conversational skills reveals that mastering them takes more time than almost any other aspect of language development. Very early on, children show awareness of turn-taking, collaborative repairs, politeness, and narrative skills. But in most cases, mastering these skills depends on developing an ability to read the social and cultural context of a conversation as it is unfolding, a skill that does not always come easily, even to adults.

Conclusions

Language is among humans' most distinctive abilities. Almost all people share this capacity. By contrast, after years of intensive and sophisticated instruction, even the most talented primates are far less linguistically competent than young children who receive no explicit language instruction at all. The capacity to acquire language is apparently so powerful that children who learn two or even three languages simultaneously do not seem to learn them more slowly than those who acquire only one (Gleitman & Bloom, 1999). And regardless of the number of initial languages, no one remembers trying to learn a language as a young child—it *just happens*.

We have seen substantial support for the view that we are endowed with a set of cognitive capacities that seem to be specifically tailored for language. That endowment is assumed to be the basis behind universals in linguistic structure throughout the world. Many cognitive and perceptual universals might well arise from stable environmental regularities, but such accounts are difficult to make in the case of language. Nonetheless, even with such an endowment, a great deal else is required for successful language acquisition. Thus, we might also have a much larger general learning ability than all other species that enables us to handle larger informational bundles much more easily and that supplements any language-specific mechanisms to make human language especially rich and complex. We might also have distinctive cognitive skills that are essential not just to language acquisition but also to a range of other cognitive activities that are distinctively human, such as joint attention, hierarchical embedding, and logical thought. These skills might again support any language-specific mechanisms in powerful ways.

At the same time, it would be too strong an interpretation to try to account for the human capacity for language solely in terms of general cognitive skill or in terms of other nonlinguistic cognitive capacities. A child's general cognitive abilities seem to have only a modest influence on his language acquisition. In some areas of thought, mature primates approach the competence levels of a 3-year-old child; yet with respect to language, they seem vastly worse off. In addition, while it is certainly true that we have other apparently distinctive capacities besides language, such as the production of art, those abilities do not seem to be obviously based on language. At present, there are no compelling demonstrations of cognitive capacities that are larger in scope than language and that can completely explain language acquisition.

Yet, aspects of language acquisition still draw on other domains of cognitive development as well. Thus, word meanings do not seem to be acquired in the same manner as the grammar of a language. Words are acquired through more general cognitive learning mechanisms, ones that are especially sensitive to the intentions of speakers. A rich network of constraints is needed to explain how word learning ever gets off the ground, but none of those constraints may be specific to language.

That all but the tiniest fraction of humans effortlessly acquires natural languages with all their remarkable complexity is one of the great wonders of cognitive science. It is all the more remarkable that this occurs without any explicit instruction and usually without any explicit formulation of rules. We also see in language acquisition a reprise of many of the key themes that have appeared in earlier chapters and that will appear again in later chapters. These include the importance of constraints, of social and cultural context, of the interplay between both domain-specific and domain-general faculties, and of the ways in which structures become fine-tuned through interactions with the environment. Language is also an intrinsically social enterprise, and yet its acquisition depends on the cognitive and representational capacities of each individual that make learning possible. Finally, we have seen that language is not just one thing with one pattern of acquisition. Grammar, word meanings, and pragmatics each have their own distinctive developmental stories and mechanisms, and while they do intersect in interesting ways, it is clear that no one overall account of learning works for these areas collectively.

STUDY AND REVIEW

SUMMARY

The Structure and Complexity of Language

- Language has generativity, which means that an unlimited number of novel expressions can be created by combining basic linguistic structures and by using basic rules.
- The main components of language are phonology (the sound patterns and rules for combining sounds into words), semantics (word meanings), grammar (including syntax—the rules for the structural relations of words), and pragmatics (how intended meaning is conveyed or understood in context).
- Universal constraints on possible grammatical structures may apply to all languages.

Acquiring a First Language

- Infants initially perceive more phonemic differences than the ones that they hear in the language spoken around them, but they soon come to perceive only the phonemes (or sounds) that are used in their native language.
- Infants begin babbling at about 4 months old. They go on to one-word utterances when they are about 1 year old and then to multiword utterances when they are around 1½ years old.
- Infants start to acquire language rules that are largely tacit and can generalize from words that they know to plural words and regular and irregular past tenses that they have never encountered before and do not know. As they grow older, however, they may overregularize plurals and past tenses until they finally are able to again use both regular and irregular constructions, thus showing a U-shaped developmental curve in language acquisition.
- Adults often use child-directed speech when talking to infants, speaking slowly and loudly, using a high-pitched voice, and accentuating the boundaries between words. As children start to incorrectly put together words, adults will often respond with recastings of what the child has said to show the child a correct grammatical form without specifically indicating that he was mistaken or giving him a rule for the correct form.

Theories of Language Acquisition

- Behavioral approaches maintain that language is learned through reinforcement and associations. But since parents rarely correct a child's grammar, this does not seem the most likely way that children learn to speak.
- Connectionist approaches use computer modeling of language acquisition to argue that humans use parallel processing and large multilayered networks of associations to learn to speak.
- Statistical learning approaches focus on language learning based on the probability of sounds co-occurring or following after each other in the speech stream. They examine how infants recognize recurring sound sequences within words or between words when they hear streams of sounds. Bayesian approaches are one way of tabulating statistical patterns, and they allow for straightforward integration of both statistical information and rules.
- Nativist approaches claim that infants are born with a language acquisition device (LAD) that enables them to recognize patterns common to all languages but that is flexible enough for the acquisition of particular words and constructions in specific languages. The LAD is dedicated to the learning of linguistic structures and not other forms of knowledge.

Discovering the Meanings of Words

- Children link words to concepts, which enables them to apply the words to the corresponding objects, properties of objects, or relations between objects. This linkage is a mapping of the words to the concepts and occurs without specific training and so quickly that it is often referred to as fast mapping.
- Constraints on word meanings, based on biases for interpreting words, limit the number of possible meanings that can be linked to a given word. There can be perceptual constraints (for example, the shape bias), conceptual constraints (for example, the whole-object bias), and pragmatic constraints (for example, that each object has only one mutually exclusive label) that help children more easily learn what words stand for.

- As children grow older, their understanding of word meanings changes. For example, they tend to both overextend word meanings (broadly applying meanings to many words) and to underextend (applying meanings too narrowly). For some kinds of words, there is also a shift from meanings based primarily on characteristic features (properties typically associated with members of a category) to defining features (properties that are necessary and specific to category membership).

The Growth of Grammar

- Common principles govern the internal structure of all languages, all of which have such categories as subjects, verbs, and objects, and certain abstract structural relations among these categories when they occur in sentences, while at the same time allowing for other structures that are unique to each language.
- Different parameters apply to specific languages, including the language's branching direction, which is the way that linguists describe different patterns of hierarchical embedding of syntactic elements in a sentence.

Effects of Age on Language Acquisition

- There may be a critical period for language acquisition, such that a language's grammar is more easily learned, as is its pronunciation without an accent, before a certain age (approximately puberty).
- Feral children may never easily learn a language's syntax if they are returned to human contact after they reach puberty.
- American Sign Language is more easily learned before puberty, just as is spoken language.
- Children who are born deaf and not exposed to language have been shown to invent their own sign language, complete with a rich, elaborate syntactic structure. This invention process occurs before the critical-period window closes.

The Domain Specificity of Language

- Aspects of language may be domain specific, with cognitive capacities tailored specifically for language, or domain general, with general cognitive abilities leading to language skills as well as to other cognitive achievements.
- Neural dissociations, such as aphasias, Williams syndrome, and specific language impairment, seem to indicate that some aspects of language are domain specific. Some cognitive structures used for the acquisition of syntax, but not semantics, may be specific to the domain of language. Despite intriguing genetic markers of language processing difficulty, the precise nature of these domain-specific structures remains a matter of active debate.
- Humans seem to have a special ability to acquire languages that is not shared with any other primates. Although chimpanzees have been taught sign language and bonobos have been taught to communicate with lexigrams, no nonhuman primate has even approached the linguistic abilities of any normal human child.

Language and Thought

- The Sapir-Whorf hypothesis held that language influences thought. But this classic view of language as dramatically changing thought in ways that are strikingly different across families of languages has not been shown to be true. In more subtle ways, however, specific languages do seem to influence the availability of certain cognitive schemas that can in turn cause differences in task performance.
- Researchers also doubt older views that languages in general cause a new stage of cognitive development by dramatically amplifying the powers of thought. At the same time, there are many smaller ways in which the emergence of language may foster the growth of cognitive skills.

Language and Communication

- Children constantly refine their abilities to understand the real meanings behind utterances. These abilities start, in more limited ways, very early with young children showing some sense of metaphor and of the ways in which speakers' motivations are relevant to the truth of their utterances. Children also show marked increases in conversational and narrative skills during the preschool and early school years.

THOUGHT QUESTIONS

1. In what ways does bilingualism seem to confer cognitive benefits? Would those benefits be reduced if the second language were acquired as an adult? Why or why not?
2. When we write out our ideas, we often find that we can create more complex thoughts and arguments than when we merely try to do so orally. In what ways might the cognitive benefits of writing be analogous to the cognitive benefits that oral language confers on nonverbal thought? In what ways are those benefits different?
3. Given that the vast majority of children rapidly acquire their first language without any explicit instruction, some argue that it is odd to grade language courses in college in the same manner used to grade other types of coursework. They believe that language competency in college should instead be treated more like passing a swimming test. Consider the pros and cons of this position and state your own view.
4. How is the acquisition of birdsong, as described in Chapter 4, similar to the acquisition of human language? How is it different?

Conclusions

Summary

For over a century, researchers have interviewed children at different ages to see how they conceptualize and talk about the world around them. As children age, their understanding of the world changes. These changes seem apparent even if the vocabulary they use is not different. Something about their thought patterns themselves seems to change with development. Consider two brothers, ages 5 and 9 years old, overhearing adults discussing various family relationships, including siblings and parent-child relations, between people that the children do not know. At one point, the 9-year-old interrupts to say that one person must be another's uncle. The adults nod in agreement, while the 5-year-old looks surprised, then confused. "How did you know that?" he asks his brother. Just such a conversation happened between two of our sons when they were young, and it illustrates a clear contrast in how they drew inferences from what was said in the overheard conversation. Our older son understood kinship terms in such a way as to realize that one must be an uncle. Our younger son could not grasp that such a relationship was logically implied by what was said.

When children talk about the world, you can quickly guess their approximate age, even when the vocabulary they use at different ages is about the same. At a deeper level than word choice, their thought patterns seem to mature with development. As a result, children of different ages sometimes interpret the same conversation in quite disparate ways.

This chapter explores how age differences affect the way that children think about and understand the world. Our goal here is to characterize the changes in cognition that occur with age. We will see right away that these changes do not just affect children's language. Instead, they take place at the level of children's conceptual knowledge, which is then reflected in their language. We will want to understand how the changes in children's knowledge and thoughts are manifested in the things children say and do. To this end, we will look at how they reason about simple real-world situations, ranging from pouring liquids into containers, to animals' life cycles, to the occurrence of day and night. We will then see how researchers use that information to infer what is changing in the child's mind.

In all these cases, we will ask how a child's understanding of the world changes with age. Does the older child simply know more facts about the world? Is the older child simply faster or endowed with a larger memory that somehow makes him see events and relations differently? Does the older child have certain ways of thinking, such as an understanding of certain logical relationships, that are unavailable to the younger child? Studying the ways that children come to know and understand the world has yielded some extremely ambitious, broad theories about psychological development. These theories have captivated professionals in many fields who work with children, affecting many aspects of their work, from school curriculum designs to psychotherapy techniques.

This chapter also explores some of the differences between the best-known theories of the growth of children's knowledge. We will consider how these approaches differ on each of three dimensions used to describe developmental changes: (1) Are changes considered qualitative or quantitative? (2) Are developments viewed as global or local? (3) Is the process of change limited and directed by foundational constraints, which are present from the start (often allied with "nature" views), or by emergent constraints, which arise over the course of development and reflect the influences of experience (often allied with "nurture" views)?

The first theorist we will discuss is the highly influential Jean Piaget. Then, as we have in other chapters, we will consider the research that has followed from his work and challenged many of his ideas. As we will see, many decades after Piaget's initial studies, researchers continue to test children with variations on his experimental tasks, and many of the phenomena he uncovered remain topics of intense interest. Along the lines of the recent work on infant cognition, which we discussed in Chapter 5, this more recent research on childhood cognition suggests that young children are far more capable than Piaget thought possible. Much as was the case with infant cognition, apparent failures by young children on some Piagetian tasks have been reinterpreted in ways that reveal that young children actually have a range of impressive cognitive abilities that serve as building blocks for later conceptual growth.

We will then turn to how children develop basic knowledge and understanding within several broad nonsocial domains that are relevant to life in all cultures, such as spatial relations, number, and the biological world. By looking into these culturally universal domains, we will be focusing on intuitive forms of knowledge and taking the perspective of the child trying to understand the structure of the world around her.

Finally, we will consider the broad social and cultural contexts within which cognitive development occurs. Children do not develop as isolated individuals trying to make sense of the world alone. Instead, they grow up in particular cultural and social settings, which are critical components in understanding their cognitive development. We will see that something as basic as living in a rural setting versus an urban setting can strongly influence how children think about the living world and that a culture's emphasis on individualism as opposed to collectivism can influence how children interpret simple events. We will consider the sociocultural perspective put forth by the Russian psychologist Lev Semyonovich Vygotsky, who believed that children are guided by the frameworks of knowledge and ways of thinking that prevail in their own culture and that they eventually come to internalize them. More generally, we will consider how parents and teachers can provide support that enables children to perform at much higher cognitive levels than they otherwise would.

In the next chapter, we will look at the child from a different perspective, one that focuses on specific cognitive skills like memory, attention, and reasoning, which enable the child to process information and negotiate the world. There, we will also examine a few specific skills—reading, arithmetic reasoning, and using symbolic representations—in which individuals' levels of accomplishment can differ significantly. The perspectives on cognitive development discussed in these two chapters are closely related, and treating them separately runs the risk of setting them artificially apart. Although they represent different aspects of cognitive development, the three dimensions of change that begin this chapter (qualitative versus quantitative change, global versus local development, and foundational versus emergent constraints) will be relevant to both discussions.

Dimensions of Cognitive Development

One of the greatest challenges in developmental psychology is to specify how a young child's mind differs from the minds of older children and adults. No one doubts that a 10-year-old knows different things about the world than a 5-year-old does. The difficulties arise in trying to carefully specify the nature of those differences. Three themes that have recurred throughout this book can provide some helpful bases for comparing and contrasting theories of cognitive development (see Figure 9.1). Each of these three dimensions can help refine our questions regarding what it is about the child's conceptual thought and understanding that changes and why.

Qualitative versus Quantitative Development

One of the oldest and most persistent issues in developmental psychology concerns whether particular patterns of cognitive change that affect the way children mentally represent or process information are best described as qualitative or quantitative. At first, the distinction seems easy enough. Recall that *quantitative development* involves smooth, continuous changes without the kind of abrupt transitions that would suggest a wholly new process or structure. *Qualitative development*, on the other hand, involves distinct and dramatic changes in structure. In cases of qualitative development in cognitive ability, the child has an entirely different kind of understanding or mental capacity than before. Although the differences between quantitative and qualitative development seem fairly straightforward, these contrasts can be difficult to apply to actual developmental changes. As an analogy, consider the problem of describing the change that occurs between day and night. While there are obvious qualitative differences between daytime and nighttime, the shift between these two states happens continuously and gradually. Each moment in which the light changes slightly seems extremely similar to the previous one.

Likewise, over the course of development, small incremental changes can create large qualitative differences. Viewed from another angle, this means that most qualitative changes can be broken down into a series of tiny steps—which can make the change look much more continuous and quantitative. These problems have led some developmental psychologists to abandon any attempts to distinguish between qualitative and quantitative changes. But to deny this contrast runs the risk of overlooking everyday intuitions about how children's knowledge of the world changes—as well as key differences between the theories that seek to explain these changes.

Given that qualitative changes can often be viewed as a series of many tiny quantitative changes, what does it really mean to call a cognitive change "qualitative"? A qualitative change in a child's way of thinking often means that his

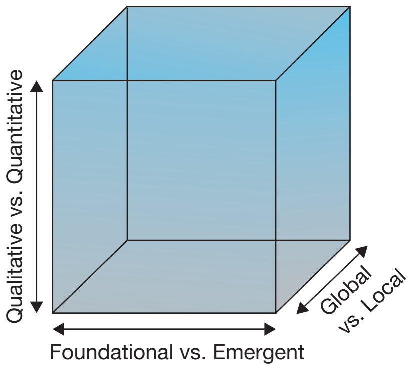

FIGURE 9.1 Three dimensions describing theories of cognitive development. Developmental theories place different amounts of emphasis on issues of qualitative versus quantitative change, global versus local change, and foundational versus emergent constraints. These three contrasts can be imagined as the dimensions of a cube that contains the full range of developmental theories. As illustrated in this chapter, most spaces within the cube are occupied by different theories, and each one's location within the cube depends on which dimensions and values it emphasizes.

thinking changes dramatically. For example, imagine showing a child a bouquet of red carnations mixed with white carnations and asking, "Which is larger—the number of red carnations or the number of carnations?" If 4-year-olds seem unable to reason that there must be more carnations overall than red carnations, while 8-year-olds understand this logic immediately, we can say that a qualitative change in logical reasoning happens between the ages of 4 and 8. By contrast, if 4-year-olds can understand this kind of logic in the context of a simpler task, and if 8-year-olds fail to grasp the reasoning in an even more complex version of the task, we might say that there is a quantitative change in logical reasoning between these ages. In this scenario, the change would be considered more continuous and incremental because children's success would depend largely on the task's level of complexity rather than on the development of a completely new reasoning capacity sometime after age 4. As we consider the theories that aim to explain how knowledge develops over the course of childhood, this distinction between quantitative and qualitative change will remain important.

Global versus Local Patterns of Development

Developmental changes in knowledge can occur either globally, across all domains of knowledge, or locally, on a domain-specific basis (Wellman & Gelman, 1998; see Figure 9.2). Accounts of global cognitive development describe changes to broad mental capacities that are thought to be used in all kinds of thinking. Thus, when this kind of **domain-general** cognitive capacity improves, it should lead to advancements in each and every domain of knowledge. For example, imagine that humans' cognitive capacity to reason about all kinds of cause-and-effect relationships is a single, broad, global ability. If this were the case, then a young child who does not understand that causes must precede effects would make errors in understanding the sequence of all sorts of events—including biological events (for example, claiming that having an infection could cause you to get germs), physics (for example, claiming that thunder could cause lightning), social interactions (for example, claiming that scolding the class caused the teacher to be displeased), and events in other domains. In contrast, in accounts of local, **domain-specific** cognitive development, children are seen as going through a series of changes in knowledge and reasoning that are unique to each domain. In this view, a child's ability to reason about causes and effects in the biological world would progress largely independently from her causal reasoning about physical mechanics or social interactions.

FIGURE 9.2 Global versus local patterns of change. When young children like those at this fountain undergo a change in their concepts about animals, do their other concepts—such as how to count the number of ducks or boats in the water or the way the stick they are holding can act as a lever—also change in roughly the same ways? Or does their intuitive understanding of biology, number, and physics each show distinct developmental patterns?

Several questions about the growth of knowledge directly pertain to the contrast between global and local cognitive development. A recurring issue focuses on whether the learning processes that adults use to acquire specialized skills differ substantially from the ways that young children acquire general knowledge about the world. One difference between children and adults may revolve around the idea that children are universal novices, while adults are only novices in more restricted areas (Brown & Campione, 1994). We will want to keep these issues in mind as we consider the development of thought in different domains and how conceptual development in children might be different from adult conceptual learning.

Q: What sorts of domains have most often been invoked in accounts of domain specificity in cognitive development?

Foundational versus Emergent Constraints

As we have seen, development always involves interactions between genetic and environmental factors. Keeping this perspective in mind, however, it is also increasingly clear that the role that each of these factors plays varies greatly between different aspects of development. One way to think about these influences is in terms of how and when the developmental path is narrowed, or constrained, toward a particular outcome (see Figure 9.3). Thus, some kinds of knowledge seem to emerge in ways that are innately con-

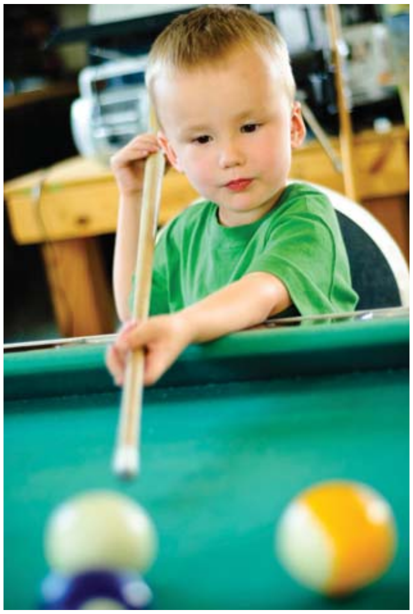

FIGURE 9.3 Foundational versus emergent constraints. When a young child starts to understand how solid objects collide with one another and cause movement, is that understanding largely guided by intuitions about physical mechanics that are present in infancy (foundational constraints) or by the knowledge the child gains from experience, such as watching billiard balls smacking together, then rolling away (emergent constraints)?

strained to follow roughly the same developmental path across a wide range of environments. For example, as we saw in Chapter 3 in the perceptual realm, binocular vision develops in much the same way in the vast majority of children. Only in extreme cases of visual deprivation or brain damage do children fail to develop the ability to mentally integrate the visual information from both eyes. The outcomes of these developmental paths (within a wide range of normally experienced environments) are limited from the outset by **foundational constraints**, which are usually thought of as genetically rooted.

Other forms of knowledge can show more variation in their developmental paths in response to environmental influences. We will refer to the limitations on these kinds of developments as **emergent constraints** because of the way their effects emerge—and come to shape thought and behavior—as a result of specific experiences. One cognitive skill that is significantly influenced by emergent constraints is the ability to recognize the symbols of a particular writing system. This ability requires extensive exposure to a specific set of symbols, and cultures vary greatly both in their uses of writing symbols and in which of those symbols children learn. A child's experiences with her own culture's writing system gives rise to the emergent constraints that guide the processes of learning to read and write in a particular language. For example, when children learn to read Hebrew or Arabic they must not only learn to encode different kinds of symbols for sounds, they must also adopt the practice of reading from right to left. This pattern can become so deeply ingrained that it also affects their automatic visual scanning patterns and can change the way dyslexia, a language-based learning disability, is manifested (Ziegler & Goswami, 2005).

In light of the understanding that genetic and environmental influences together contribute to all aspects of development, it remains valuable to consider their relative contributions to particular developmental paths. In doing so, we can contrast the cases in which foundational constraints dominate with the cases in which emergent constraints are more central. Couching this contrast in terms of foundational versus emergent constraints (rather than as a contrast between "nature" and "nurture" or between "innate" and "learned" behaviors) captures the interactional nature of development while also representing the contrast between biologically determined learning frameworks and those that arise through experience.

In many areas of cognitive development, psychologists continue to debate the relative roles of foundational constraints (arising from genetic factors) and emergent constraints (arising from environmental factors). Consider, for example, the vigorous debates presented in Chapter 8 about how children come to know a language. Some theorists believe that the language learning process must be supported by powerful foundational constraints. They argue that young children's experiences with language are insufficient to explain how children learn complex systems of grammar and that the process must be guided by a rich set of foundational constraints. In contrast, other theorists contend that there are few foundational or genetic constraints on language learning. They propose that the child is able to extract rich information about language from the environment, using a more general (less foundationally constrained) learning system that is highly attuned to sound patterns and correlations. In this view, as the child gradually acquires linguistic knowledge, this knowledge establishes the emergent constraints that guide further learning.

Most major theories of cognitive development can be understood in terms of where they lie along each of the three dimensions we have considered: qualitative versus quantitative development, global versus local change, and foundational versus emergent constraints on development. As we explore how children's knowledge and understanding change, we will want to keep these dimensions in mind. Each can provide a useful way of clarifying what kinds of changes are taking place and how they are occurring. We will focus initially on Piaget's theory of cognitive development from the toddler years into early adolescence, referring back to these dimensions to better understand how Piaget's theory contrasts with other theories (see Figure 9.4).

FIGURE 9.4 **Piaget and young children.** Piaget is best known for his work on cognitive development that occurs as preschoolers, who are in the preoperational stage, develop into school-age children and enter the stage of concrete operations.

A Closer Look at Piaget's Theory

Jean Piaget is as central to the study of children's cognitive development as he is to the study of infant cognition (see Chapter 5). Although his theory has been challenged and reevaluated in many ways, it has remained a foundational point of reference for many researchers. As described in Chapter 5, Piaget believed that the child is born with a bundle of built-in sensorimotor reflexes. As the infant learns about the world from experience, these reflexes are modified and transformed into new *schemes*, which, as we have seen in our discussion of infant cognition, are patterns of understanding and interacting with the world. These schemes are the basic building blocks in Piaget's theory of the young child's mental life. As the child gains more experience, his schemes combine, interact, and grow more elaborate. For Piaget, these changes in the schemes' structure and complexity explained the child's progress through later periods of cognitive development.

In this view, the child's acquired knowledge exerts a broad influence on future learning. When the child masters certain knowledge, this change enables him to make a qualitative transition into a new way of thinking and of understanding the world. Piaget also viewed these transitions largely as domain general, affecting all domains of knowledge. For example, Piaget argued that when the preschooler develops a sufficient understanding of the concepts of "greater than" and "less than," this enables the emergence of a new form of logic known as **transitive reasoning**. Transitive reasoning (also known as transitive inference) involves reasoning about known relationships of stimuli to infer a relationship between the stimuli that were not initially directly related to each other (for example, if A is taller than B, and B is taller than C, then A must be taller than C). As a result, children who can use transitive reasoning perform qualitatively differently from children who cannot on many tasks that involve comparing unequal sizes or amounts. In Piaget's view, children develop a whole new cognitive ability or structure; the child's learning experiences foster the development of the new cognitive structure, but it is the new structure itself that, once it reaches a certain degree of complexity, launches the development of the next new structure or cognitive ability.

Piaget's theory posits four major periods of cognitive development: the *sensorimotor period*, the *preoperational period*, the *concrete operational period*, and the *formal operational period* (see Table 9.1). The discussion in Chapter 5 focused on the sensorimotor period, which, in Piaget's view, makes up the first 2 years of cognitive development. This chapter focuses on the next two periods: the preoperational and concrete operational periods, and particularly on the shift from preoperational to concrete operational thought. Piaget believed that during these two periods, children initially grasp the structure of the world and begin to substantially elaborate and flesh out that understanding over time.

Q: Where along each of the three dimensions of cognitive development would Piaget's theory be situated?

The Preoperational Period

According to Piaget's theory, children emerge from the sensorimotor period at about age 2, having gained a crude ability to think in terms of simple symbols, which Piaget believed enables them to mentally represent ideas that are not completely driven by action and perception. The emergence of language is the most obvious hallmark of this new ability. They then enter the **preoperational period** (approximately ages 2 to 7), during which they lack the capacity to think about the world abstractly. Instead, Piaget held that preoperational children, while having learned symbols such as the words of their language, are unable to use those symbols in flexible ways that help them to break down a task into its critical components and represent it as a set of lawfully interacting elements. Thus, a preoperational child might remark that a ball of dough gets wider under a rolling pin. However, Piaget found that the same child could not

Period of Cognitive Development	Age	Characteristics	Relevant Cognitive Skills
Sensorimotor	Birth–2 years	The infant represents the world in terms of her own sensations and reflexes.	Object permanence
Preoperational	2–7 years	The child is egocentric, ignores all but one aspect of a problem, fails to use basic operators such as compensation, reversibility, and identity.	Symbolic representations
Concrete operational	7–12 years	The child can apply operators to concrete information, but fails to apply them to abstract or hypothetical information.	Classification, conservation, seriation, transitive reasoning
Formal operational	12 years on	The child is able to think logically about things that are not immediately present and can engage in hypothetico-deductive reasoning.	Scientific reasoning tasks

TABLE 9.1 Piaget's four periods of cognitive development. According to Piaget's theory, transitions between these periods involve sweeping, across-the-board transformations in the nature of thought. Although children show reliable patterns of failures and successes on the experimental tasks that Piaget devised, psychologists are still debating how accurate he was in interpreting what kinds of cognitive changes underlie these patterns.

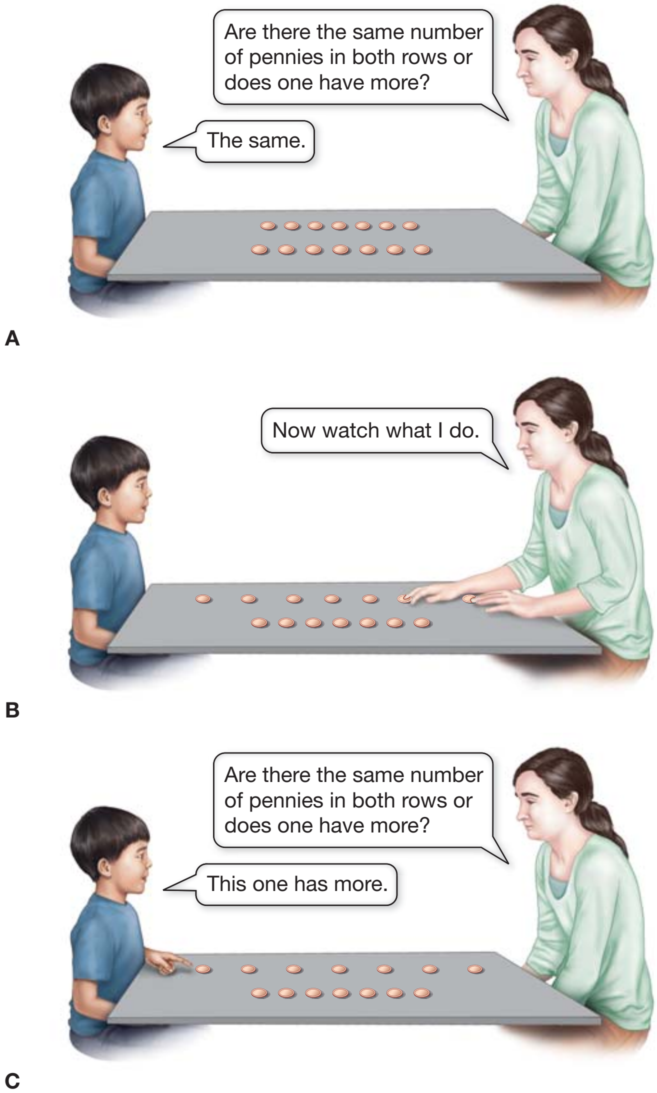
isolate the relationship between the ball's width and its other physical properties. Thus, the child could not understand that the increase in its width must be accompanied by a corresponding decrease in its height. More generally, because the preoperational child lacks the ability to think about relations between concrete properties such as height and width, he cannot see how a change in one property might necessarily imply a change in another property. By contrast, older children realize that the ball must logically become shorter in a way that compensates for its increasing width.

Piaget's theory predicted that children in each period except the last one are largely unable to grasp the kinds of concepts and problems that require cognitive abilities developed only in the next period. In his research, Piaget observed how children of different ages fared on specific types of tasks, and he made strong claims about their abilities based on their performance on these tasks. The most famous and best studied of these tasks are the **conservation tasks**, in which children are asked to judge whether certain physical properties of an object, such as its size or amount, are "conserved" (remain unchanged) when the object is transformed along different sorts of dimensions. Our ball of dough is one such example—that is, an increase in width must be associated with a decrease in height because the amount of dough remains the same.

To make the concept of conservation more explicit, consider one of the tasks used to test whether children have mastered the conservation of number. In this type of conservation task, an experimenter shows the child two rows of objects: let's assume they are coins. Initially, as shown in Figure 9.5, the coins are arranged in two identical rows, with each row having the same number of coins with equal spaces between them. The experimenter then asks the child whether both rows have the same number of coins or if one row has more coins. When the child responds that they have the same number of coins, the experimenter asks the child to watch carefully, then spreads out one row so that the coins in that row now form a much longer line. Again, the experimenter asks the child whether one row has more coins or if they both have the same number. Many preschoolers will now answer that the longer row has more coins.

Part of Piaget's genius lay in his ability to devise similar tasks to test children's understanding of conservation with many different kinds of quantities, such as number, liquid volume, mass, and length (see Figure 9.6). Piaget argued that children fail at conservation tasks because they lack the critical mental **operators**, or formal mental tools, needed to consider the relations between sets of properties. Operators are therefore logical, rule-based ways of comparing mental representations of situations before and after transformations.

In particular, Piaget believed that preoperational children lack the logical operators of *compensation*, *reversibility*, and *identity*. The operator of **compensation** involves noting that a change in one dimension compensates for a change in another dimension. In the example of the two rows of coins, the children notice that one row is longer than the other after the experimenter spreads out one of the rows of coins. But if they lack the operator of compensation, they do not understand that the increase in length is due to an increase in the space between the coins. The operator of **reversibility**



Are there the same number of pennies in both rows or does one have more?
The same.
A
Now watch what I do.
B
Are there the same number of pennies in both rows or does one have more?
This one has more.
C

FIGURE 9.5 **Piaget's number conservation task.** Children in the preoperational stage seem to see the change in the length of a row of coins as relevant to the number of coins in the display, therefore failing to "conserve" number.

involves noting that a change can be reversed or "run backward" to return things to their initial condition. Thus, children who lack the operator of reversibility fail to notice that the longer row—which they believe has more coins—can easily be transformed back to the length of the shorter row without removing any coins. The operator of **identity** involves noting that values on a dimension are the same. In the case of the rows of coins, this means noting that the critical dimension of numerical value does not change—it remains constant despite the other changes. But children lacking the operator of identity do not realize that the number of coins remains the same. Piaget argued that in the preoperational period, children do not have these operators and, as a result, are unable to conserve in any area. He also believed that preoperational children's lack of mental operators lead them to focus excessively on one dimension of a transformation (for example, length) while ignoring other relevant dimensions (for example, density), a phenomenon called **centration**. But he said that once children gain new mental computational and representational tools that enable them to solve one conservation task, they begin gradually learning to use these operators on a wider range of conservation tasks.

Q: Provide three specific examples of different conservation tasks.

Piaget expanded his theory to explain the difficulties that preoperational children have with many other kinds of tasks besides conservation. One such task is the **seriation** of objects, the ability to order objects according to a shared property, such as length or size. A seriation task might involve taking a pile of sticks of different lengths and putting them in order from longest to shortest. This ability requires an understanding of the transitive ordering relationships among the objects on a particular dimension, such as length—for example, if A is greater than B, and B is greater than C, then A must be greater than C on that dimension. Piaget also applied his theory to children's performance on **classification** tasks, which involve sorting objects according to a consistent criteria, such as color, shape, or size.

Most relevant to this chapter, however, are the ways in which Piaget used the same fundamental principles to

Task	Transformation	Question
Number		Are they the same number?
Liquid volume		Do they have the same amount of liquid?
Mass		Do they have the same amount of clay?
Length		Are they the same length of rope?

FIGURE 9.6 **Conservation tasks.** Piaget found that children in the preoperational stage (about age 2 to 7) seemed to fail to conserve across many kinds of changes. These examples show some of the transformations Piaget used to test children's ability to conserve number, liquid volume, mass, and length.

explain how preoperational children understand concepts in such diverse domains as number, space, time, biology, and physical mechanics. He believed that there are no a priori mental processes or structures that are specifically suited for particular domains. In his view, a child's success in understanding each domain of knowledge follows directly from how well she can pick up on that domain's important patterns using broad, general cognitive capacities. As the child gains knowledge, her cognitive structures modify themselves somewhat to fit what she has learned about the environment (see the discussion of *accommodation* in Chapter 5). But these changes are constrained in important ways by the child's stage, or period, of cognitive development.

The Concrete Operational Period

According to Piaget, at roughly age 7, most children enter the **concrete operational period**. The child moves into this period by acquiring the same mental operators that he previously lacked, such as reversibility, identity, and compensation. During the concrete operational period, from about age 7 to 12, children gradually expand their use of these mental operators by applying them to a broader range of problems (see Figure 9.7). As a result, concrete operational children start to respond correctly on conservation, seriation, and classification tasks. It may take several years, however, before they can smoothly use identity, compensation, and reversibility across all tasks and situations.

The mechanism of change that enables a child to progress from preoperational thought to concrete operations is one of the less clearly explained aspects of Piaget's theory. In general terms, Piaget suggested that the knowledge structures of one stage, such as preoperational thought, become progressively elaborated to a critical point, where they become a launching platform for the next stage. The child's mental structures at the end of one stage start to lay the groundwork for the structures of the next stage, and through accommodation and assimilation, there is a qualitative restructuring of the child's thought. Concrete operational thought, however, is not the final stage for most children, for this period also has significant limitations that bind children to the here and now. Although concrete operational children use concepts such as compensation and transitivity to reason about concrete situations, Piaget argued that they cannot reason about what would happen if a situation were different from the way it is. For example, they might have difficulty reasoning about how the United States would be different if it were a mirror image of itself (with San Francisco on the East Coast and New York on the West Coast). Such reasoning about hypotheticals was said to require an ability to generate a range of hypotheses and explore the implications of each one. Piaget held that this kind of thinking requires a set of more abstract mental operators that the child acquires only in the final stage: formal operations.

FIGURE 9.7 Concrete operations. Recycling objects by sorting them into different types is a form of classification activity. Piaget argued that only in concrete operations do children fully understand how to consistently classify objects and understand the relationships among classes, such as superordinate-subordinate relations.

The Formal Operational Period

Formal operational thought has not been studied as much as preoperational and concrete operational thought, and we will discuss it only briefly here. The **formal operational period** was thought to emerge around age 12, and its hallmark was the ability to engage in **hypothetico-deductive reasoning**, the ability to think systematically about different possibilities that might depart from the current reality (Inhelder & Piaget, 1958). According to Piaget, this form of reasoning is supported by new mental operators that enable adolescents to propose hypotheses, mentally explore their logical consequences, and rule out alternative hypotheses. Thus, an important aspect of a child's advancement into the formal operational period is the ability to reason logically without reference to the immediate surroundings (which constitute the concrete world of the concrete operational child). Tests of formal operations have often involved giving a child a physical system, such as a set of pulleys, and seeing whether he can figure out how the system works by systematically testing different hypotheses. Piaget believed that a younger child would try to learn how the system works by trial and error, often failing to explore critical components of the system.

The child's achievements during the formal operational period were often thought to represent the emergence of "scientific thinking skills," the ability to plan and perform experiments by isolating individual variables and seeing how they change when they are systematically manipulated one at a time (Klahr, 2000; Kuhn & Angelev, 1976; Kuhn & Brannock, 1977; Kuhn et al., 2009). In contrast, children who are not yet in the formal operational period would simply tinker with different possibilities rather than thinking them through and applying them one by one. Indeed, one group of researchers has described the developmental transition from the concrete operational period to the formal operational period as going from an engineering model (how can I get this to work?) to a scientific model (how does this work, and what are its critical causal features?) (Schauble et al., 1991).

Piaget and Inhelder's best-known studies of the development of formal operations focused on a task in which children had to figure out how to change the length of time it takes a small pendulum to swing back and forth. The children could vary the length of the pendulum's string, the weight of the pendulum bob, and the height from which they dropped the bob to see what would cause the pendulum to swing back and forth more quickly (see Figure 9.8). Children in the concrete operational period often failed to carefully test the effects of changing a single variable while holding everything else constant. For example, these younger children typically did not compare the effects of using different bob weights with the same string length and drop height, or using different string lengths with the same bob weight and drop height. These younger children rarely realized that the string length was critical and that the bob weight and drop height did not matter. Younger children also failed on a number of other tasks that required making systematic changes to a system to isolate the critical variables.

The formal operational period differs from earlier periods in Piaget's theory in the sense that not all children achieve it. During normal development, the vast majority of children eventually progress well into concrete operational thought, but Piaget and Inhelder maintained that a significant number of people never attain formal operations, even in adulthood. In addition, there seems to be considerable cultural variation in the proportion of a population that achieves formal operations (Dasen, 1977). These variations raise questions about whether formal operations really represents a natural period of cognitive development that emerges when concrete operational thought is sufficiently developed.

Piaget was not unique in proposing that the major patterns of developmental change involve across-the-board reorganizations of children's internal representational and computational capacities. Several other thinkers also embraced this view of cognitive development. For example, we will see that Vygotsky's (1978, 1986) sociocultural view of cognitive development also proposed broad, sweeping changes in children's modes of thought, even though Vygotsky hypothesized quite different mechanisms of change. As we evaluate Piaget's theory, we should keep in mind that some criticisms of the domain-general patterns of change he proposed may extend to other domain-general theories of development as well.

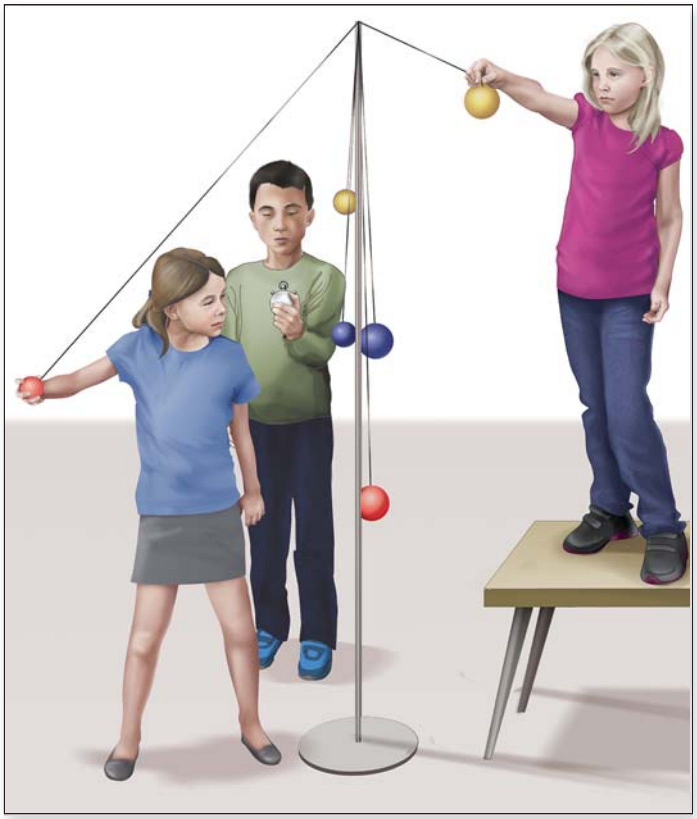


FIGURE 9.8 **Formal operations.** In Piaget's pendulum task, children try to figure out what variables (length of the string, weight of the ball, or height from which the ball is dropped) determine the rate of swing. In the diagram, the boy is timing how long it takes for each ball to go through one complete swing cycle. Piaget argued that children must be in the formal operations stage to be able to systematically control variables so as to unambiguously isolate length as the only critical variable influencing periodicity.

Q: What are some cognitive operations that, according to Piaget's theory, are common to success in conservation tasks during the period of concrete operations?

Alternative Explanations of Piaget's Theory and Results

Piaget's theory of cognitive development covers an extraordinarily broad range of phenomena, including language, space, number, time, causality, logic, and dreams (for overviews, see Brainerd, 1978; Flavell, 1963; Ginsburg & Opper, 1988). This breadth arises naturally from his theory of domain-general qualitative changes in the ways that children represent information. According to Piaget, these global changes should have predictable effects on almost any cognitive domain, including children's thinking about physical, social, and abstract phenomena. In addition, Piaget was extraordinarily creative in designing empirical studies that would uncover ways in which younger children's thinking differs from that of older children.

If Piaget's account were even roughly correct, it would offer a truly unified theory of cognitive development—and the vast majority of his many studies and observations do yield essentially the same results when they are repeated today. The more controversial question, however, is whether these studies truly provide an accurate test of his claims. Researchers have subjected his work to intense scrutiny over the past few decades (Brainerd, 1978; Fischer & Bidell, 1998; Gelman & Baillargeon, 1983). New studies have raised many questions about Piaget's account and have also revealed new patterns of evidence, leading to the emergence of important new theories about children's cognitive development.

One way to test a theory like Piaget's is to assess it experimentally using carefully designed variations of his tasks to determine whether alternative explanations for children's task performance might be more plausible than Piaget's account. In doing so, researchers follow a method similar to the one discussed in Chapter 8 for testing whether egocentrism affects early language development. They ask whether much younger children can succeed at simpler versions of the task that still tap into the specific ability of interest—and whether even older children fail at more sophisticated versions of the tasks.

Researchers set up studies with variations on Piaget's tasks to examine the bases for children's failure or success on the tasks (see Figure 9.9). For example, 5-year-old children might fail a conservation task for any of the following reasons: (1) As Piaget proposed, they might lack the critical cognitive structures or abilities. (2) Even if they are capable of the type of reasoning or understanding that the task is designed to test, a particular version of the task might require other kinds of cognitive skills that are beyond the reach of most 5-year-olds. For example, the task might require remembering more information than most 5-year-olds can, or it might impose demands on attention that make it too difficult for 5-year-olds. (3) When the children are presented with the task, they might not realize which aspects are most important to keep in mind and so they might fail to encode the problem correctly. If they were shown how to encode it, however, they would do fine. (4) If some aspect of the task seems to imply a particular kind of response, the children might be responding based partly on how they believe the experimenter wants them to answer. Piaget's theory would be supported only if the children consistently fail on the conservation task for the first of these reasons.

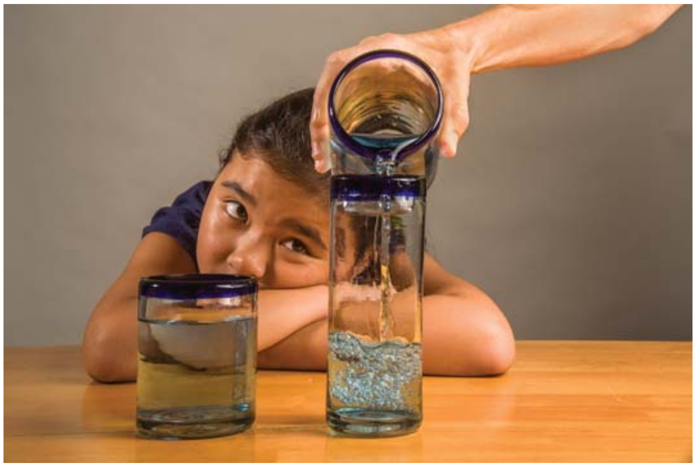

FIGURE 9.9 Why do young children fail on Piaget's conservation tasks? Following Piaget's early studies in which children failed on conservation tasks like this one examining conservation of liquid in different-sized glasses, researchers have proposed alternative reasons for why children fail on these tasks, raising questions about Piaget's theory of cognitive developmental stages.

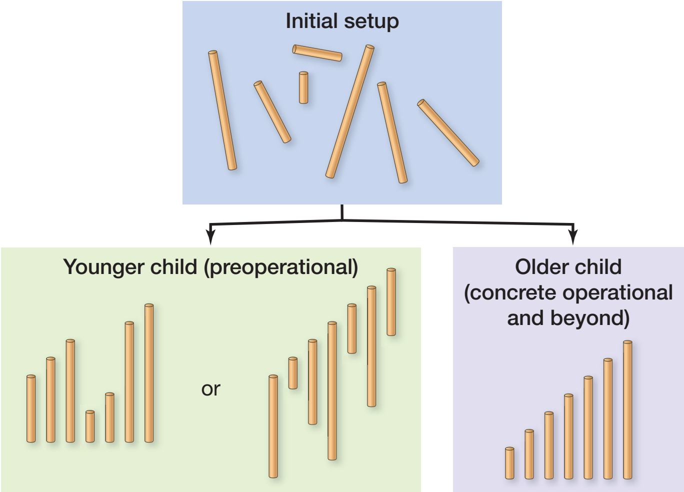
Another way to empirically assess alternative explanations for Piaget's results would be to conduct a similar set of studies with adults. In such studies, the experimenter could slowly increase the task's demands on encoding, attention, and memory to make it more difficult. The experimenter could also set up the tasks to subtly imply that a particular (incorrect) response is desired. The alternative explanations for Piaget's findings would gain support if the adults fail at the more difficult or unclear versions of the tasks in ways that resemble young children's failures. Since most adults would be considered cognitively mature in Piaget's view, their failures would help clarify how factors other than those that Piaget aimed to test could influence performance on the tasks he designed.

As we consider specific Piagetian tasks in detail, we will see several studies in which children seem to fail at Piaget's tasks for reasons 2 through 4. This evidence seems to undermine Piaget's own explanation for the children's failures (reason 1). Other studies have shown that, contrary to Piaget's theory, much younger children can sometimes show elements of formal operations, the most advanced level of cognitive development in his theory (Klahr, 2000; Klahr et al., 1993; Zimmerman, 2000). In addition, when the tasks are very complex in ways that tax memory and attention, even adults frequently make errors in formal operational thinking, such as failing to explore all the necessary manipulations of variables in a scientific experiment. All of these



Initial setup
Younger child (preoperational)
or
Older child (concrete operational and beyond)

FIGURE 9.10 **Seriation.** In Piaget's seriation task, the child is asked to arrange a set of rods in order from shortest to longest. Preoperational children fail at this task. They often line up the rods as increasing in length at one end, but ignore the other end, or they correctly order a few rods at a time but are unable to arrange the whole set continuously. Piaget thought that children younger than about 7 typically fail at this task because they lack the mental operator that supports transitive reasoning.

patterns of behavior lend support to the alternative explanations for Piaget's results.

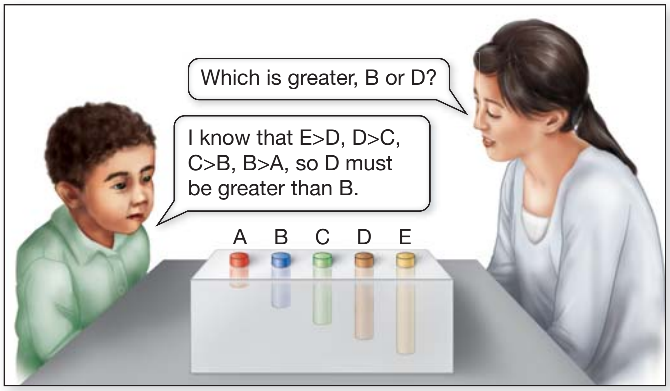
In the studies designed to test the alternative explanations for the patterns of failures and successes on Piaget's tasks, young children typically still make errors. But in many cases, their performance also vastly improves in ways that would be difficult to explain if the children truly lacked certain cognitive structures, as Piaget suggested. Consider, for example, the cases of seriation, thinking about classes, and conservation.

Seriation Piaget developed classic seriation tasks, in which a group of objects must be ordered according to a shared property, such as size or height. One of these tasks is to order rods according to their length, which is difficult for children younger than roughly 7 years of age (see Figure 9.10). Their failures at these tasks have often been cited as clear evidence that they lack the ability to use transitive reasoning to understand the relationships between several pairs of inequalities (for example, to understand that if Adam is taller than Bill, and Bill is taller than Chris, then Adam also must be taller than Chris). Piaget claimed that preoperational children's cognitive structures do not allow them to use transitive reasoning when they attempt seriation tasks (Halford et al., 1998).

If the younger child truly lacks the ability to use transitive reasoning, then it should be possible to show clear differences between younger and older children on any task that requires this skill. But consider for a moment how Piaget's classic seriation tasks actually test a child's transitive reasoning. A child is shown a series of rods of different lengths and asked to order them from shortest to longest. Doing so correctly requires careful attention to the way each rod's length relates to the others. If you can remember all those relationships, you will quickly know that if rod A is longer than rod B, and rod B is longer than rod C, then rod A is also longer than rod C. You must also remember to look at both ends of the rods and not be swayed by what looks like constant length increases along the tops if the bottoms are also changing relative to each other.

The key question about Piaget's seriation task is whether children younger than around 7 fail because they are incapable of transitive reasoning or because of other elements of the task. For example, younger children may have trouble remembering how the length of each rod relates to the lengths of the others. If so, perhaps solving the memory problem would make transitive reasoning easy for them. Peter Bryant and Tom Trabasso conducted an elegant study to figure out whether young children might be failing at seriation tasks because of the tasks' memory demands (Bryant & Trabasso, 1971). This study clearly illustrates how carefully designed experiments can tease apart the reasons that children fail at Piagetian tasks.

Using the setup shown in Figure 9.11, Bryant and Trabasso extensively trained young children to compare pairs of colored rods to determine which was longer. The children learned the length relationships for pairs of rods by associating the lengths with the color of the rods and memorizing the inequalities in the lengths of these different-colored



Which is greater, B or D?
I know that E>D, D>C, C>B, B>A, so D must be greater than B.

FIGURE 9.11 **Memory and transitive reasoning.** In Bryant and Trabasso's study, researchers trained children by pulling pairs of colored rods out of a holder and showing the children the size differences between the rods. The children memorized the length inequality relationships (E>D, D>C, C>B, B>A) so that they were able to correctly report size inequalities when just looking at the rods inserted in the box. They were then asked about several new inequalities, which they could only determine through transitive reasoning (for example, D>B). In this scenario, in which they were trained on the memory component of the task separately, preoperational children could use transitive reasoning to figure out the novel inequalities. This finding suggests that young children had failed at Piaget's original seriation task because of problems with memory or attention, not because they were incapable of transitive reasoning.

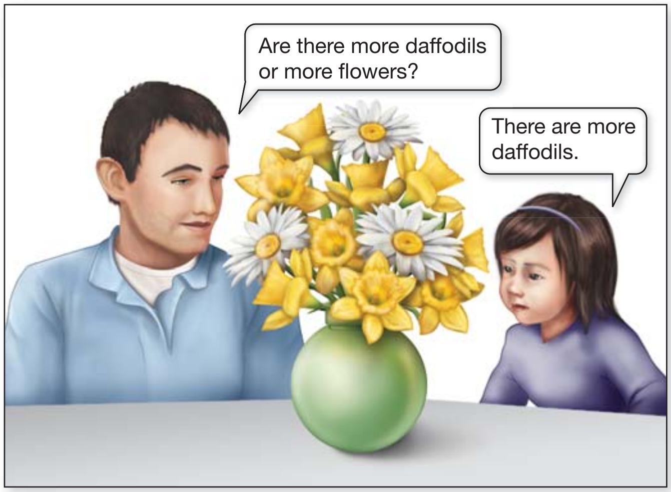
rod pairs. They then were presented with pairs of rods that they had never directly seen side by side. To determine those length relationships, the children had to use transitive reasoning. The memory training had striking effects on the children's performance. Once the younger children had demonstrated reliable memories for the length relationships they were taught, they could easily make judgments about the new inequalities, presumably by using transitive reasoning (for example, recognizing that if rod D is longer than rod B, and B is longer than A, then D also must be longer than A). The transitive reasoning component of the task did not seem to cause them any problems.

Bryant and Trabasso's study suggests that by devising the right experimental task, such as training children to memorize a set of length inequalities before using those inequalities in transitive reasoning, researchers can disentangle transitive reasoning skills from memory capacity. Moreover, their findings suggest that children younger than about 7, whom Piaget considered preoperational, may not have problems with transitive reasoning itself. Rather, they are more likely to fail at transitive reasoning tasks because those tasks make larger memory demands than young children can manage (see Chapter 10). To defend Piaget's account, you would have to show that the new version of the task is too different from the original one to serve as a true test of transitive reasoning (Halford, 1993). Such accounts would have to show that reducing the children's memory load by training them to remember some inequalities somehow does away with their need to use real transitive reasoning to determine the novel length relationships. (This is not an easy thing to show about Bryant and Trabasso's study.)

Q: Why might children who actually understand transitive reasoning fail on most transitive reasoning tasks?

Thinking about Classes Seriation is just one of many tasks that Piaget used to support his theory. He also considered how children reason about classes when they are thinking about categories of objects. Because Piaget's model was based on domain-general (global) changes, he believed that all of a child's mental processes, including her understanding of classes, are limited in similar ways by the child's stage of cognitive development. Thus, he held that a preoperational child lacks the logical operators necessary to understand certain kinds of relationships, including **class-inclusion relations**—that is, how different classes in a hierarchy relate to each other and how broad superordinate categories can encompass narrower, subordinate categories. These operators include transitivity (recognizing that supersets contain categories directly subordinate to them as well as objects that are subsets to those subordinate categories) and equivalences (realizing that two things are the same in some critical respect even as they vary in another respect). For example, a child who has these operators would understand that if *toy poodles* are a subset of the category *poodles*, and *poodles* are a subset of the category *dogs*, then *toy poodles* must also be a subset of *dogs*. Similarly, a child would understand equivalence in a case where a set of blue and red triangles forms a class that is distinct from one formed by a set of blue and red squares. In Piaget's view, the limitations on preoperational children's understanding of these kinds of relationships keep them from realizing how hierarchically arranged categories relate to each other (Inhelder & Piaget, 1958, 1964).

In line with his theory, Piaget documented preschool children's striking failures to understand classification. In one of Piaget's tasks, a preschooler was shown a bouquet of flowers consisting of nine daffodils and three daisies and then was asked whether there were more daffodils or more flowers (see Figure 9.12). Many preschoolers responded that there were more daffodils—which was logically impossible. Of course, even if there are more daffodils than any other kind of flower, the daffodils still must be a subset within the set of all flowers. Piaget interpreted this failure in reasoning about class-inclusion relations as evidence that the children lacked the appropriate mental operators to infer transitivity and hierarchical relations between classes.



Are there more daffodils or more flowers?
There are more daffodils.

FIGURE 9.12 **Classification in preschool children.** When asked, "Are there more daffodils or more flowers?" in a mixed bouquet of nine daffodils and three daisies, a preoperational child may say that there are more daffodils. Piaget argued that preoperational children cannot reason about two classes at different levels (in this case, daffodils and flowers). In his view, this limitation explains why they seem to mistake the fact that there are more daffodils than daisies for evidence that there are more daffodils than flowers.

Piaget also believed that preoperational children have difficulty understanding how classes are defined. He argued that they do not recognize that once a class is set up and defined by a set of properties, such as all red things, that criteria have to remain constant throughout all subsequent uses of the class. Rather, Piaget found that when sorting things into classes, preschoolers frequently abandon one criterion and switch to another. A 4-year-old might begin sorting things into a class based on the criterion of color and, before finishing, end up switching to the criterion of texture. Piaget also noted that instead of grouping objects based on a single criterion, such as having four legs, preschoolers sometimes sort objects based on their thematic relationships. For example, imagine an exercise in which a child is shown pictures of three barnyard animals (a cow, a horse, and a sheepdog), three animal areas (stables, a dairy barn, and a doghouse), and three kinds of animal food (oats, hay, and dog food). A researcher then asks the child to "put the ones together that go together." A 4-year-old might put the horse, the stables, and the oats together; might group the cow, the barn, and the hay; and then might put together the dog, the doghouse, and the dog food. Because there are no logical common criteria uniting the items in each group, the groups are not true classes in the logical sense. In contrast, at around 7 years of age, a child would form true class-based clusters of animals, dwellings, and foods. Piaget believed that the younger child fails because he does not yet have the mental operators necessary to understand the logical bases of classes.

The developmental changes that Piaget described for reasoning about classes have been subject to the same concerns as his accounts of transitive reasoning and seriation: Could factors other than the ones Piaget proposed be responsible for these changes in performance? Apart from Piaget's view that domain-general limits constrain children's reasoning abilities, other possible factors include the tasks' demands on memory and attention, the arbitrariness and meaninglessness of the tasks for younger children, and potential misunderstandings of the experimental situation or the experimenter's intentions. Consider, for example, how children's performance on classification tasks changes when the classes are made less arbitrary and more meaningful (Rosch et al., 1976).

The **basic level of categorization** falls at an intermediate level of specificity. It is narrower than the very general, superordinate categories, such as animals, furniture, and clothing, but broader than highly specific subordinate categories, such as collies, kitchen chairs, and T-shirts. As Figure 9.13 shows, the basic level corresponds to such things as horses, dogs, tables, chairs, pants, and shirts. At the basic level, all category members are both maximally similar to each other and maximally distinct from members of other categories. At the superordinate level, such as the category *animals*, members need to have only a few common features to belong to the category. On the other hand, within a basic-level category like *horses*, there are few obvious differences between members, such as Arabian horses and quarter horses. Children's earliest word labels also tend to fall at the basic level of categorization, and these words tend to be among the shortest and most frequently used words in a language (Murphy, 2002; Murphy & Lassaline, 1997; Rosch et al., 1976).

There are many distinctive features of basic-level categories that reinforce the idea that this is the most cognitively natural level of categorization and perhaps therefore the easiest to think about (Murphy, 2002; Murphy & Lassaline, 1997; Rosch et al., 1976). The question therefore arises: Could young children reason about classification more easily using basic-level categories? Eleanor Rosch and her colleagues explored this possibility by asking young children to sort or group together items that resembled each other at either the basic level of categorization or the superordinate level (Rosch et al., 1976). Thus, a child might be given four kinds of toy *vehicles* and four different kinds of *clothing* and asked to group the items that go together (superordinate categories), or they might be given four kinds of toy *cars* and four kinds of *shirts* to sort (basic-level categories). The same preschoolers who failed to sort based on superordinate categories showed no problems sorting based on basic-level

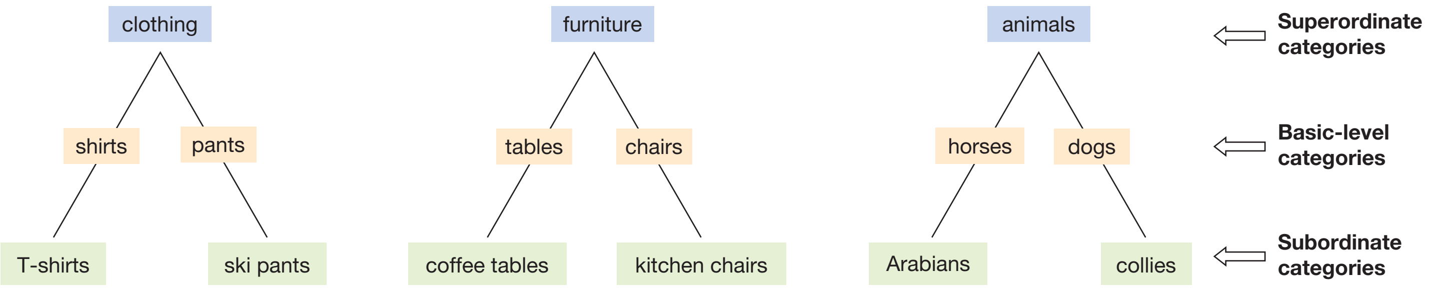


FIGURE 9.13 Basic-level categories. The basic level is an intermediate level of categorization that seems to be especially salient, psychologically natural, and easy to think about. Preschoolers are much better at sorting objects into basic-level categories than they are at using other category levels. This finding suggests that young children's failures at class-inclusion reasoning may have more to do with their difficulties thinking about the relevant categories than with missing the mental operators pertaining to classification.

categories; they easily put all the shirts together and all the cars together. Thus, younger children are capable of the kind of feature-based, logical classifications that they fail at in Piaget's sorting tasks.

If their mental abilities only allowed them to sort items thematically, preoperational children would be unable to sort by class regardless of the categories. Their much better performance with basic-level categories raises the serious possibility that they fail to sort by superordinate categories either because it requires processing larger amounts of information than the children can keep in mind at once or because the categories themselves are unfamiliar or arbitrary. In fact, Rosch's studies were just the start of a line of research showing that young children can think about categories in surprisingly sophisticated ways, especially at the basic level. If young children have a good understanding of how a category relates to other familiar information, this knowledge also seems to help them reason about the category.

Children also seem to be more capable of class-inclusion reasoning than Piaget thought. For example, if preschoolers are shown a group of five "boy" frogs and two "girl" frogs and then asked whether there are more boy frogs or more frogs, they will make the usual class-inclusion mistake—claiming that there are more boy frogs. But if they are asked instead if there are more boy frogs or more in the "family" of frogs, then they will correctly say that there are more in the family (Markman & Siebert, 1976). The label "family" may help the child solve this problem by drawing her attention to relationships organizing the whole "collection." This pattern of findings raises questions about Piaget's original account, given that such a small change in the question can significantly change children's performance (McGarrigle & Donaldson, 1974). More broadly, researchers have found that young children are able to think about categories in ways that suggest not only an appreciation of class inclusion but also the advantages of learning about categories as a whole as opposed to merely learning about the individuals that make up those categories (Cimpian & Park, 2013; see Scientific Method box).

Q: What are some ways of making classification tasks easier for preschoolers?

Conservation Hundreds of studies have reexamined Piaget's conservation tasks from different perspectives to see whether his explanations for children's failure to conserve hold up under scrutiny. The full story of this research is complex (see Brainerd, 1978; Gelman & Baillargeon, 1983), but we only need to examine a few studies to see that some of the findings deeply challenge Piaget's theory.

Consider, for example, preschool children's apparent inability to conserve number. In the number conservation task, children are asked to compare the number of coins in each of two equal lines and then to compare them again after the experimenter has spread the coins in one line farther apart. Does the child fail, as Piaget supposed, because she cannot think in terms of principles such as reversibility (what would happen if the spread-out coins were moved closer together again) and identity (no coins were added or removed in the transformation, so there must be the same number before and after it)? Alternatively, does she have all the cognitive capacities necessary to answer correctly, but simply misunderstands what the researcher is asking?

A pioneering series of studies by Margaret Donaldson and her colleagues raised serious questions about how children in the preoperational age range (about 2 to 7 years old) interpret Piaget's number conservation tasks. As we saw in Chapter 8, in interactions with others, even very young children take into account pragmatic factors, such as others' actions and intentions as well as aspects of the social context, to infer meaning and to guide their interpretations of what is wanted in a task. Perhaps these factors can also influence young children's performance on conservation tasks.

Donaldson and her colleagues suggested that the traditional number conservation task is confusing for children because it is so pragmatically unusual (Donaldson, 1978, 1983; McGarrigle & Donaldson, 1974). How often does someone ask how many things there are in a display, then purposely manipulate those things and ask about the number again—unless the questioner thinks it likely that the number of things has changed? Repeating the same question may suggest to the child that the experimenter is asking again because she has changed the number. To explore this possibility, Donaldson modified the task in a simple way that significantly changed the pragmatics of the interaction—that is, the intentions that the child attributed to the experimenter.

In one of Donaldson's variations, which we will call the "clumsy experimenter" variation, the experimenter pretends to slip and accidentally change the length of one row of objects, so that it becomes either longer or shorter than the other row. In a different variation, the child sees a "naughty teddy bear" mess up the display, making one of the rows either shorter or longer than the other, before being scolded and sent away. In both of these variations on number conservation tasks, preschoolers succeed much more often than they do in Piaget's original version. In these variations, they frequently say that the number of objects has not changed, despite the change in the row's length.

SCIENTIFIC METHOD: Early Motivation to Learn about Kinds over Individuals

Hypothesis:

Young children are motivated to learn about kinds (or categories) of objects from reliable sources and prefer to learn new information about kinds of objects than to learn new information about particular instances, even though the instances are more concrete.

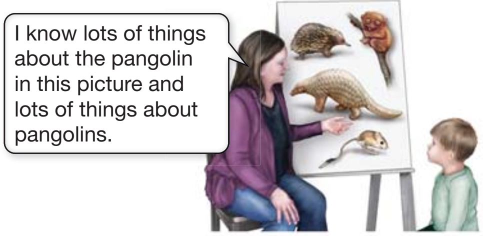
Method:

1. There were 48 children having an average age of 4 years 9 months who participated in the study.
2. There were 24 children in the knowledgeable-adult condition and 24 children in the ignorant-adult condition.
3. In the knowledgeable-adult condition, the experimenter told the child that she knew a great deal about a set of four pictures and, for each picture, invited the child to choose whether he wanted to learn from the experimenter about an individual novel animal ("the one *pangolin* in this picture") or the kind of animal ("this kind of animal, *pangolins*").
4. In the ignorant-adult condition, the experimenter told the child that she knew nothing about the set of pictures and invited the child to choose whether he wanted the experimenter to guess something about "the one *pangolin* in this picture" or about "this kind of animal, *pangolins*."

Results: With the knowledgeable adult, children strongly preferred to learn about the kind of animal. With the ignorant adult, children showed no significant preferences but some tendency to prefer guesses about the individual animal. The preference for learning about kinds with knowledgeable adults therefore is not simply because children generally prefer to hear information about kinds; they do so only when they think that the information is likely to be of high quality.

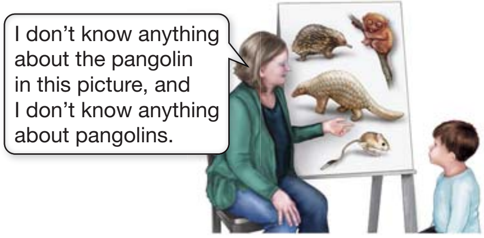
Conclusion: Even though young children might be thought to prefer to first learn about single concrete instances of categories, in fact they prefer to learn high-quality information about entire kinds at a more abstract level.

Source study: Cimpian & Park (2013).



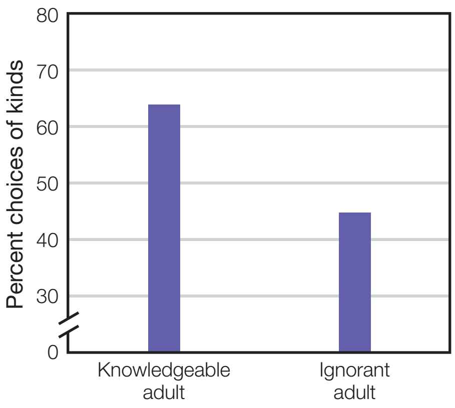
Knowledgeable adult

I know lots of things about the pangolin in this picture and lots of things about pangolins.



Ignorant adult

I don't know anything about the pangolin in this picture, and I don't know anything about pangolins.



It seems that in Piaget's original task, the child might be thinking, "I just told him the number of coins in each row is the same. Why is he asking me the same question again? He must have changed the number somehow, and he wants to see if I can tell. Since one row is longer than it was before, I guess he must have added something and that's why he is asking." In Donaldson's pragmatically different variations, however, the experimenter never intentionally changes the rows of objects and seems to be asking the question a second time simply to make sure nothing has changed (see Figure 9.14). Donaldson's claim that young children often fail at the original task because they misinterpret the experimenter's intentions gained further support from another task variation. In this variation, the younger children often answer correctly when the question about number is asked only once, which avoids any pragmatic confusion (Rose & Blank, 1974; Samuel & Bryant, 1984).

Donaldson's critique of pragmatically odd components in Piaget's number conservation task that might mislead young children can also be extended to Piaget's other conservation tasks (Donaldson, 1985; Gelman & Baillargeon, 1983). All of the classic versions of these tasks, whether they test conservation of number, weight, liquid volume, or another property, involve the odd practice of asking a child the same question twice, before and after intentionally manipulating the materials. Donaldson's studies show that young children

FIGURE 9.14 Changing pragmatics and conservation of number. In variations on Piaget's number conservation task, either a clumsy experimenter or a "naughty teddy bear" seem to accidentally change the length of one row. Because the child does not see the experimenter intentionally change one row and then ask about number a second time, the pragmatics of the task are changed dramatically. In these altered tasks, preoperational children become much more likely to conserve number. Adapted from McGarrigle & Donaldson (1974).

do not have the kind of central cognitive deficits for understanding conservation that Piaget proposed. Nonetheless, even in the modified tasks that reduce pragmatic demands, younger children still make more mistakes than older children. This pattern suggests that the odd pragmatic cues in the original tasks do not fully explain young children's failures. What other sorts of factors might be at work?

One type of influence on children's performance has to do with complexities of the task that make it more difficult, even though they are irrelevant to the type of reasoning that the task is designed to test. Suppose, for example, that a child fails a conservation of number task because the task uses numbers that are too large for the child to track. After all, if an adult observed two equal-sized piles of 324 coins and then saw an experimenter move one pile around so that it took up more space, even the adult might fail to conserve—responding to the question "Which has more coins?" by simply picking the pile that seemed larger. To test whether this kind of complexity is a factor in children's conservation task performance, researchers can simplify the tasks by using fewer objects. For example, a child might be asked to compare a row of three objects with a row of two objects. In addition, the question "Which has more?" may be ambiguous. The child may think that this is a question about which overall size or length is greater, rather than a reference to the number of objects. To avoid this problem, an experimenter could teach the child that the "winner" of two displays is the one with more objects and then ask, "Which is the winner?" With these changes to the number conservation tasks, even preschoolers often succeed on the tasks (R. Gelman, 1969, 1972).

Children still do not perform perfectly on these modified tasks, however, which raises questions about where the additional difficulties lie. Given the substantial improvements that young children achieve on the simplified tasks, it is likely that their remaining problems have to do with the tasks' demands on memory and attention, and the need to interpret the pragmatics of the experimental situation, rather than with the kind of global, qualitative differences in reasoning that Piaget theorized.

Although children's mental abilities are not strictly limited across-the-board by the constraints that Piaget described, children may still undergo some global developmental shifts in the biases and strategies that guide their thinking. That is, when younger children take stock of a problem, they may focus on different kinds of information than older children do. This difference in focus may lead younger children to answer incorrectly, even though they are capable of using the kind of logic required to solve the problem. For example, younger children might focus on compelling perceptual features of displays and discount recent history. Thus, when they are asked whether the volume of water in a display has changed when it is poured from a short container into a tall one, they might focus on the tall beaker's height and disregard the fact that the same water was recently in a shorter, wider beaker. This failure appears similar to the one Piaget described, but it may actually reflect a lapse in attention or memory of the sort that even adults sometimes show, rather than an inability to use certain logical operators. In a related vein, younger children might remember the last piece of information they received (for example, that the water is now in the tall beaker) and weigh that information more heavily than their knowledge of what happened earlier. Either of these biases could explain many of children's conservation errors.

These mistakes are easier to understand if you consider that even adults are susceptible to perceptual illusions about quantity. Most adults will assume that a tall, thin glass holds more than a shorter, fatter one unless they see the liquid poured from one glass into the other. Adults also tend to underestimate the volumes of spheres and cubes and overestimate the volumes of elongated shapes. (This bias is common knowledge in retail sales: candy bars, cereal boxes, and shampoo bottles are often elongated to give an illusion of larger volume.) Children are subject to the same perceptual biases. Now suppose that they also tend to find the end state of a transformation much more salient than the past states before the transformation. In this case, children would be taken in by the perceptual illusion that the taller container, where the liquid ends up, seems to have a larger volume than the prior, shorter container. They would fail the conservation task, but not necessarily because they lack the necessary mental operators.

Piaget was aware of many of these possible pitfalls in his theory. He acknowledged that young children seem to focus excessively on beginning and ending states and ignore the transformations themselves, especially their reversibility and how one dimension compensates for another. He also relied on the notion of centration, arguing that young children have great difficulty focusing on more than one dimension of a task, such as both height and width in the case of liquid volume. But he assumed that this happens because younger children lack the mental operators that enable them to understand transformations. More recent findings indicate that younger children do not seem to show qualitative differences from older children in terms of their ability to understand and reason about seriation, classification, and conservation. Instead, researchers have found that younger children sometimes seem to be overloaded by the tasks' demands on memory and attention, and they tend to focus on different aspects of the problems than older children.

Beyond his research on seriation, classification, and conservation, Piaget also studied children's understanding of many real-world concepts, including their thoughts about dreams, living things, aging, spatial relations, and causality. In all of these areas of knowledge, he tried to explain children's errors in terms of qualitative differences in children's cognitive capacities at different ages. In each of these cases, challenges to Piaget's explanations have been raised that resemble the critiques of his theories about seriation, classification, and conservation. Although younger children do fail at Piaget's experimental tasks, follow-up studies have shown how difficult it is to point to global, qualitative differences in the ways that preschoolers and elementary school children mentally represent information. Younger and older children certainly differ in what they know and what they can do, but describing those differences as qualitatively different stages of general cognitive development has proved quite difficult.

Q: How might pragmatic factors make a child who understands conservation fail on conservation tasks?

Domains of Knowledge

One consequence of the research that challenges Piaget's domain-general theory has been a surge of interest in how development proceeds in specific domains of knowledge. It appears that the domains of psychology, physics, spatial layout, number, and biology each show distinctive patterns of cognitive development guided by their own domain-specific constraints. The nature of those constraints—whether they are largely foundational and innate or emergent and developing over time within each of these domains—is more open to debate. Thus, children may approach the world with core cognitive systems that are constrained from the start for learning about specific kinds of input, such as spatial relationships, number, or biological patterns. Alternatively, children may start with more general, all-purpose learning systems in which they take in and begin to interrelate bits of information about the world over time, putting this information together into larger structures of knowledge that start to take on a life of their own and exert emergent constraints that are unique to that domain. When scholars envision a domain as being constrained by foundational and innate constraints, they often refer to such domains as **core domains**, suggesting that these are basic universal cognitive components shared by all infants throughout the world and which then become elaborated on and combined in more powerful ways over the course of development (Carey & Spelke, 1996; R. Gelman, 2009; Spelke & Kinzler, 2007).

As is so often the case in development, this distinction between the roles of foundational and emergent constraints is not an either/or situation. Both types of constraints always work together, even as one type may constrain the developmental process to a greater degree at particular times. For example, domain-specific foundational constraints may provide a necessary "foothold" for initial learning in a given area. Then, as the child learns more, this new knowledge may contribute to emergent constraints that guide later learning and the knowledge structures that are created. In each of these domains, we will see how the child's knowledge emerges in ways that challenge the older views of global, stage-based change, favoring instead the idea of domain-specific knowledge "journeys" that are quite distinct to each area of knowledge. Thus, we will see how children's understanding of space, number, and biology each takes on a life of its own with unique developmental patterns.

Spatial Relations

We saw in Chapter 5 that infants can track an object's location in a small space and that, on a larger scale, young toddlers can sometimes find their way back to a starting point in a novel setting. Mentally representing the spatial layout of an environment, however, is a more complex task. This ability becomes increasingly important in the preschool and elementary school years, as children come to navigate more extensive environments independently. This more complex ability raises similar issues to those that we considered in the earlier discussion of infants' spatial abilities: How do children know where they are relative to where they started, and how do they keep track of desired objects?

As a child's increased mobility allows her access to larger and more cluttered environments, it becomes more difficult for her to see all the terrain she has covered at once. A child must internally represent the space to keep track of where she is and where she wants to go. If a child loses track of her location, she needs to be able to reorient herself using familiar aspects of the environment and their relationships to each other. For many years, psychologists have known that humans and other animals use **cognitive maps** by which they mentally represent the spatial layout of their environment to infer distance, direction, and ways of navigating (Tolman, 1948). But the research tradition examining how nonhuman animals learn the layout of an environment has only recently merged with the study of humans' spatial and navigational skills to explore how humans develop an understanding of spatial layout. Taken together, these lines of research are suggesting new ways of addressing some of the phenomena that Piaget examined.

Piaget made a number of proposals about how children develop the ability to mentally represent the layout of an environment and other spatial relationships (see Chapter 5 for the discussion of Piaget's views about infants' spatial knowledge). One of Piaget's ideas that was especially relevant to cognitive maps was his notion that young children can think about and remember spatial layouts and relations only in terms of their own point of view (that is, egocentrically) and not in terms of independent coordinates, like the longitude and latitude on a map (Piaget, 1936/1953, 1954). (This idea is closely tied to Piaget's theories that young children use language egocentrically, as described in Chapter 8.) In line with this idea, Piaget found that young children responded egocentrically in several tasks testing spatial orientation.

In one of Piaget's best-known tasks, the three mountains task, he constructed a scene made out of three papier-mâché mountains, each with distinctive colors and landmarks. The three mountains were placed on a board in clear and unambiguous spatial relation to each other (see Figure 9.15). Children were asked to describe what a doll who was sitting at a different spot than the child would see and to choose what the doll would see from among pictures of four different vantage points of the scene. The researcher then asked the child to reconstruct the scene from each of the four points of view by placing the three mountains on an empty surface and then putting a doll in such a position that the doll would see that view. In each case, children younger than about 7 years old responded in a manner that was interpreted as spatially egocentric. Thus, they often thought that the doll (who was in a different position than they were) would still see just what they saw, and they had enormous difficulty understanding how the scene would look from a point of view other than their own. Piaget concluded that younger children are unable to take more than one perspective on a scene and are unable to free themselves from their own particular point of view. He assumed that this behavior represents a very general cognitive deficit that reflects being in the preoperational stage.

In other tasks related to the child's sense of object location, if a young child initially learned that an object was in a corner of the room that was to her left, she would still look to her left for the object later, even if she had turned around so that the object was now to her right. Older children would not make this mistake, since they would use the object's relationships to other features of the environment to guide their search, rather than the object's relationship to their own body orientation.

Other studies suggested, however, that even young children could sometimes think about spatial relationships in less egocentric ways. For example, consider what happened when children were instructed to place a doll where it could "hide" from a policeman. In this situation, even 3-year-old

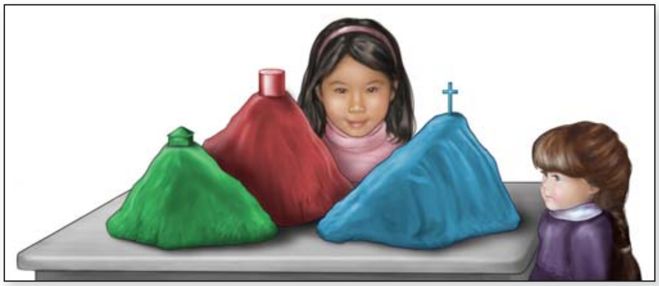

FIGURE 9.15 Piaget's three mountains task. A classic demonstration of apparent egocentrism in young children. Egocentrism was thought to influence the child's understanding of spatial relations.

children were more successful at overcoming their egocentric perspective to take the doll's "viewpoint," presumably because the task seemed more familiar and accessible to them (Hughes, 1975). Given the conflicting findings about whether young children think about spatial relations egocentrically, researchers began to wonder if egocentrism is really a consequence of being in a preoperational period of cognitive development. Another possibility, as we saw in Chapter 8's discussion of egocentric language, is that many children, and even adults, may resort to egocentric thinking when cognitive tasks become very challenging.

A separate line of animal research gave rise to a new perspective on spatial cognition that had strong implications for humans (Gallistel, 1990; see also Pick, 1983). The animal research helped clarify two crucial points about spatial cognition: (1) An organism can use many kinds of information to track its spatial location, and (2) the type of spatial information that an organism relies on depends partly on the particular task and setting. Thus, the animal might draw on one kind of information in one context and another kind in a second context. These animal studies also suggested why young children perform so differently on various types of spatial tasks. For example, a small enclosure may be mentally represented differently from the way a large room is represented, which in turn may be represented differently from the way a village is represented (Acredolo, 1990; Learmonth et al., 2002). Additional cognitive abilities may be involved in grasping the spatial relations in maps and scale models and determining how they correspond to their real-world counterparts (DeLoache, 1987, 1989). Yet another set of spatial abilities may be involved in manipulating small objects such as tools (Newcombe et al., 2013; Spelke et al., 2010). To understand how humans' spatial knowledge develops, we first need to consider a few of the many ways in which an organism keeps track of its location.

Landmarks can provide one source of spatial information by serving as consistent reference points (see Chapter 5). Both people and other animals can navigate by estimating distance and direction in relation to these salient objects in the environment. Of course, for landmarks to be useful, we must note how they appear from different angles. Then, based on our viewpoint, we can figure out an approximate sense of direction and location relative to the landmark. If we also know the landmark's actual size, then its perceived size can convey an approximate sense of how far away it is.

A second method of locating ourselves in space is highly reliable but involves little attention to local landmarks. This method makes use of the **geometric information** in an environment. That is, we construct a mental representation of the environment's overall shape. Most natural scenes have an asymmetrical outline (see Figure 9.16). Recognizing this outline and knowing where we are relative to its edges and overall shape can become a powerful means of knowing our location. This way of representing location works well even when local landmarks or other small features of the landscape change. It can also work well in low light or with limited visual acuity (Gallistel, 1990).

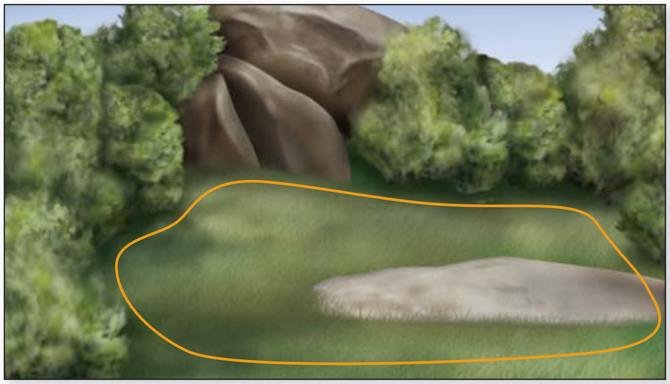

FIGURE 9.16 Navigating with contour information. The asymmetrical terrain in natural environments creates contours that allow an organism to identify its unique location within that environment. This sense of place, which occurs largely outside of awareness, appears to be one of the earliest-emerging capabilities in humans and one that is shared with many other animals. The orange line illustrates how this location has a kind of shape, or contour, that is defined by the larger surfaces on the perimeter of the clearing.

Using geometric information only fails in perfectly symmetrical artificial environments. For example, in a rectangular room, geometric information will always be ambiguous. Because the enclosure is symmetrical, every point in the room corresponds to a second point where the available geometric information is exactly the same. Imagine yourself in the room shown in Figure 9.17. Based

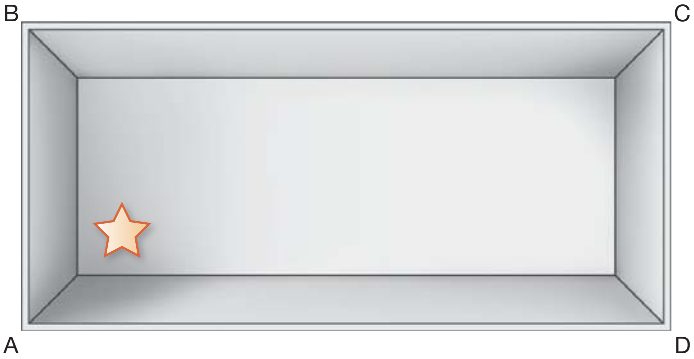

FIGURE 9.17 Ambiguous contour information in an artificial environment. What would happen if you were located at the star and used only contour information to remember this location? You would recall facing the corner with a long wall on your left and a short wall on your right. In this kind of artificial, symmetrical environment, however, this set of contour information also matches a second location: corner C. Rats, young children, and even adults (if they are kept from using landmark information) will incorrectly choose C about as often as they correctly recall A, even if there is a vivid distinguishing landmark at A.

on geometric information, you recall that when you are facing the walls, an object in the room is near the corner where a long wall on your left meets a short wall on your right—but that relation specifies two locations in the room, not just one. Researchers have made use of this potential problem, which applies specifically to using geometric information in symmetrical environments, to test whether subjects are using this geometric information to recall locations. They may ask subjects to return to a particular spot in a symmetrical room and pay attention to the types of errors they make. If the subjects choose both of the corresponding locations equally often, even when other available information specifies the one correct location, then it can be inferred that they are primarily using geometric information (the contours of their environment) to remember where objects are.

Q: What are two different ways of navigating through space?

When rats' spatial abilities are tested in artificial rectangular enclosures, they show errors suggesting that they often rely heavily on geometric information and ignore other forms of information on location (Cheng, 1986; Cheng & Gallistel, 1984). Imagine that a rat is put into a rectangular box, where it discovers food in a particular location. The rat is then briefly moved to another enclosure, where it is spun around in the dark so that it is fully disoriented. When it is put back into the first box, it correctly locates the spot where it previously found food only half of the time, even when there are unique landmarks in the box that correspond to where the food is hidden. The rat's error during the other half of the trials reveals its use of geometric information. It mistakenly chooses the mirror-image location that corresponds to the original location of the food. Thus, the rat seems to learn the location in terms of the overall shape of the environment.

The animal research raised the question of whether, in some circumstances, young children might show the same pattern of mistakes. Remarkably, when young preschoolers were disoriented and put in small, symmetrical enclosures, they behaved very much like the rats (Hermer & Spelke, 1994, 1996). They seemed to rely exclusively on geometric information, and roughly 50 percent of their searches incorrectly led to the second, mirror-image location suggested by geometric relations. Like the rats, they made these mistakes despite the salient landmarks that pointed to the correct location. Nonetheless, even though this strategy of orienting by geometric information leads to errors when it is used in symmetrical enclosures, it is an excellent strategy in the natural world, where environments are almost never perfectly symmetrical. In natural environments, the shape of an area can almost always serve as a unique guide to location (Lee et al., 2012).

As suggested earlier, the type of spatial information that is used depends in part on the setting. Children and other animals seem to rely on geometric information in small rooms (say, 4 feet by 6 feet). In considerably bigger rooms, however, both children and animals rely less on geometric cues and may use landmark information along with simple spatial relations, remembering, for example, that the object is a bit to the left of one side of a landmark (Burgess, 2006; Learmonth, et al., 2002; Lourenco & Huttenlocher, 2007). They may use geometric information less often in large rooms because it is harder to see the whole room at once to determine its shape (Lavenex & Banta Lavanex, 2006). Other studies have shown that even in small enclosed spaces where geometric cues are uninformative, such as square rooms, children can still reorient themselves if the cues are not wall colors or landmarks, but surface textures such as gradients of raised dots that vary in density (Lourenco et al., 2009; Nardini et al., 2008).

As children grow older, they become increasingly able to use other sources of information, such as landmarks, to orient themselves and to find hidden objects. They usually start successfully using landmarks at about age 5, which is also the age at which they increasingly refer to objects in terms of relative spatial locations (for example, "to the left of"). Some researchers argue that language helps children to integrate different forms of spatial information, such as landmarks and layout, into one coherent representation of space (Shusterman et al., 2011; Spelke, 2003; Spelke & Lee, 2012).

Others counter that although children begin using more spatial language at the same time that they become increasingly able to use multiple sources of spatial information, these linguistic changes do not actually *cause* new spatial abilities to emerge (Newcombe et al., 2013; Sovrano et al., 2002; Twyman & Newcombe, 2010). This question is still being debated. Either way, the earlier, Piagetian view of younger children's spatial knowledge as being purely egocentric has not held up, as newer evidence has shown how and in what circumstances children use different types of spatial information (Acredolo, 1978, 1990; Hughes, 1975).

We have seen that younger children rely more on geometric information in smaller environments, while older children can more easily integrate other kinds of spatial information. Nonetheless, the development of navigational skills is not a matter of replacing one way of mentally representing layout with another way. Older children and adults certainly still use geometric information as a guide to location. In some circumstances when adults are distracted, they will even favor geometric information over other kinds of spatial information, even ignoring landmarks and other local cues. Similarly, in some kinds of simplified navigation tasks, younger children and even infants as young as 6 months can be guided to increase their use of landmark information and other local cues (Learmonth et al., 2002; Lew et al., 2004; Newcombe, 2002).

Taken together, the evidence from research suggests that, at all ages, people can use a navigational system that keeps track of geometric information as a source of spatial knowledge. But recent studies suggest that they do not use all the available geometric information and instead tend to encode such things as "long wall to the left of the short wall" rather than precise angles between walls (Hupbach & Nadel, 2005; Spelke et al., 2010). As children grow older, they become better able to flexibly use and integrate many different sources of spatial information and to use more of the available geometric information, such as angles. They also become better at coordinating geometric cues with other forms of information, such as landmarks, for orienting or locating objects.

It is not yet clear just how distinct the brain systems that use geometric information are from those that use other forms of spatial information (Cheng & Newcombe, 2005; Lew, 2011). But there is an emerging consensus that navigation, orientation, and object manipulation ultimately involve a complex interplay of several different forms of information. Many of these appear to have roots or simpler forms that are evident even in infancy but that can take years to become fully integrated into an efficient and flexible system of spatial cognition.

Q: What facets of geometric information are not fully grasped by younger children and infants?

Number

Along with spatial and navigational skills, another area of intuitive knowledge that young children acquire through experience is their understanding of number. Every culture uses some system of mathematics in everyday life. Most adults are able to count groups of items and use addition and subtraction to compute changes to those groups. As described in Chapter 5, even young infants seem to be sensitive to number. In this chapter, we focus on the intuitive knowledge of number that seems to be spontaneously acquired in the real world in early childhood, outside formal instruction in school. For example, some of the most important aspects of quantifying the world involve identifying what sorts of things to count in the same set or class (see Figure 9.18), how to assign numbers to groups of things, and how numbers relate to each other. (We will look at aspects of school-based instruction of mathematics in Chapters 10 and 11.)

FIGURE 9.18 Understanding counting. Knowing how to count requires understanding what sorts of things are sensible to count as one group. In this market scene, we might choose to count individual food items, types of foods, people, males or females, sellers or buyers, or human-made versus natural things, among many other choices. These choices require a grasp of meaningful categories and of which kinds of things are countable, an understanding available even to very young children but not to any computer.

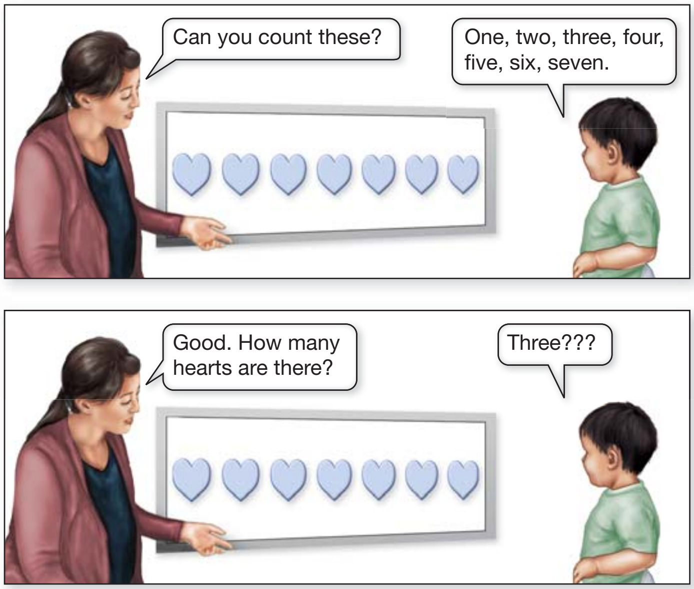
We saw in Chapter 5 that infants seem to have some sense of numerosity of small displays and some intuitive arithmetical skills that give them a sense of what changes when small amounts are added or subtracted. But even with all their impressive achievements, infants' understanding of number is very different from that of preschoolers, who in turn differ from older children in this area of knowledge. Take, for example, the case of counting aloud. Because preverbal infants obviously cannot count this way, researchers can only infer that they can somehow extract information about quantities from small displays. For example, one study found that 18-month-olds, but not 15-month-olds, look longer at a video in which a hand points successively to each of six objects while a voice in their own language counts up to 6 than they look at a video in which the hand moves back and forth between the same two objects while the voice counts to 6 (Slaughter et al., 2011). They do not show any difference in looking, however, if the voice counts in another language or if they hear different beeps instead of spoken numbers.

Researchers have hypothesized that preschool children have implicit knowledge of the counting principles of one-to-one correspondence (one number label per object), stable order (numbers are always counted in the same order), cardinality (the last number counted is the total number of objects in a group), abstraction (anything can be counted), and order irrelevance (it doesn't matter which object is counted first or in which order), although the young children do not always count accurately (Gelman & Gallistel, 1978). Toddlers show their first attempts at counting at about age 2, and their early attempts at counting show strikingly consistent patterns. Children around this age seem to know that counting always involves using the same labels in the same order ("1, 2, 3 . . ."), even if the labels they use are idiosyncratic. Thus, a 2-year-old might consistently count, "1, 2, 3, 5, 6, 11" (Gelman & Gallistel, 1978). Toddlers also seem to know that counting involves using just one label per object. By age 3½, children can easily tell when others violate this one-to-one correspondence principle (Gelman & Meck, 1983). Knowledge of these counting principles suggests that preschool children have a relatively sophisticated understanding of numbers and how they are used. As we have seen, some inkling of the one-to-one correspondence principle may emerge even before children are able to count.

Yet, in other ways, very young children have been found to show some serious limitations in their understanding of numbers. Even though they understand that they can begin to count with any one of the objects, they do not usually understand—sometimes until as late as age 10—that a count can proceed in any order whatsoever—for example, from left to right or right to left (Kamawar et al., 2010). More significantly, for a young child, the counting routine often does not serve as a way of figuring out how many things there are. A 3-year-old might correctly count a group of seven objects aloud, but still not realize that this means that there are seven objects present (see Figure 9.19). Early on, counting is simply a verbal routine performed with objects, but it may be somewhat disconnected from mathematical understanding (Wynn, 1990, 1992).

Q: Which counting principles are typically mastered by preschool children, and which counting principles take longer to develop?

Researchers disagree on how young children's counting routines become integrated with other aspects of their mathematical knowledge during the preschool and early elementary school years. Some psychologists argue that children's numerical knowledge is closely linked to the quantity of number labels in their language (Le Corre et al., 2006). Supporters of this view point to early evidence that languages with very few number labels may deprive speakers of counting ability. For example, the Piraha, a small Amazon tribe whose terms for numbers include only "one," "two," and "many," seem unable to count or to use any of the counting principles (Gordon, 2004). According to this view, the counting principles cannot emerge as basic insights without significant support from language.



Can you count these?
One, two, three, four, five, six, seven.
Good. How many hearts are there?
Three???

FIGURE 9.19 **Limitations on counting by preschoolers.** Although young children seem to master counting routines quite well early on, they often do not realize the relation between the last number of the count and the number of objects counted.

The supporters of an alternative view argue that the development of counting skills and early mathematical knowledge does not depend so much on language for their growth and elaboration. Instead, they hold that numerical knowledge is largely separate from language, both in terms of the brain areas that support these two types of knowledge and the ways they develop (Gelman & Butterworth, 2005). These researchers point out that cultures with few number terms actually show much greater numerical competencies when they are examined more closely. Other support for this second view comes from studies of children with specific language impairment (SLI), a condition described in Chapter 8. Children with SLI show significant delays in language development, which also affect their counting-out-loud routines. Nonetheless, they seem able to learn basic principles of arithmetic in ways that are independent of their struggles with language (Donlan et al, 2007). Thus, this second view considers young children's counting routines to be based on an implicit, domain-specific understanding of number and to develop without major influences from the particular language that a child speaks (see Figure 9.20). In addition, young children's nonlinguistic abilities to estimate quantities may relate to the development of an understanding that the last number counted indicates the quantity of items in the set. Preschoolers

FIGURE 9.20 Counting across cultures. Children all over the world engage in counting but vary considerably in their counting patterns and how they link counting to other forms of mathematical knowledge.

who are especially good at estimating gain that insight about counting at an earlier age (Wagner & Johnson, 2011).

A more nuanced perspective arises from work on the understanding of number by Nicaraguan home-signers, deaf people who use systems of invented hand gestures to communicate with hearing friends and relatives (see Chapter 8). They grow up in a culture where number is clearly important, but their home-created language has no number symbols, and they have difficulty thinking about precise number values much higher than 3 (Spaepen et al., 2011). Thus, even though they know numbers are important and understand discrete numbers up to 3, they tend to switch to a more approximate estimation system when they encounter even modestly large numbers. Above and beyond the debate about how much language contributes to understanding number, however, it is clear that preschoolers' numerical abilities surpass what Piaget envisioned, since he argued that real numerical understanding was not present until the transition to concrete operational thought around age 7 (Piaget, 1952).

Developmental research on number skills has also raised questions about how children's intuitive concepts of number change between infancy and middle childhood (Carey, 2009; Wynn, 1995, 1998). Older children develop a new system that is responsible for more sophisticated mathematical thought and complex computations, and as the study of the Nicaraguan home-signers suggests, language may be central to this second system. A child may take several years, from age 3 to roughly 7, to fully benefit from the subtle but powerful clues that language can provide about more sophisticated aspects of mathematics. This gap of several years between the point when a child can first use number terms to count and the time she is able to talk about mathematical relationships may help explain why early counting often doesn't result in knowing how many things there are.

One line of research suggests that children's increasing understanding of number words and plural forms helps them to see more complex and systematic numerical relationships (Carey, 2001, 2009). Somehow, children with "number-rich" languages manage to learn that numbers above 3 continue to each have a discrete value (Huang et al., 2010). In addition, the more parents talk to their children about number-related topics in these languages, the earlier the children make the transition to understanding that the number 4 corresponds to exactly four things, even when socioeconomic factors and other aspects of parents' language use are controlled (Levine et al., 2010). Children may achieve this insight by noticing patterns in the way small numbers are used in their language, and then seeing how those patterns apply to larger numbers as well. In this form of learning, which is often called **bootstrapping**, children appear to build on their early insights about small numbers, using these patterns as a foundation for understanding new and quite different kinds of number concepts (Carey, 2009; Negen & Sarnecka, 2012; Slusser & Sarnecka, 2011).

As with spatial knowledge, research on the development of mathematical thought suggests several important themes about how this area of knowledge begins to take shape in childhood. Three of these themes are most prominent:

1. The principles that govern our ways of thinking about numbers and mathematical relations share some common properties across all cultures. In particular, almost every culture's number system shares fundamental assumptions about what numbers are, how they are connected to countable objects, and what sorts of operations can be performed on the numbers derived from counting representations.
2. The development of mathematical thought involves changes in several kinds of knowledge systems, including a system for estimating large numbers and a system for precise operations on small number values, such as 1 and 2. Some forms are nonverbal and relatively inflexible, like the information handled by the estimation sys-

tem. Other forms can be easily stated in language, such as mathematical rules and principles. This language-related type of mathematical knowledge creates a foundation for more powerful and abstract mathematical thought and helps transform the very concept of number.

3. A final pattern concerns the distinction between knowing how to do something and being able to succeed at it consistently at all levels of complexity. One group of mathematics researchers has related competence to mathematical skills by describing three components of competence and applying them to the progression of mathematical development (Gelman & Greeno, 1989; Greeno et al., 1984). They distinguish between knowing abstract mathematical principles, like the principles of counting mentioned earlier (conceptual competence), knowing how to perform the behaviors that fit with particular principles (procedural competence), and being able to figure out which principles to use for a particular task (utilizational competence). These researchers argue that competence with the principles comes first, but that being able to apply the principles to real problems requires both of the other facets of competence in order to plan and perform mathematical operations. In this view, young children can keep the counting principles in mind fairly easily, but using them is more difficult and requires further mathematical development. The principles become more applicable to the real world as the child develops performance skills and an increasing awareness of which skills to use for specific tasks.

Which dimensions of cognitive development best characterize the emergence of intuitive mathematical thought? In terms of the three dimensions introduced at the beginning of this chapter, number exhibits a rich interplay of several distinct processes. Early number skills during the preschool years may draw heavily on local, number-specific forms of cognition that are guided strongly by foundational constraints, such as estimation skills and possibly some counting principles. During this period, change may be largely quantitative. Then, a qualitative shift in number concepts seems to take place, when numerical skills seem to become subject to more emergent constraints. This change may be facilitated by experience with a number-rich language. As we will see in Chapter 10, more domain-general cognitive skills like memory and attention become critical as we consider higher levels of mathematical reasoning and computation. Across the full sweep of development, numerical cognition draws on all the different dimensions that describe cognitive development. Thus, it illustrates how a developing system can have many interacting components, which make developmental change quite different at various ages.

Q: How is linguistic input related to the emergence of mathematical thought?

Biology

Young children seem to develop naive, or intuitive, theories about broad slices of the natural world that we might loosely associate with domains such as biology, physics, and psychology. Their collections of beliefs are thought to resemble theories because they are about abstract causal patterns in the world, have some degree of connectedness or coherence, serve as a basis for making predictions, and seem to evolve over time (Gopnik & Wellman, 1994, 2012). They are not like scientific theories in that they are often very sparse in terms of details (Keil, 2012), but they do reflect ways in which children and adults develop intuitive beliefs about areas of the natural world that they may never have learned about through formal instruction. These intuitive areas are often known by such labels as folk physics, folk psychology, and folk biology. We start here with a discussion of the development of folk biology, which is an intuitive understanding of living things and biological processes that occur in the natural world. We will be asking whether young children start off very early with an understanding of the living world as a distinct realm or whether folk biology only emerges as a distinct form of intuitive theory several years later in development.

Over the course of childhood, we develop a great many beliefs about the biological world, many of which we come to take for granted. These include ideas about birth, growth, death, and the inheritance of traits in plants and animals. They also include ideas about disease, contagion, and healing, as well as a host of beliefs about how living things function and how they are adapted to their environments.

Cross-cultural research suggests that several aspects of intuitive biological thought are universal (Atran & Medin, 2008). For example, people in all cultures share the following biological beliefs: (1) Groups of animals and plants can be organized taxonomically—that is, systematically in hierarchical categories based on how they naturally relate to each other. (2) Animal and plant types have distinct essences—that is, their observable properties arise from crucial, defining, deeply rooted qualities. (3) Organisms have properties that are adapted to their needs within their niches—that is, the physical environments they inhabit (Atran, 1995, 1999; Berlin, 1992; Medin & Atran, 1999). For example, people throughout the world believe that a local bird is (1) part of a hierarchy of different kinds of animals, (2) a member of its category because it shares essential

DEVELOPMENT AND SOCIAL POLICY

Sputnik and Intuitive Science

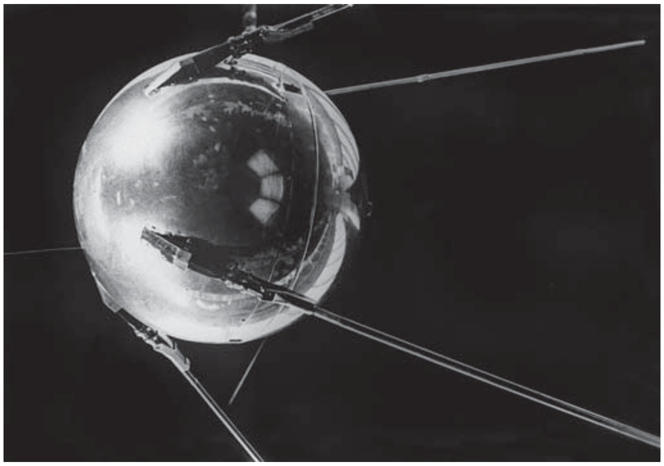


FIGURE 9.21 **Sputnik.** The launching of the world's first artificial satellite by the Soviet Union in 1957 set off a wave of initiatives focused on improving science education in the United States.

On October 5, 1957, U.S. citizens were shocked to learn that the Soviet Union had launched Sputnik, the world's first artificial satellite (see Figure 9.21). In response to this achievement, the United States undertook an all-out effort to make its children more scientifically literate. Large resources were devoted to enhancing science education at all levels, from elementary school to graduate school, with the National Science Foundation playing a particularly central role (Atkinson, 1999). The program succeeded in some respects; technological and scientific innovation in the United States continues to outpace that of many other countries. Yet, on tests of scientific knowledge and reasoning, U.S. children continue to be outperformed by children in other countries. In the late 1990s, the Third International Math and Science Study revealed that after the fourth grade, children in the United States started to fall dismally behind students in other industrialized countries (Schmidt et al., 1997, 1999). In response to these findings, congressional hearings examined the weaknesses in U.S. science education, and President Clinton vowed to address the crisis head-on. Yet, a similar 2009 study by the Program for International Student Assessment (PISA) showed that U.S. students ranked no higher than 17th in the world in their knowledge of science (National Center for Education Statistics, 2009). But it is not clear what the U.S. students' persistently poor performance on science-related standardized tests really means for the future of science education and innovation in the country. In short, we don't know which aspects of science education matter most for increasing the number of leading scientists

properties with all the category members, and (3) particularly suited for the environment in which it lives. All adults therefore come to appreciate many of the distinctive properties and relations that distinguish living things from everything else. Thus, their biological thought comes to have its own special properties that make it distinct from other domains of knowledge (Hull & Ruse, 1998; Sterelny & Griffiths, 1999). Furthermore, because these core biological beliefs seem to be universal, all children must come to know them at some point in development (see Figure 9.22).

In addition to these core principles, children learn a host of more specific ways that the living world differs from the nonliving world, as well as many biological distinctions, such as that between plants and animals. They learn that living things reproduce, grow, and die, and that living things must ingest food and water to be able to grow and reproduce. They learn that members of the same plant or animal category can change their shape and appearance radically over the course of development: a baby becomes an adult, a tadpole becomes a frog, and a caterpillar becomes a butterfly.

FIGURE 9.22 **The living world.** As fancifully depicted in the painting *Tropical Forest with Apes and Snakes* (1910), by Henri Rousseau, the living world includes a fantastically diverse array of organisms. How do children come to understand that all these organisms are in the domain of biology?

in a country. Although the average citizen has only a rudimentary understanding of many natural phenomena, such as the changing seasons, it is not clear whether this broad lack of knowledge influences how scientists are trained in universities or how children end up choosing a scientific career path. There is a clear need to link public policy questions about investment in science education to studies of whether such investments really make a difference for the state of science in a country.

Over the past few decades, research in cognitive development has started to influence beliefs about how to teach science. For example, a report issued by the National Research Council called *Taking Science to School* emphasized two themes that should underlie the instruction of science in the schools (National Research Council, 2007). First, science instruction should focus on the gradual growth and accumulation of knowledge that builds on earlier knowledge learned over several years, as opposed to providing snapshots of unrelated topics over various years. Second, children bring to elementary school some basic intuitions about domains such as space, number, biology, and physical mechanics. Because these areas of scientific inquiry, called *privileged domains* of science, have roots in children's very early intuitions about the world, science teachers can build on students' rudimentary understanding in these areas, rather than seeing students as limited by Piagetian stages in which certain kinds of reasoning and knowledge are impossible.

As we have seen, children's intuitions in these domains are sometimes mistaken, but their early knowledge can still serve as a foundation for future learning rather than being dismissed as a useless bunch of misconceptions. Unfortunately, past instructional programs have too often focused primarily on children's failings and ignored their powerful ways of tracking the important relations they encounter in the world. As researchers uncover more details about how children's intuitive understanding of privileged domains emerges, science education will be able to build on this understanding in powerful ways that make sense to students.

This new approach emphasizes continuities over time rather than stages and limitations in both cognitive development and science education. It will, however, require major efforts from schools and teachers to develop coherent instructional programs in science in which each year's coursework systematically revisits core ideas in deeper and deeper ways, building on what was taught in prior years. Ideally such an approach could be adopted across many schools, so that children who change schools would still share their classmates' scientific knowledge base, which their teacher could continue to build on. To achieve such an integrated science curriculum across schools and districts, however, will require a team effort among schools, government officials, and citizens.

How do children develop these biological beliefs, and what mistakes do they make as they acquire adult knowledge?

Q: What are some universal core biological beliefs?

Here we will consider in detail two different sets of proposals that describe how children learn about living things. The first set of views, which we will refer to as late-emerging biology views, assumes that even very young children's impressions of living things are embedded within larger explanatory systems that provide them with a sense of why those things are the way they are. In these views, children use a theory for explaining the social world called *naive psychology* and a theory for explaining the physical world called *naive physical mechanics*. Thus, these views propose that young children can interpret and explain things only in psychological terms or in terms of simple physical interactions between objects. Applying these ideas to children's biological knowledge, proponents mostly assume that children explain animal properties in psychological terms and explain plant properties in simple physical terms (Carey, 1985, 1995). According to these views, as children develop, they come to realize that neither the psychological nor the physical system of explanation is fully adequate for explaining the properties of living things, and they begin to develop a new, specifically biological system of explanation. This biological explanatory system is based on the idea that living things are systems made up of smaller systems, such as the muscles and the digestive system. Their biological thinking also takes into account the ways that these smaller systems serve specific functional roles that help an organism survive in its environment.

The second set of views, which we will call early competence accounts, holds that even very young children think of biological things as different from other kinds of things and accordingly explain their properties and actions as distinctive, too. According to these views, most developmental change in biological thinking consists of becoming more capable of applying biological explanations to specific phenomena and different kinds of situations and gaining more detailed knowledge of biological mechanisms (Hatano & Inagaki, 1999; Inagaki & Hatano, 2002, 2004, 2006; Kalish, 1997; Keil, 1992; Keil et al., 1999). These views are often blends of views that emphasize enrichment of core domains, increasing access to these domains for more and more tasks, and shifting biases in terms of which kind of explanatory system first comes to mind. They all share the idea that living things have so many distinctive features that very young children start to see the living world as a distinct domain long before they understand how biological systems work.

As we did in the discussions of spatial navigation and number sense, we will use Piaget's views as a point of departure here. Piaget documented several ways in which preschoolers seem to use **animism**—the tendency to imbue inanimate things with psychological motivations such as desires and beliefs—to explain the physical mechanics of objects, the movements of the sun and clouds, and the behavior of plants in intentional terms. For example, young children may think that the sun moves because "it wants to" and that the bridge broke because "it was angry" at the person on it. Piaget argued that young children are incapable of reasoning in purely physical, causal, and mechanical ways. He saw young children as having great difficulty disentangling explanations about animate things from more mechanical, inanimate explanations—that is, they seemed unable to separate the world of the mind from the world of the physical (Piaget, 1926/2007).

Some of Piaget's other notions about young children's cognitive limitations also strongly suggest constraints on early biological thought. According to Piaget, a young child, who is presumably egocentric, would likely assume that other animals think as she does. Thus, she might freely apply human mental states to other animals. In Piaget's view, children in the preoperational period, who presumably have difficulties with conservation, would therefore also have great difficulty understanding biological processes like digestion that involve any kind of physical transformation. In some ways, Piaget's account sounds very much like the late-emerging biology view in which much of early biological thought is believed to be embedded within a naive psychology. Unlike that view, however, Piaget suggested that young children very often confuse psychological and physical thought, rather than using each of them as a distinct explanatory system.

As we have seen in other domains, the patterns in children's responses that Piaget documented have been replicated in other studies, but later researchers have interpreted those patterns in new ways and drawn different conclusions about children's understanding of biology. In addition, researchers have clearly shown that preschoolers are fully capable of reasoning in physical, causal, and mechanical ways (Bullock et al., 1982; Koslowski, 1996; Shultz & Kestenbaum, 1985). One of the most extensive critiques of Piaget's interpretation came in a series of studies by Susan Carey, who sought to reconcile the findings about preschoolers' capabilities with Piaget's earlier observations (Carey, 1985). After examining the young children's responses in Piaget's animism studies, Carey argued that these children were not really mixing psychological explanations with physical, mechanical ones, as Piaget had claimed. Instead, she interpreted the animism data as showing that young children tend to use psychological interpretations too broadly, especially in applying them to living things. The children's occasional uses of psychological explanations for occurrences in the inanimate physical world does not, in Carey's view, undercut the wealth of evidence that preschoolers can reason easily about physical causality.

To test her view, Carey developed several methods for studying how children attribute biological properties to animals and nonliving things. To compare how children's prior knowledge influences their thinking about biological questions, Carey asked children questions about whether some familiar biological terms, such as *heart*, and some unfamiliar terms, such as *omentum* (a tissue covering the intestines), could apply to various living and nonliving things. For example, she might tell a child that humans have an omentum and ask the child if dogs have an omentum. If the child believed that dogs are living beings, he would say that dogs do have an omentum. Thus, in such a property induction task, the child would induce which other entities have a property based on a known example. This **property attribution** method assumes that the kinds of guesses a child makes about what properties apply to living things can reveal the underlying conceptual system that the child is using to think about living things.

Consider another example from Carey's research. A 4-year-old might be asked whether the following biological properties apply to humans: Do people eat? Do people sleep? Do people breathe? Do people have babies? Do people have bones? Most 4-year-olds will answer "yes" to each question about humans. The interesting part of the task concerns how young children answer similar questions about other animals and about nonliving things. Here, children's errors are sometimes dramatic and surprising. Consider this interchange with a 4-year-old:

Interviewer: Do worms eat?
Child: No.
Interviewer: Do they have babies?
Child: No, they just have little worms.

Like this child, preschoolers are often reluctant to attribute many basic biological properties to simpler animals such as worms and insects. How can this be? How can a child have roughly the correct idea about what biological properties like eating and having babies mean and fail to apply them to virtually all animals? If a child has even the crudest idea of the real biological purposes of such properties, surely she would realize how essential they are to all living things.

This pattern was so compelling that Carey concluded that younger children must not really understand those properties in a true biological sense. That is, they do not understand the essential functions that these properties serve. Carey proposed that this lack of understanding arises because the children have no broader biological system of explanation within which to embed these specific properties. The children in Carey's study were not responding to the questions randomly, however. Instead, they were interpreting those basic biological properties by embedding them within a psychological mode of explanation. In such a psychological explanatory mode, we sleep "because we feel tired and want to rest"; we eat "because we feel hungry and know that food will taste good and make us feel full"; we have babies "so that we can cuddle them and take care of them." Thus, Carey's approach suggests a "biology-out-of-psychology" view of the development of biological understanding, in which biology emerges relatively late as an independent theory. Children seem to interpret basic biological properties entirely in terms of the human psychological motivations that are associated with them.

If children understand these biological properties only in a psychological way, it makes sense that they would not apply them to simple animals that do not have mental states like ours. Young children believe that since worms do not have rich thoughts and desires, they do not eat, sleep, or have babies *in the psychological sense* in which children seem to think about these properties. Thus, in deciding whether these properties apply to other animals, children largely focus on the extent to which the animals seem behaviorally and psychologically similar to humans (see Figure 9.23). Because dogs show some psychological sophistication, young children believe that they are much more likely to have these basic biological properties than are "simpler" animals.

This late-emerging biology view suggests that early on, children understand biological ideas only in psychological terms. Then, over time, they experience a major conceptual revolution in the way they attribute properties to living things. They replace the early psychological interpretations with a distinct set of biological explanations. These new ideas allow the child to see for the first time that eating serves a general biological function—it allows all animals to get the nutrients they need to move, function, and grow.

Carey's model differs from a Piagetian approach in important ways. For one, Carey described a local, or domain-specific, revolution in conceptual understanding. This change reflects the emergence of a specific theory of biology, rather than the kind of underlying global change in cognitive structures that Piaget proposed. In addition, the more detailed patterns of reasoning that Carey documented are quite different from what Piaget might have predicted. Young children's reluctance to attribute psychologically interpreted properties to simpler animals, for example, runs contrary to the animism that Piaget interpreted in children's responses.

Carey's late-emerging biology model is not the only way to explain this pattern of results, however. Indeed, another line of research suggests an alternative account that stresses children's early competence in biological knowledge. This alternative view becomes apparent upon a closer inspection of Carey's property attribution method. Are preschoolers completely unable to interpret properties in a biological sense and therefore limited to explanations that fall within a psychological explanatory system? Or could they simply be misunderstanding which of their several explanatory systems is relevant to the task? As adults, we often shift between different kinds of interpretations. For example, if I hear that someone has a "big brain," I might interpret that either as a figurative statement about intelligence or a literal one about a biological organ, drawing very different inferences in each case. Perhaps children can also shift between different types of interpretations.

To test this possibility, researchers can try to pose the questions about biological properties in a way that signals which explanatory system is relevant without providing any details about it. For example, the researcher might tell

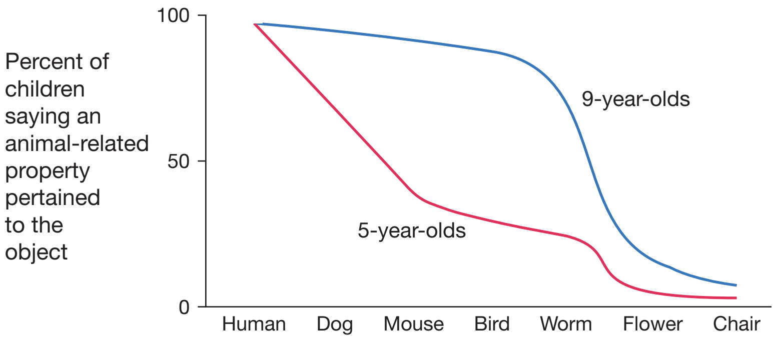

FIGURE 9.23 Attributing biological properties. In Carey's original studies, younger children seemed to decide whether animal-related biological properties pertained to different categories of living and nonliving things based on the extent to which those things seemed behaviorally similar to humans.

a child, "When I ask about whether worms eat, I am asking about eating in the sense that it helps the body move and grow." If the child then correctly attributes eating to worms, this could indicate that she understood the concept all along, but didn't know the researcher was asking about that particular concept. Another approach is to engage the child in a brief, general conversation about how animals can be like machines in some ways, with inside parts that serve specific functions for the animals. After having this discussion, the researcher then asks the child the same questions about applying biological properties. The same younger children who made many errors in the original property attribution task may now respond much like the older children in Figure 9.23 (Gutheil et al., 1998).

These studies raise the strong possibility that even young preschoolers may not lack biological thought. Instead, the broader context seems to strongly influence whether they choose biological explanations over psychological ones. In some contexts, even young children will use biological explanations and apply them in generalized ways that indicate a far-reaching application of biological ideas. Cross-cultural research has provided evidence for this early competence view. One study focused on Mayan children living in traditional agricultural communities in Mexico's Yucatán Peninsula. Even very young children showed no tendency to apply biological traits exclusively to humans and animals that were psychologically similar to humans. Instead, the children applied biological properties to all animals in generalized ways that reflected a true naive biology, rather than the absorption of biology into psychology (Atran et al., 2001).

It may be that the human-centered bias emerges only in certain cultures, around age 5. One study showed that in a wide range of cultures, 3-year-olds do not show a bias to apply biological traits only to humans. This tendency only seems to emerge in 5-year-olds when they are raised in urban environments, which apparently stress a human-centered view of nature (Herrmann et al., 2010). Related studies also show that the human-centered view is not a universal feature of children's biological reasoning. It depends on several aspects of culture, including the kinds of conversations parents have with their children about the living world (Medin et al., 2010). Thus, in cultures in which people live closer to nature, young children may have a much earlier bias toward relying on biological explanations.

The same theme arises in several other lines of research on the development of biological thought. Psychologists have studied children's beliefs about how properties are passed down to offspring (Hirschfeld, 1996; Springer & Keil; 1989; Waxman et al., 2007), about disease and contagion (Keil et al., 1999), about how biological things adapt to their environments (Greif et al., 2006), about the kinds of essences inside living things (S. Gelman, 2003), and about the coherence of causal mechanisms underlying biological processes (Erickson et al., 2010). All of these studies seem to indicate that preschoolers show an early competence with biological thought. They understand the category of *living things* to which both animals and plants belong, and they have a cluster of beliefs about how living things differ from other sorts of things.

Q: How do late-emerging biology views of the development of biological thought differ from early competence accounts?

If even young children show some early competence with biological reasoning, how does their thinking about biology develop over the course of childhood? The evidence suggests that children do not build up biological knowledge by first learning specific, concrete bits of information, then eventually progressing to abstract rules and principles. Instead, they seem to learn some initial, abstract patterns and then gradually fill in all the concrete details and mechanisms that fit with those patterns. This "abstract-to-concrete shift" in children's mastery of biological concepts has been documented in several cases. One example is the way children come to understand the concept of "insides." Preschoolers expect animals to have insides, and they think that insides play a critical role in influencing the animals' outsides as well as affecting their behavior (R. Gelman, 1990; S. Gelman, 2003). They also think about animal insides differently from the way they think about machine insides: animal insides help the animal survive, whereas machine insides help meet the needs of the machines' users (Keil, 1995). In this case, preschoolers show a relatively abstract causal understanding about what insides are for—but this conceptual understanding is not necessarily based on any knowledge of specific, concrete details. In fact, preschoolers may know little or nothing about what insides actually look like (see Figure 9.25).

Any description of how biological knowledge develops will have to explain how children's understanding of abstract patterns and causal relationships can emerge before they know anything about the relevant concrete details. Young children seem to be able to extract some rough sense of what makes living things different from nonliving things without needing a fully worked-out theory (Au & Romo, 1999). This learning process suggests that the popular metaphor of children as "little scientists" testing specific theories about the world may be flawed. At least in the biological domain, children often seem to have powerful hunches, but no more than a vague knowledge of the details.

By at least age 3, children seem to be aware of some of the distinctive patterns that characterize the biological world, especially its more abstract principles and causal relationships. They can use this early knowledge to begin

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

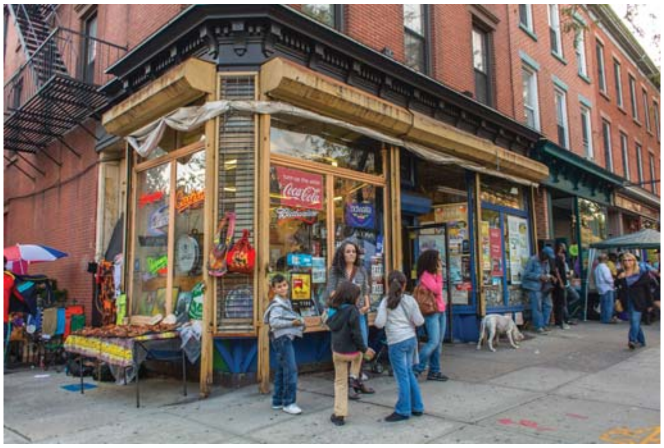
Biological Knowledge and Exposure to Nature

Most developmental studies assume that the outcome or "end state" of development is the level of knowledge common among college students or other adults in mostly urban, technological societies. But what happens when that end state is neither the normal state of mature knowledge nor especially sophisticated? This is arguably the case with the development of biological knowledge (Wolff et al., 1999). After all, the most salient living things that the average city dweller encounters are probably other humans. By contrast, an inhabitant of a rural area experiences a much broader range of biological forms (see Figure 9.24). In the realm of naive biological thought, people who grow up in urban cultures may have a relatively impoverished understanding.

Work with children in "biology-deprived" environments and with children in "biology-enriched" environments suggests that lack of experience with nature affects biological understanding (Atran et al., 2001, 2004; Herrmann et al., 2010; Medin & Waxman, 2007; Ross et al., 2003). Compared with adults who regularly encounter many diverse forms of nature, adults in biology-deprived environments show greater difficulty attributing biological properties, categorize the living world at less specific levels, reason in less sophisticated ways about biological problems, and think about biological essences differently. Their children also show comparable difficulties (Atran et al., 2004). The influence of specific cultures on this domain of thought seems to emerge around age 5, suggesting a more universal, common framework in younger children (Herrmann et al., 2010).

Different amounts of exposure to nature may play a role, as may the different ways that members of a culture talk about humans and other living things (Anggoro et al., 2010; Taverna et al., 2012). Cultures may also differ in how they expose children to animals, both in real life or indirectly through various media. When children from urban, rural, and Native American communities were asked to name all the animals they could, urban children more often named exotic animals they had learned about from picture books and other media (such as lions, tigers, and elephants) than common examples from their urban environments (such as squirrels and pigeons). Rural children, and to a greater extent Native American children, named more local animals (Winkler-Rhoades et al., 2010). Thus, while young children often benefit from learning through others (S. Gelman, 2009; Keil et al., 2008), direct experience is also important.

Because urban adults may have such limited knowledge of biology, examining urban adults to learn about the development of biological knowledge may produce a skewed account. In most cultures, the normal developmental path may lead to the early emergence of rich biological knowledge. Younger children in urban or suburban areas may tend to interpret biological properties in psychological ways because they have grown up in a biology-deprived culture. More broadly, the study of how knowledge develops in any domain risks telling a distorted story if the mature state of knowledge is measured according to cultural norms that do not represent most cultures (Medin et al., 2010; Waxman et al., 2007).



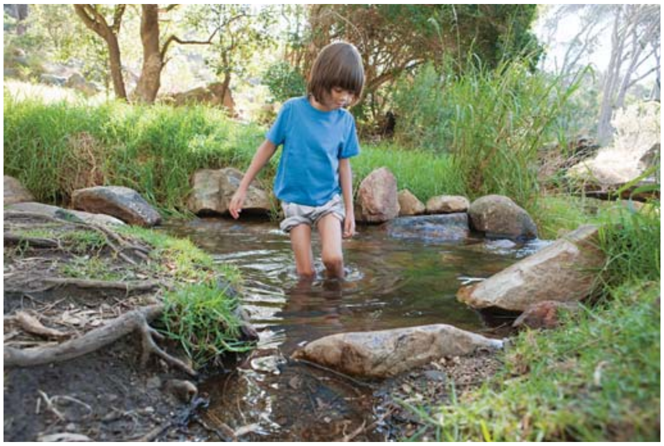


FIGURE 9.24 **Developing biological thought in urban and rural youth.** It now appears that urban children may have a different and simpler set of beliefs about biological properties than children raised in rural environments.

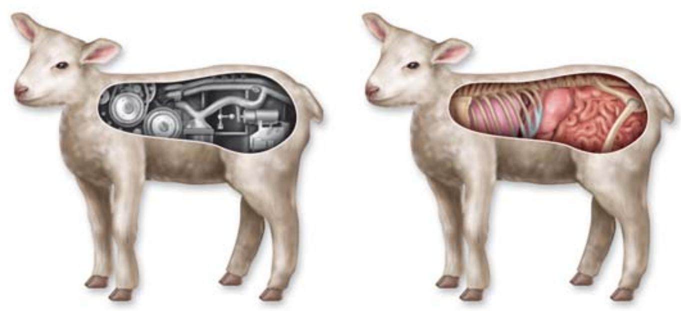

FIGURE 9.25 **Ignorance of insides.** Children younger than 5 frequently confuse what sorts of “insides” belong in machines and animals. Thus, many young children will not be able to choose which kind of insides shown here goes with a lamb or with a car. Yet, at a more abstract level, the same children have a reliable understanding of differences between the categories of machines and animals. Adapted from Simons & Keil (1995).

reasoning about living things—so, in that sense, they do have a distinct biological knowledge. At the same time, they do not know much about the specific mechanisms of how living things work. In this area, children show dramatic developmental changes during the preschool and elementary school years.

Young children may adopt certain broad assumptions about the living world that enable them to see some of its distinctive patterns without knowing the details. One such assumption may be **vitalism**, the belief that living things are distinctive because of a vital force inside them that is responsible for growth and movement (Inagaki & Hatano, 2002, 2004). Vitalism is in fact a very old idea that dates at least as far back as ancient Greece. It seems vague and unscientific to most adults in industrial cultures today, but it helps us understand something about children’s early biological thought.

Figure 9.26 shows the child’s vitalist beliefs. Some young children hold the view that food and water instill a force in animals that enables them to move and be active (without this force, the animals become increasingly inactive and tired). They believe that if there is a surplus of this vital force beyond these needs, the surplus is used for growth and health. Younger children do not always understand the direct link from food and water to growth and health, but older children come to see food and water as having a more direct influence. Along with vitalism, children also show a naive **essentialism**, in which they assume that living things have inner essences that are responsible for their surface properties (S. Gelman, 2003). Together, the general theories of vitalism and essentialism may be the most critical components of early biological thought.

A final feature of children’s biological thought seems to be a tendency to interpret animals’ and plants’ properties in terms of the functions they serve. Thus, children may want to know what the parts of animals and plants “are for” more often than they would ask this question about the parts of nonliving natural objects, such as rocks (Greif et al., 2006; Keil, 1992). They use functional explanations more broadly than older children by extending them more often to nonliving natural objects (Kelemen, 1999). Yet, adopting functional explanations more strongly toward the living world early on may help children begin to understand its distinctive nature. Interestingly, preschoolers also seem to know that while it makes sense to ask what the parts of an animal are for (for example, the claws, the stripes, the fangs), it makes less sense to ask what the animal as a whole is for—even though it would be a reasonable question to ask about a tool (Greif et al., 2006).

Q: What are vitalism and essentialism, and what roles do they play in early biological thought?

Other Domains of Thought

We have examined how children’s intuitive knowledge develops in the domains of spatial layout, number, and biology. Here we will briefly consider how early understanding emerges in a few other domains: physical mechanics, substance beliefs, and cosmology. Comparing the ways that knowledge develops across all of these domains reveals an interesting commonality: in the preschool years, children start to develop some structured hunches about patterns in the world. Over the course of childhood, they develop more detailed beliefs about the specific mechanisms that give rise to these patterns in each of the domains.

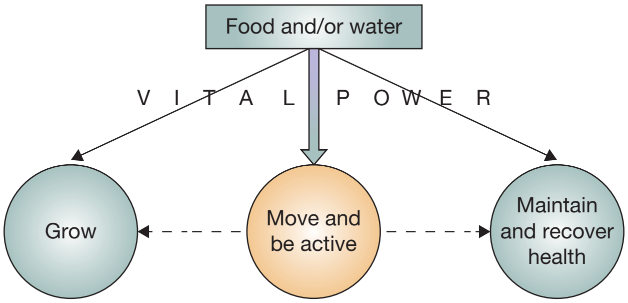

FIGURE 9.26 **Vitalism in young children.** As captured in the diagram, young children believe that food and water provide a vital force that enables animals to become active (as indicated by the thick arrow). When there is a surplus of this vital force, it acts as an impetus for growth and for maintaining and recovering health (as indicated by the dashed arrows). As children grow older, the direct links between food and growth and health are more clearly understood (as indicated by the thinner arrows). Adapted from Inagaki & Hatano (2004).

Beliefs about Physical Mechanics The domain of physical mechanics concerns beliefs about solid objects' behaviors, such as trajectories and collisions (Riner et al., 2000). In Chapter 5, we saw that infants seem to be aware of a few mechanical principles: (1) They seem to understand *continuity*—the idea that objects exist continuously and move on connected paths and are unable to jump from one place to another without occupying the intervening space. (2) They appear aware of the principle of *solidity*—the idea that solid objects cohere as bounded wholes and cannot interpenetrate. (3) They seem to understand the *contact* principle—the idea that objects cannot influence other objects without touching them; they must make contact. Infants also develop very different expectations about how inanimate objects behave compared with social beings. We can think of this early intuitive understanding about physical objects as the beginnings of "naive physics," or folk physics. As children leave infancy and enter the toddler and preschool years, they refine and elaborate on these broad patterns.

Many early childhood beliefs about physical objects are the legacy of these intuitions from infancy. Preschoolers know that unsupported things must fall and that even supported objects will fall over when set off-balance (Baillargeon, 2002; Dan et al., 2000; Keil, 1979). They pay more attention to patterns that conform with underlying mechanistic notions, assuming, for example, that a certain configuration of blocks is likely, but not certain, to fall over (Griffiths et al., 2004). Preschoolers also show further elaborations on intuitions from infancy about how inanimate objects differ from animate or social beings. When they are asked to explain the behaviors of simple devices, such as a box with levers, they clearly prefer mechanical causal explanations over social or biological explanations (Bullock et al., 1982; Gelman & Lucariello, 2002). Similarly, they explain violations of physical norms (such as an object floating in the air) in very different causal terms from moral violations (such as stealing) and from transgressions of social conventions (such as driving on the wrong side of the road; Lockhart, 1981).

During the elementary school years, children begin to understand in more detail how physical mechanics works. For example, while younger children think of physical forces as intrinsic characteristics of objects, older children come to see forces as "acquired properties" that affect objects because of the ways they interact with other objects, such as by being given a push—that is, objects have no forces until they acquire them by being influenced by other objects (Ioannides & Vosniadou, 2002). Elementary school children also come to understand how an object's length and weight can affect its balance, which is part of the general process of realizing how levers work (Siegler, 1981).

Though children show many early capabilities in understanding physical mechanics, they do hold some misconceptions, as do infants (see Chapter 5). For example, younger children tend to adopt oversimplified rules that can lead them astray. Thus, shortly after infancy, they seem to use a gravity rule that unsupported things must fall straight down regardless of how the support is removed (Hood et al., 2006). They predict that an object that rolls off a table will continue moving straight out from the edge for a moment, then drop straight down in a cartoon-like way. By the time children are 5 or 6 years old, they start to understand that an object rolling off a table will fall in a curved path, but they still make errors—which persist into adulthood—about the paths of objects dropped from moving carriers.

When children who are younger than about 3½ years old see a ball dropped into a curved tube, as shown in Figure 9.27, the "straight-down" rule is so strong that it often seems to cause them to see the ball come out of the wrong tube, the one whose bottom is directly below the dropping point (Hood, 1995). When children are made more familiar with the tubes, they predict more correctly where the ball will emerge (Bascandziev & Harris, 2011), but their initial mistakes indicate their difficulty inhibiting the "straight-down" rule without such training (Hood et al., 2006).

The more salient finding, however, is the extent to which some traces of these early ways of thinking about physical objects persist into adulthood. Thus, the belief sometimes persists even when the physical constraints of the task make such a straight-down path impossible (Caramazza et al., 1981; Krist, 2000; White, 2012).

In addition, both children and adults make incorrect predictions about trajectories, movements after collisions, and the natures of forces on objects (Bertamini et al., 2004; Clement, 1993; Espinoza, 2005; Proffitt & Gilden, 1989: White, 2012). Many aspects of physical mechanics remain

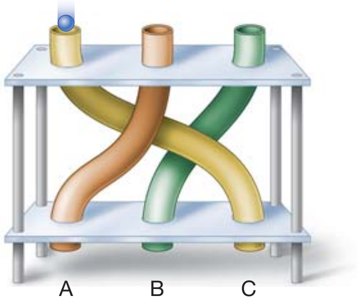

FIGURE 9.27 The straight-down rule. Until about age 3½, children often assume that an object dropped in a solid tube must emerge from the tube directly below where it was dropped. Older children and adults clearly expect the ball to emerge from the bottom of the tube into which it was dropped. Adapted from Hood et al. (2006).

difficult to understand throughout adult life, perhaps as a legacy of the strong biases that emerge in infancy and early childhood.

Beliefs about Substance Children's beliefs about substance concern what things are made of, how different substances combine, and how they change over time (Nakhleh & Samarapungavan, 1999). Even young preschoolers understand that certain phrases, such as "some blicket," refer to the stuff that something is made of while others, such as "a blicket," refer to the whole bounded object (Imai & Gentner, 1997). They also know that a small part of a pile of a certain substance is likely to be made of the same stuff as all other parts of the pile (Au, 1994). Similarly, they know that destroying a chair by grinding it into small pieces does not change the substance that makes up the chair (Smith et al., 1985). After preschool, there are considerable, but more subtle, developments in children's understanding of substances. Only after age 10 or so do children start to understand the relations between weight, density, and volume, and their implications for the nature of substances (Lehrer et al., 2001; Smith et al., 2004).

Beliefs about Cosmology Cosmology concerns beliefs about the earth, moon, and stars, including their origins, relationships to each other, and phenomena such as day and night and the seasons. Young children sometimes view their world as flat, and they think of the earth as being more like everyday objects, such as trees, tables, and rocks, rather than resembling planets, moons, and stars (Vosniadou & Brewer, 1992; Vosniadou et al., 2004; Vosniadou & Skopeliti, 2005).

In one sense, the development of beliefs about cosmology forms an important contrast with the development of knowledge in core domains such as physics, psychology, and biology. Beyond very general beliefs about the cosmos that come from physical mechanics, there seem to be few, if any, cosmological beliefs that all young children share. Instead, cosmology is a domain in which cultural variations can result in dramatic variations in beliefs. Some of these differences may arise from the degree to which a particular culture sees the earth in ways that are unlike the properties of everyday objects (see Figure 9.28). Thus, one report suggests that Australian children may come to understand aspects of cosmology earlier than British children, perhaps because most maps and globes depict Australia as "underneath" the rest of the world, such that people and things would "fall off" if the earth were an everyday object like a table (Siegal et al., 2004). In addition, children's cosmological beliefs may be more fragmentary and internally inconsistent than knowledge from more foundational or core domains, since the scientific view of the earth as a sphere is counterintuitive to what the children observe. Children pick up scientific knowledge of the earth and sun and stars from many separate sources, such as their parents, school, and the media, rather than from their own observations, and as such the fragmentary ideas that they acquire can be heavily influenced by local cultural practices (Panagiotaki et al., 2006; Siegal et al., 2011).

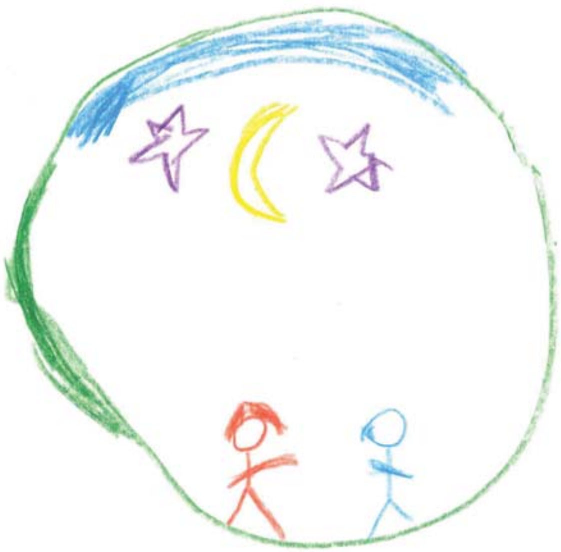

FIGURE 9.28 Cosmological beliefs. Shown here is a 6-year-old's drawing of the earth and heavens. This child includes the idea of a sphere but has the people, stars, and sun all dwelling inside the sphere—quite different from scientific depictions. From Siegal et al. (2011).

Across all these domains, children's structured hunches about patterns seem to develop before more detailed beliefs about mechanisms. Over the course of development, children seem to blend domain-general ways of learning about the world with an early awareness of the patterns specific to each domain. In addition, a modest number of core domains may provide the early, basic foundations of thought across all cultures. These foundational or core domains of knowledge likely include space, number, biology, psychology, physical mechanics, and substance. Other more secondary domains of knowledge might arise either as a subset of a single core domain or as a combination of several domains. This view suggests that there are a small number of core domains, and that our intuitions about these core areas of knowledge—in combination with general laws of learning—enable us to grasp most of the patterns around us (Wellman & Inagaki, 1997). Researchers interested in this possibility have developed computer models to simulate the ways in which abstract knowledge of a specific domain might develop before more concrete, specific knowledge (Kemp et al., 2007).

Sociocultural Views of the Development of Knowledge

Above and beyond all the patterns of development discussed in this chapter, one other set of factors must be taken into account: sociocultural influences. Sociocultural influences involve the ways in which social interactions and the broader cultural context provide a framework for information and guide children's learning processes. Sociocultural views of the growth of knowledge are not in opposition to other theories of cognitive development. Instead, they provide insight into an additional overlay of processes that contribute to the growth of a child's knowledge and cognitive skills.

To see how these influences work, consider again how early biological thought emerges in children of different cultures. Differences arising from cultural practices affect early biological thought in a variety of ways—even among different North American cultures. Broadly speaking, American Indian children are more often taught that they are part of nature, whereas European-American children are more often taught that they are separate from nature. American Indians talk more about how each person must play a role within the natural world, while European Americans talk more about protecting nature as its caretaker (Bang et al., 2007).

These differences lead to different kinds of causal schemas dominating interpretations of biology, such that the children in these cultures develop different ways of understanding and interpreting biology. European-American children who grow up in urban cultures tend to reason about biological properties in more superficial ways and tend not to see commonalities between humans and other animals. Rural European-American children and rural American Indian children living on a reservation have more complex beliefs about biology than urban children do, but even these groups differ in their specific explanations. Rural American Indian children tend to make attributions about biological properties to organisms that are very attentive to ecological relations, such as predator-prey patterns. In contrast, rural European-American children tend to make attributions that are more centered around traditional taxonomies (for example, mammals, birds, insects) as well as goals (for example, good for eating; Ross et al., 2003).

Along with these broad, conceptual differences, cultures can also instill in children different beliefs about detailed biological mechanisms. For example, children may adopt different ways of thinking about essences based on their culture's views of the body. Thus, while both American Indian and European-American children believe that offspring inherit certain properties from their parents through biological means, American Indian children particularly stress blood as the biological essence that likely mediates inheritance. This belief seems to follow from their particular community's frequent references to blood when talking about biological phenomena (Waxman et al., 2007). In short, cultures set up strong biases toward certain kinds of biological perspectives and interpretations. At the same time, cultures also suggest ways that highly specific and concrete biological mechanisms fit within those frameworks (Atran & Medin, 2008).

The idea that cognitive development must be considered within broader sociocultural influences has a long history in developmental psychology and can be seen as mostly distinct from views held by Piaget, who tended to focus on the child as an autonomous individual. In Piaget's work, the development of knowledge was mostly described in terms of the child's discoveries about the world through direct experience, much like a completely isolated scientist conducting experiments. But a little reflection reveals that this view could not possibly tell the whole story of the growth of knowledge (S. Gelman, 2009; Harris, 2002; Keil et al., 2008). All members of a culture must expand on their own understanding by relying on knowledge that exists in the culture at large.

Vygotsky's Views

Lev Vygotsky, whose views of language were discussed in Chapter 8, was among the earliest proponents of the sociocultural view of cognitive development. In the early twentieth century, Vygotsky developed a theory of how social and cultural factors influence cognition. He argued that a child's cultural context and social interactions often mediate her interactions with the world (Vygotsky, 1978, 1986). Thus, the child is not an isolated individual learning about the world independently. Rather, she is part of a community, which plays a crucial role in packaging and presenting information. Her direct experience is greatly supplemented by these more indirect, mediated presentations, so she has to learn how to rely on the information that others present (Harris & Corriveau, 2011; Keil et al., 2008). Vygotsky concluded that children's social interactions, both through language and through the influences of large cultural institutions, profoundly influence their cognitive growth (Rowe & Wertsch, 2007; Wertsch, 1991, 1998).

Vygotsky saw the child as absorbing many aspects of culture through language and other cultural practices. The child comes to think like other members of a culture by internalizing higher-level, culturally specific aspects of cognition. Vygotsky believed that over the course of development, these internalized aspects of the child's culture becomes a fundamental part of the child's way of thinking. Vygotsky's views were likely influenced by his strong support of the Russian Revolution and the transition to a new classless, socialist society (Vygotsky, 1930/1994). In Vygotsky's lifetime, Russia and the subsequent Soviet Union underwent extraordinary changes in the structure of its society while also trying to unite many vastly different cultures spread over 11 time zones into one society. In that sociocultural context, it is not surprising that a young scientist might focus on the ways in which culture can transform thought.

We have seen that in infancy, cultural factors already affect the ways that infants and caregivers communicate through social referencing, joint attention, imitation, and emotional contagion. More sophisticated cultural influences tend to become evident after infancy. Two concepts figure prominently in accounts of sociocultural influences on children's cognitive development: *zones of proximal development* and *scaffolding*.

A child at a particular level of cognitive skill might stay at that level for a long time without an adult's help. According to Vygotsky, the adult provides guidance that can make it easier for the child to transition into the **zone of proximal development**, which is the next level of skill or understanding that a child can achieve in cognitive development. Vygotsky and many of his followers suggest that having some sense of those zones is a major part of successful teaching. Thus, a gifted teacher might first get to know the student enough to assess his level of cognitive development, and then carefully craft a lesson to support the child's transition to a new level of understanding. To fall within the zone of proximal development, the lesson must be more advanced than the child could achieve on his own, and yet close enough to his current abilities (that is, "proximal") to be attainable with the teacher's help.

In the process of supporting and guiding the child's learning, adults and older children are often described as **scaffolding** the child's cognitive development (Bruner, 1975). Much as an apprentice is trained by master craftspersons (Rogoff, 1990), children participating in a scaffolded learning experience receive guidance that enables them to take part in more advanced tasks than they could perform alone (see Figure 9.29). These experiences often increase the child's performance and feelings of mastery without making him aware of all the supportive scaffolding that made his achievements possible.

Consider, for example, an adult teaching a child how to make a bed. Rather than giving the child a list of explicit verbal instructions, an adult might scaffold the task by laying out all the materials in the order in which the child would need them, thus guiding the child through the process while giving him the sense of working independently. The mattress pad and bottom sheet could be set on the bed, with the mattress pad partially unfolded and around one corner of the bed. When the child finishes with them, the adult might casually provide the top sheet and the blanket in a similar way. Finally, the adult could set out the bedspread, pillows, and pillowcases in a similar way that

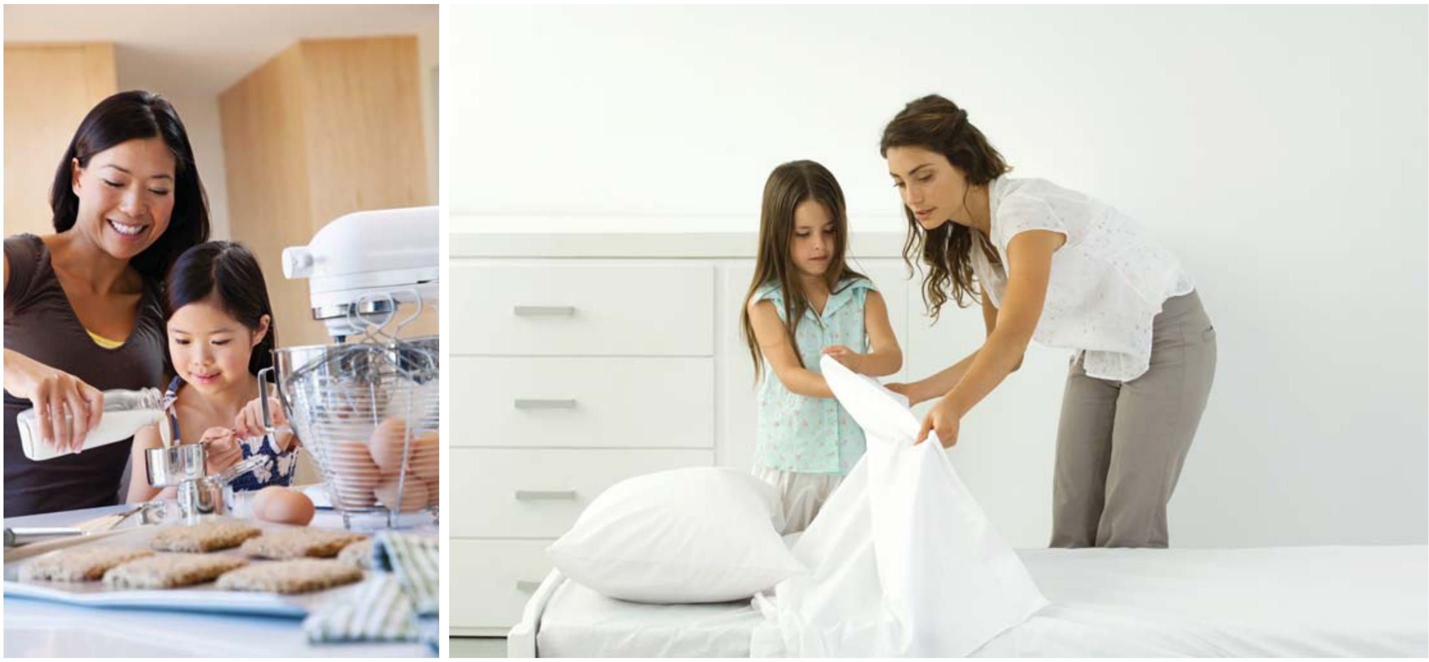

FIGURE 9.29 Scaffolding. Parents, teachers, and other adults often help children to attain new skill levels by providing support in subtle ways that help give the child a sense of achievement, a process called scaffolding. In some cases, adults can provide scaffolding without giving the child verbal instructions.

guides the child. A child who can easily make the bed with this subtle help might be confused or overwhelmed if all the bedding was laid out in an unstructured manner. One advantage of this kind of scaffolding is that the child may be largely unaware of just how much support he is receiving.

It is clear that social interactions and cultural differences do exert significant influences on the processes of cognitive development. Sociocultural views of development can also be instrumental to understanding how the cross-cultural psychological differences we see in adults emerge and take shape over the course of childhood and beyond. In the next chapter, we will turn from the growth of intuitive knowledge of the world to the development of cognitive skills such as memory, attention, reasoning, and several academic abilities. There we will see a different facet of the sociocultural view—namely, the social and cultural factors that affect which sorts of cognitive skills are most important to accessing information in one's culture. Thus, the child's cognitive development helps her more effectively learn in specific ways from the culture around her just as her engagement with the broader culture spurs and supports her cognitive development. Each process reinforces the other.

Conclusions

Even young preschoolers are remarkably good at comprehending many aspects of the world around them. Although there is not, at present, a single correct account of how knowledge develops in core domains, we have seen that a number of themes emerge from the research in this area.

There is little evidence of the kind of global, across-the-board shifts in the ways children represent the world that Piaget proposed. In case after case, claims for this kind of developmental process have been superseded by other more compelling explanations. Contrary to earlier views, preschool children do not merely recognize surface similarities or simply notice things that are most frequent or typical. They grasp cause-and-effect relationships and other sorts of relations in various domains, and they can use their understanding to make inferences in these domains that go beyond the obvious.

In light of these capabilities, the empiricist views of knowledge development do not fare well. These views tend to see the child as gradually building up his knowledge in a bottom-up manner, starting from concrete sensory details. In fact, children can often sense complex, domain-specific patterns in the world without being able to explicitly describe them. Young children apprehend patterns that are unique to each domain, including the spatial contours of an environment, the distinctive causal relations associated with living things, and some of the properties of numbers, long before they have mastered the details of these domains or developed the ability to precisely explain their knowledge. On the other hand, extreme nativist views that see the child as knowing everything and simply recognizing instances of things they already know do not fare well either. Real developmental change occurs during the preschool and elementary school years, and this change gives rise to the dramatically different response patterns that children show in many tasks as they get older.

The development of biological thought illustrates that there are other ways of explaining these significant changes in children's responses besides the kinds of complete conceptual revolutions that Piaget supported. Instead, children seem to draw on several distinct explanatory systems from an early age, including mechanical, psychological, and biological systems. Young children differ from older children and adults, however, in terms of which kinds of explanations are most readily available to them in specific contexts. They may also differ from older children and adults in how well elaborated each of those explanatory systems is. In some cases, a developmental shift in the kind of explanations a child gives may reflect that the child has come to view a different explanatory system as most relevant to the task at hand, rather than the emergence of a totally new system.

When faced with more recent evidence, the old view of development as proceeding from the concrete to the abstract is hard to sustain. Children seem to be sensitive from the start to information of all types, not just basic physical features or other concrete particulars. Nonetheless, it is probably also wrong to assume that the development of domain-specific knowledge consistently proceeds from general, abstract patterns to more concrete, detailed knowledge. Instead, children seem to extract all levels and kinds of information from the world in parallel. As a result, the development of intuitive knowledge of these basic domains seems to consist of mastering each of these levels of information—from the abstract to the concrete—with increasingly precise understanding, and integrating them. This process may require a blend of cognitive systems, including not only the awareness of frequencies and correlations that supports associative learning but also a grasp of rule-like relations that guide and constrain learning. In addition, such blended views will also have to take into account the sociocultural contexts in which such knowledge growth occurs.

Research into the growth of knowledge may seem remote from the everyday concerns of parents, teachers, and other care providers who work with children. In fact, the links between these domains of cognitive development and many of the ways we interact with children are quite direct and important. Curriculum design in the schools, pediatricians' explanations of illnesses, and techniques of child psychotherapy are all informed by studies of how children understand the world as young preschoolers and how their understanding changes over the elementary and middle school years.

STUDY AND REVIEW

SUMMARY

Dimensions of Cognitive Development

- Most of the theories of children's knowledge of the world can be contrasted in terms of where they stand on three dimensions: qualitative versus quantitative development, global versus local patterns of development, and foundational versus emergent constraints on development.

A Closer Look at Piaget's Theory

- Jean Piaget's theory of cognitive development argued for global, qualitative changes in cognitive structure that have sweeping influences on all areas of cognition. Piaget's view was dominant for much of the second half of the twentieth century, and its influence has only recently diminished.
- Piaget believed that preoperational children (ages 2 to 7) lack the ability to think about the world flexibly. He tested their cognitive understanding by observing how they performed on conservation tasks. He believed that they failed on these tasks because they lack the mental operators of compensation, reversibility, and identity. Moreover, he said that they focus excessively on one dimension of a transformation (centration) and ignore relevant other dimensions.
- According to Piaget, children in the concrete operational period (ages 7 to 12) can reason about objects that are in their immediate surroundings. They acquire the mental operators of compensation, reversibility, and identity. They are able to use transitive reasoning and begin to succeed on conservation, seriation, and classification tasks.
- Piaget believed that the formal operational period emerges when children are about 12 years old. During this period, they can think logically about objects or ideas that are not physically present or are contrary to fact.
- Later research has suggested that the difficulty that younger children have in conservation tasks may not really reflect a qualitatively different cognitive structure but rather different ways of understanding task demands and the influences of cognitive factors (for example, memory or attention) not central to the task at hand.

Domains of Knowledge

- Recent studies have focused more directly on development of cognition in specific domains, such as spatial layout, number, and biology. In each of these domains, younger children seem to recognize some fairly abstract, domain-specific patterns even before gaining detailed knowledge of the domains.
- In the case of spatial layout, there are several ways in which a child can know her location in space. Piaget believed that young children can only think of spatial layouts egocentrically—that is, from their own point of view. But later studies showed that in familiar and accessible tasks, children are able to overcome the egocentric perspective. Even young children might use a method that involves noticing the contour of the environment, an ability that emerges early and that can override other spatial information, such as landmarks.
- The child's understanding of number undergoes considerable change in preschool and middle childhood. The systems that enable infants to detect number and engage in some forms of subtraction and addition remain in place, but they are supplemented over time with new systems that enable more complex computations and a deeper understanding of numbers and their manipulations. Studies of children's counting behaviors have been especially revealing in this area.
- In the case of biology, one of the major patterns of change may be from abstract senses of how biology is distinct from psychology and physical mechanics to more mechanistic understandings of how biological processes work. Researchers have asked whether young children come to initially understand the living world based on intuitive psychology or if a distinct intuitive biology emerges early on in a manner that is more independent of intuitive psychology.
- Several other domains have also been investigated. These include children's understanding of physical mechanics, their notions of substance and material transformation, and their sense of cosmology (beliefs about the earth, sun, and stars). In all cases, preschoolers' intuitions in these domains represent an advance over infancy. But this early knowledge will still undergo considerable growth and change in later childhood. Moreover, some domains, such as physical mechanics, may have a more common core set of beliefs across cultural groups than other domains, such as cosmology.

Sociocultural Views of the Development of Knowledge

- Vygotsky's theory of sociocultural development emphasized the ways in which a child's immersion in a larger culture has important supporting influences on cognitive development.
- All development occurs in specific sociocultural contexts that enable the child to make cognitive progressions that might otherwise not be possible. Social interactions between parents and their children, as well as between other mentors and children, help children get over some cognitive development hurdles more easily.
- Adult mentors enable children to move into zones of proximal development, which are new levels of cognitive competence that are just beyond a child's current abilities. This is often achieved when adults engage in scaffolding, providing supporting environments that ease a child's cognitive load.

THOUGHT QUESTIONS

1. Imagine that you are designing a large amusement park and are instructed that you should lay out the buildings, paths, and other terrain features to optimize the chances that preschoolers will be able to find their way back to their parents in case they get lost. How would you structure the environment?
2. Children often have a particularly hard time learning about the number zero. Given what we know about the development of counting and other number concepts, why should zero pose a special challenge?
3. Suppose you want to accelerate children's ability to understand the common biological properties of plants and animals. How might you structure the daily lives of children in a naturalistic manner so as to foster an earlier awareness of what is common between these two types of living things?
4. Scaffolding by parents and other mentors can often foster conceptual growth and skill development in various areas and often occurs in ways that the child is largely unaware of. What might be some of the costs and benefits of making a child explicitly aware of scaffolding as it occurs?

KEY TERMS

animism (p. 330)
basic level of categorization (p. 316)
bootstrapping (p. 326)
centration (p. 310)
classification (p. 310)
class-inclusion relations (p. 315)
cognitive map (p. 321)
compensation (p. 309)
concrete operational period (p. 311)
conservation task (p. 309)
core domain (p. 320)
domain general (p. 306)
domain specific (p. 306)
emergent constraint (p. 307)
essentialism (p. 334)
formal operational period (p. 311)
foundational constraint (p. 307)
geometric information (p. 322)
hypothetico-deductive reasoning (p. 311)
identity (p. 310)
landmark (p. 322)
operator (p. 309)
preoperational period (p. 308)
property attribution (p. 330)
reversibility (p. 309)
scaffolding (p. 338)
seriation (p. 310)
transitive reasoning (p. 308)
vitalism (p. 334)
zone of proximal development (p. 338)

Conclusions

Summary

Parents are often perplexed by what their children can remember and pay attention to. A concerned mother carefully repeats the family's phone number to her kindergartner before his first day of school, only to discover that he remembers, at best, three digits. Yet, the same child can rattle off the names and superpowers of each of his 24 action figures. In this case, his memory for details far surpasses that of the parent who sits down with him to learn about his collection. How can a child show such an impressive memory in some situations and only minimal capabilities in others? This question falls within a larger set of questions about the development of cognitive skills. The same child who shows such intriguing variations in memory abilities will also show comparable variations in attention. In one situation, he might seem to be distracted and unable to focus on his parent's explanation of how a new television works, while in another he may become so totally fixated on a video game as to tune out the rest of his environment, including repeated calls to come to dinner.

Our challenge in this chapter is to better understand several aspects of cognitive development that can help explain these apparent inconsistencies. Chapter 9 focused on the growth of children's knowledge about the world around them. In this chapter, we focus on the development of cognitive skills that enable children to process and use information.

First, we will examine the growth of memory. We will discuss how children encode, store, and retrieve memories and how the maturation of various brain regions affects memory. We will consider whether a person's level of expertise in an area can be a more powerful influence on memory performance than his age. That is, can a 5-year-old obsessed with action figures develop a better memory for action figures than an adult? More generally, we will see how and why young children's memory abilities differ from those of older children and adults and how they change during childhood. We will also consider several explanations for infantile amnesia, the strikingly consistent lack of memory in older children and adults for their experiences before about age 2½.

We will then turn to attention and the ways in which an individual is able to focus on information that is relevant to a task while remaining vigilant about other potentially useful information, such as hearing when someone calls her name. We will ask why young children seem to have more attentional challenges than older children and adults. For example, why do children sometimes seem unable to concentrate on a task for an extended period? And why do these same children sometimes become so absorbed in an activity that they miss critical incoming information, such as a parent's warning? We will also see how children's executive skills, the cognitive abilities that allow them to monitor and direct their thoughts and perceptions, influence the development of their attentional strategies.

Next, we will consider the development of several kinds of reasoning that seem very different in adults and children. These include the varieties of reasoning that support drawing analogies, thinking scientifically, and thinking about and evaluating knowledge itself. In this chapter, we will try to characterize the differences—and some similarities—between these kinds of reasoning in children and adults. We will explore whether some of the differences arise from problems in the ability to conceive of certain kinds of relations, such as analogies, or whether they arise from difficulties in managing and keeping track of different pieces of information at the same time or in quick succession. We will also ask whether even very young children might show some early roots of each of these skills when the experimental tasks are relevant and familiar to them.

Finally, we will examine three specific cognitive skills: reading, mathematical reasoning, and the ability to use maps and models. Young children lack these skills; yet, aspects of each of them can become entirely automatic for most adults. Do these emergent skills develop in a fundamentally different way from those that are present even in infancy? How do these skills, which seem so laborious at first, become almost effortless? We start by considering one of the most basic cognitive skills: memory.

Memory

Our mind and brain change with every experience. Some aspect of each experience leaves a trace in both our thoughts and our neural structures. This much is shared not only by humans of all ages, but by almost all creatures, whether they are simple animals with modest neural circuits or primates closely related to us. Examining memory from a developmental perspective involves asking two basic questions about how memory changes with age: How do our abilities to process and store information change? And how do the neural structures that support these processes change? Answering these questions offers insights into memory development and can also help us understand the nature of memory at any age.

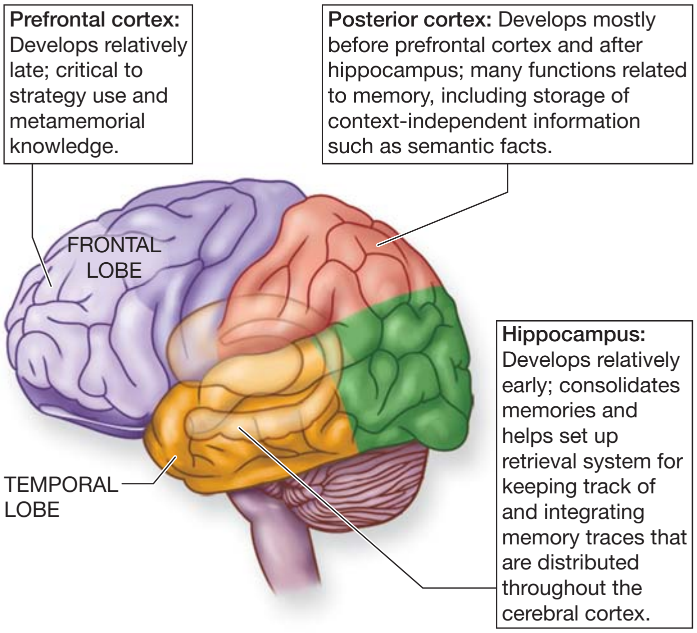
Any pattern of habituation, any modification of an action based on experience, and any recognition or imitation requires memory. Infants are even able to build new memories based on their prenatal experiences, as described in our earlier discussion of learning from sounds heard while in the womb (see Chapter 3). Yet, it seems obvious that younger children often have less effective memory skills than adults. Young children can be notoriously poor at remembering phone numbers, homework assignments, or who gave them which birthday presents. Children seem to have more difficulty than adults at encoding and storing information, as well as retrieving it later, but these seemingly simple differences can have a wide variety of causes. Moreover, as mentioned earlier, young children can demonstrate a surprisingly good memory in some circumstances. A child might long remember that a parent promised to do something, that a sibling was given preferential treatment, or that a favorite cartoon character acquired a new magical power. To better understand what aspects of memory change with development and why the same child often shows dramatic differences in memory, it is useful to first consider some basic memory processes and the parts of the brain that support them.

Q: What are some examples of the existence of memory abilities in young infants?

Components of Memory

Successful remembering depends on several processes. First, the information must be represented in the mind in a systematic, structured manner. **Encoding** is the process of turning information into a mentally useful representational format. Then the information must be stored in that form for an extended period of time. **Storage** is the process of preserving information in memory over time. Finally, the memory must be retrieved when it is needed. **Retrieval** is the process of finding a memory in storage and bringing it to mind for use, usually in a conscious manner.

Each of these three basic memory processes is thought to involve many interconnected brain regions (see Figure 10.1). Most important for developmental considerations are structures within the temporal lobes, the frontal lobes, and the posterior cortex (Munakata, 2004). The temporal lobes of the cortex are located on the right and left sides of the brain, starting near the temples and extending toward the back of the head. Deep within these lobes is a set of structures that seem to be critical for storing new, conscious memories of experiences. One such structure, the **hippocampus**, plays an especially important role in forming and consolidating memories. More specifically, it is involved in integrating information from the many memory traces that are stored throughout different regions of the cerebral cortex. If it is damaged, there may be difficulty in consciously accessing new memories. The frontal lobes are also involved in many aspects of memory, including both memory storage and retrieval, and they contribute significantly to the use of various memory strategies. The front-most region of the frontal lobes, known as the **prefrontal cortex**, is often most heavily involved. Finally, posterior regions of the cortex tend to be involved in remembering knowledge that is not associated with specific learning experiences, such as knowing that dogs have four legs.



Prefrontal cortex: Develops relatively late; critical to strategy use and metamemorial knowledge.
Posterior cortex: Develops mostly before prefrontal cortex and after hippocampus; many functions related to memory, including storage of context-independent information such as semantic facts.
FRONTAL LOBE
Hippocampus: Develops relatively early; consolidates memories and helps set up retrieval system for keeping track of and integrating memory traces that are distributed throughout the cerebral cortex.
TEMPORAL LOBE

FIGURE 10.1 Memory and brain regions. Several distinct components of the brain interact to create a fully functioning adult memory capacity. Many of these areas and their connections develop throughout childhood. Three of the most prominent systems are the prefrontal cortex, the posterior cortex, and the hippocampus.

Some aspects of memory development are likely to relate to patterns of brain development. Because memories involve interactions of all the brain areas just discussed as well as some other regions, any description of how the maturation of a specific brain region supports some aspect of memory development must also take into account how that region interacts with other parts of the brain. To better understand the development of specific facets of memory and the associated brain functions, it is helpful to consider some of the different forms of memory and their associated brain structures.

Different forms of memory known as *sensory memory*, *working memory*, and *long-term memory* can be distinguished roughly in terms of when they occur in the course of processing new information. As information comes in through the senses, it first briefly registers in **sensory memory**, even when the information is not consciously noticed. Sensory memory for visual information, or *iconic memory*, is thought to last roughly half a second before it decays, whereas sensory memory for sounds, or *echoic memory*, can last up to a few seconds. Sensory memories are first encoded in the same brain regions that handle preliminary and intermediate processing of sensory information. For example, the visual cortex near the back of the brain is thought to be responsible for iconic memory (Hollingworth & Luck, 2008).

Working memory, which is sometimes called *short-term memory*, involves specifically attending to and processing the incoming information from sensory memory. Working memory has a limited capacity, which was classically described as seven pieces of information, plus or minus two (Miller, 1956). More recent accounts suggest that the typical capacity may be smaller and that seemingly larger working memory capacities are achieved by *chunking* (Cowan, 2001), or linking together separate pieces of information into a larger unit that can be treated as one item in memory. (Think of remembering 2, 4, and 0 in a phone number as "240" to make three pieces of information into one chunk.) Information in working memory tends to last about 15 seconds before it either decays or is "pushed out" of working memory by new, incoming information, or processed and transferred into long-term memory. We can maintain information in working memory for much longer by consciously attending to it and perhaps by repeating or verbally rehearsing it, as we all do when trying to keep a phone number or an address in mind. These working memory processes involve complex interactions between several brain regions (D'Esposito, 2007). Most notably, the prefrontal cortex helps to actively manage what information is attended to and the way it is maintained in working memory. Verbal rehearsal, for example, involves interactions between the prefrontal cortex and language-related brain areas. Similarly, for visual images, a complex cortical network that includes frontal and temporal areas maintains mental images in visual working memory by sustaining neural activity until the images can be processed into long-term memory (Palva et al., 2010). Working memory is often characterized as the "bottleneck" of the memory process, where information capacity is severely constrained before information passes through to long-term memory.

Long-term memory has a vast capacity and can last a lifetime. In contrast to working memory, in which information's sensory qualities predominate, information in long-term memory tends to be organized in terms of its meaning. Thus, the sound similarities between words often seem most prominent in working memory, whereas similarities in meanings are more salient in long-term memory. Long-term memories seem to take some time to consolidate before they are robustly stored. They can therefore be quite fragile at first and easily lost when events such as a severe concussion occur. Unlike information in working memory, which remains in conscious awareness, much information in long-term memory can exist outside of awareness until it is accessed. Long-term memory storage is distributed throughout many regions of the cortex and involves other brain regions, such as the thalamus. Most critically, it involves the hippocampus, which is responsible for helping to transfer information from working memory to long-term memory.

Hippocampal damage can block the ability to transfer information from short-lived working memory into more permanent long-term memory (Squire, 1987). An adult with substantial hippocampal damage might seem to perceive and experience the world normally, but much of what he experiences will not be transferred out of working memory. He might, for example, introduce himself to someone, shake his hand, learn his name and repeat it back, but then 20 minutes later, he might repeat the exact same sequence, as if he had never met the other person at all (Scoville & Milner, 1957). If, as some have argued, very young children have especially immature hippocampal structures, they may show some similar memory problems.

Types of Long-Term Memory

Understanding long-term memory is critical to understanding current proposals about how memory develops. Three distinctions are typically discussed: *explicit versus implicit memory*, *procedural versus declarative memory*, and *semantic versus episodic memory*. These distinctions do not represent rigid boundaries, as the different ways of characterizing memory often overlap. As we will see, a single memory can be explicit, declarative, and semantic. But each of these different aspects of long-term memory contributes somewhat differently to understanding how memory develops.

Explicit Memory versus Implicit Memory One way to distinguish between types of long-term memory is to consider the difference between explicit and implicit memory. **Explicit memory** is memory for information that is consciously recalled and can often be stated verbally, like a new acquaintance's name or a historical fact. **Implicit memory**, on the other hand, may influence behavior but is usually outside of conscious awareness (see Figure 10.2). Some patients with hippocampal damage who cannot form new explicit memories still seem to be able to form implicit memories. Thus, even though a patient might introduce himself to you repeatedly as if you were meeting for the first time, he might retain some memory traces about you in other implicit ways. If, for example, you shook hands with him once while hiding a pin in your hand, he might later avoid shaking your hand. He might remain unaware of having met you and of having been pricked, but nonetheless behave in a way that showed that he had retained some information (Milner et al., 1968). As we will see, given that explicit memories are often recalled verbally and given that implicit memories can be demonstrated outside of awareness and without language, some researchers suspect that very young, preverbal children may rely more on implicit forms of memory. In addition, as described later

A

B

FIGURE 10.2 **Explicit and implicit memory. (A)** A child uses explicit memory when she consciously recalls a specific event, such as a visit to the zoo. **(B)** She uses implicit memory when her behavior mostly occurs outside of awareness, as when she automatically ducks when entering or exiting a familiar playhouse.

in this chapter, some have suggested that we cannot recall memories from very early in life because these memories may be stored implicitly.

Q: How are explicit and implicit memories different?

Procedural Memory versus Declarative Memory

Closely related to the contrast between implicit versus explicit memory is the contrast between declarative and procedural memory. **Declarative memory** can be described as "knowing that" memory, as in knowing that an event has occurred or that a particular fact is true. In contrast, **procedural memory** involves "knowing how" to perform actions or procedures, such as tying your shoes or riding a bike. As a rule of thumb, declarative memories typically involve information that can easily be verbalized (or "declared"), though this is not a requirement. Procedural memories, on the other hand, are often implicit, like a sense of how to ride a bike. Despite their overlaps, though, these two pairs of categories (explicit/implicit and declarative/procedural) are not precisely the same. Thus, a procedural memory can be explicit—for example, you can be quite consciously aware of remembering the procedure for baking a cake. And a declarative memory can be implicit—for example, if you read a passage in which a certain word is consistently misspelled, you may implicitly remember that misspelling later by being more accepting of it (Jacoby & Hollingshead, 1990). These unusual examples illustrate the nuanced distinctions between forms of memory. Overall, however, there is a significant overlap between explicit and declarative memories and between procedural and implicit memories.

Some theorists have suggested that the ability to form procedural memories develops before the capacity to form declarative memories (Mandler, 1998, Nelson, 1995). Infants and young children can clearly learn to carry out simple processes that certainly involve procedural memory. It is less clear whether preverbal children have declarative memories, and earlier researchers often assumed that these memories were linked to the onset of language. Many current researchers, however, tend to think that children can form declarative memories well before the onset of language, and some have investigated this possibility using *elicited imitation tasks*. In these tasks, a child is taught an ordered series of actions that involves manipulating objects—such as turning a knob, pulling a lever, and sliding a latch to open a door—then asked to reproduce it after a substantial delay. Six-month-olds have great trouble recalling the actions in the correct order, but 20-month-olds can do so effortlessly. This ability has been interpreted as indicating that by 20 months, children can form a declarative (and explicit) memory for their actions (Bauer, 2002a, 2005, 2006, 2007; Mandler, 2004; McDonough et al., 1995).

It may seem that recalling and reproducing the sequence of actions would draw on procedural memory, but the need to recall the actions *in the correct order* is key to the argument that these tasks require declarative memory as well. Reproducing each action relies on procedural memory, which is available to younger infants, but recalling the order of the sequence is thought to be declarative. If that logic is correct, there is evidence for declarative memory well before the first year of life (Bauer, 2005; Hartshorn & Rovee-Collier, 1997). Using related tasks and similar lines of reasoning, some have argued that young infants also have explicit memories (Rovee-Collier, 1997). Indeed, it may be that rudimentary versions of both declarative and procedural memory (and of explicit and implicit memory) are present quite early in infancy and develop in parallel, rather than implicit and procedural memory serving as the precursor for explicit and declarative memory (Bauer et al., 2010; Howe & Courage, 1993).

Semantic Memory versus Episodic Memory Memory researchers also distinguish between two facets of declarative memory. The first, **semantic memory**, refers to knowledge of facts about the world, without necessarily remembering how or when the information was learned. The second, **episodic memory**, refers to memories of specific events that have been experienced at a particular time and place (Tulving, 1972). For example, after attending a birthday party, a child might recall, as a semantic memory, that birthday parties have lots of presents and a cake. Recalling the party as an episodic memory, she may remember that the party happened on a rainy day, that she played particular games there, and that she ate too much cake. Many episodic memories are also **autobiographical memories**—memories of one's own specific experiences as a participant in an event.

Many scholars believe that children's semantic memory emerges earlier than their episodic memory (Nelson, 2001; Perner, 2001). Thus, a preverbal child who has been to several birthday parties may have developed a strong semantic sense of what birthday parties involve while remembering relatively little about the specific birthday parties she has attended, perhaps blending several parties together. Similarly, a toddler may have trouble recalling a specific visit to the zoo despite being able to describe the zoo in great detail. Episodic memory may have evolved relatively recently, and some researchers argue that it exists only in humans (Tulving, 1985, 2001; Wheeler et al., 1997).

Early episodic memories are typically fragile, as evidenced in the ways that children often mistake how they learned a piece of information. Rather than keeping track of where the new information comes from, a process known as **source monitoring** (Johnson et al., 1993; Mitchell & Johnson, 2000; see also Atance & O'Neill, 2005), they often fail to notice its source. After touching a pool of water to determine its temperature, for example, a child may claim to have learned this information by smelling the water (O'Neill & Chong, 2001). Source monitoring is necessary to build up episodic memories, which include a great deal of source-specific information about experiences and situations (Johnson, 2005). For example, the child who touched the water may still have a memory of experiencing the pool, but because she remembers using a different sense, she is likely to confuse the memory with other memories about water. Thus, the specific episodic memory of the experience will become fragile in contrast to a stronger semantic memory of the typical temperature of pools of water. Young children have greater difficulty with source monitoring, often remembering only the event itself and much less about their own experience of acquiring particular knowledge (Roberts, 2002; Roberts & Blades, 2000). Evidence also suggests that the late-developing prefrontal cortex is intimately involved in source monitoring (Mitchell et al., 2004). Since this area of the brain continues to develop well into adolescence (Casey et al., 2005; Gogtay et al., 2004; Huttenlocher & Dabholkar, 1997), it is not surprising that it has been implicated in childhood difficulties with source monitoring.

Children's limited source monitoring abilities also affect experimental tasks that involve remembering experiences over long intervals. In one study, children ranging from 3 to 8 years of age participated in some hands-on demonstrations with an adult called "Mr. Science" (Poole & Lindsay, 2001). When the children were asked to recall aspects of the demonstrations immediately afterward, they did very well. Then, 3 months later, the researchers had the parents read the children a book about Mr. Science on 3 consecutive days. The book described two real events that had occurred when the children participated in Mr. Science's demonstrations, as well as two fictitious events. After listening to the descriptions, the children were later asked about what had really happened, and 35 percent of them reported that the fictitious events had really happened. Finally, the children were reminded of all the stories read from the book and were told that only some of the events had actually occurred. They were instructed to think about what had really happened, as opposed to things in the stories that were made up. These instructions considerably improved accuracy for the older children but not for the 3- and 4-year-olds (Poole & Lindsay, 2002). These younger children seemed unable to access their memories in a way that identified the sources and allowed them to evaluate their accuracy. Children who are 3 and 4 years old also easily confuse events they have actually seen with televised versions of similar events, while older children are more able to distinguish these two kinds of information (Roberts & Blades, 1999).

Thus, source monitoring is an important cognitive process that supports the development of episodic memory. In addition, source monitoring helps to bind features to specific memories (for example, a child might bind the facts that the day was warm and noisy to a particular birthday party) and contributes to skills that guide information flow and management (Raj & Bell, 2010; Shing & Lindenberger, 2011). In turn, such skills can enhance source monitoring, and ultimately episodic memory, by shifting focus to certain kinds of information. For example, when 4-year-olds were instructed to focus on how a speaker was feeling, that focus on emotional features enhanced source monitoring of the event (Crawley et al., 2010). More generally, source monitoring ability in early childhood is related to the abilities to shift attention, maintain elements in working memory, and inhibit incorrect responses, what we will later describe as *executive functioning* (Rajan et al., 2013).

Q: How is source monitoring related to episodic memory development?

Aside from source monitoring, episodic memories may also depend on an ability that emerges during the preschool years to step back, think about ourselves in a past environment, and recall how we experienced a particular event. Indeed, a well-developed episodic memory may require an ability to think about our own mind and have a sense of how we acquire and act on information (Perner et al., 2007). That kind of full-fledged episodic memory may not really be present until at least age 4 (De Haan et al., 2006; Fivush, 2011; Sluzenski et al., 2004; Tulving, 2002; Wheeler et al., 1997).

Even though several forms of memory seem to be present early in development, they may be much more fragile early on and susceptible to degradation and decay. Thus, preschoolers and young children clearly have episodic memories and source memories, but those memories are not nearly as robust as they are in children a decade older. Later-developing brain regions, such as the prefrontal cortex and parts of the hippocampus, may be responsible for integrating diverse forms of information and for storing that information in more robust forms as the brain regions become more mature (Nelson, 1997; Serres, 2001). During the elementary school years, when these structures mature considerably, children also show improvements in the complexity and amount of information they can recall and in the accuracy of their recall over longer delays (Bauer, 2006; Howe & Courage, 2003; Howe et al., 2009; Ofen et al., 2012).

Memory Strategies

By early adolescence, we have acquired many ways of improving the power of memory. Memory strategies are explicit techniques we use to enhance the encoding, storage, or retrieval of information. For example, if you are trying to remember a set of objects to take on a trip, you might try to enhance your encoding by carefully examining each item and noticing its distinctive features. You could also try to improve storage of memories by repeating the names of the items several times out loud. Finally, you might try to boost retrieval of memories by thinking of categories of items you might need for different kinds of activities planned for the trip, such as hiking equipment, reading materials, formal wear, and swimming gear. Strategies like these can be remarkably effective tools for enhancing memory, yet most children under 7 rarely use them. What changes between early childhood and adolescence that enables children to use memory strategies? To understand the problem, it helps to look at a classic memory pattern known to researchers for over 100 years.

Imagine that a researcher reads you a list of 15 random numbers at a rate of, say, 2 numbers per second and then immediately asks you to recall them. Which numbers would you most likely remember? Despite some minor individual variations, the pattern that adults show in this kind of task is among the most replicated in psychology, with the best recall for items at the beginning and the end of the sequence and a drop in recall for items in the middle (Glanzer & Cunitz, 1966). The **serial position curve** is the graph that describes this pattern of recall by plotting how often each list item is successfully recalled against its "serial position"—that is, its order in the series. As Figure 10.3 shows, results for fifth-graders track a typical, U-shaped serial position curve (Sarver et al., 1976).

Adults do well in the first part of the curve largely because they can use various strategies to store information. One common strategy is **rehearsal**—that is, simply repeating to oneself the information to be remembered. Rehearsing the information a few times apparently helps to transfer it from working memory to long-term memory (Baddeley, 1985).

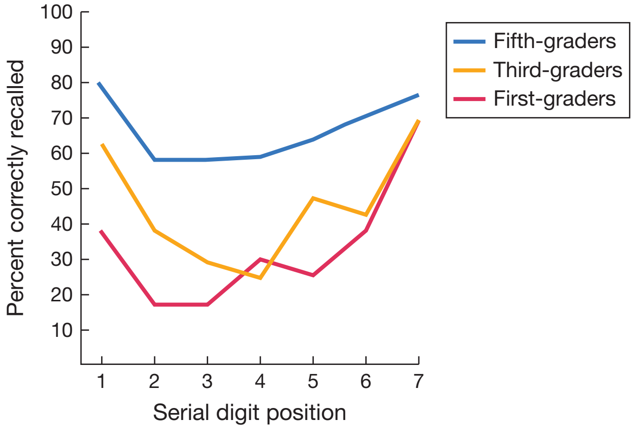


FIGURE 10.3 **Serial position curves and age.** These curves represent children's typical recall patterns for a sequence of seven random numbers. Older children recall the first few items well (primacy effect) and the last few items well (recency effect). Primacy effects reflect the spontaneous use of strategies, such as verbal rehearsal, while recency effects reflect the last contents of working memory. Younger children do not show strong primacy effects, presumably because they do not spontaneously use memory strategies. Adapted from Sarver et al. (1976).

The higher recall rate for items early in the series, shown at the front of the curve, is known as the **primacy effect**, and it is largely caused by the use of memory strategies. As the numbers keep coming at a pace of two per second, your rehearsal falls behind. It becomes impossible to keep rehearsing the first numbers while incorporating later numbers. As a result, these later numbers tend to get "bumped" out of working memory and displaced before they can be encoded and stored. This "bumping" explains the drop in memory performance around the middle of the serial position curve.

The end of the curve shows that recall improves for the last few items on the list, a pattern known as the **recency effect**. This effect occurs because the last few items to be remembered remain in working memory when the list is finished. Because there are no later items to displace the items at the end of the list, people can retrieve them from working memory directly. Preventing adults from rehearsing while the list is presented reveals the contrast between the primacy effect and the recency effect. Without rehearsal, performance on the first part of the curve drops to the same level as the middle section, while performance at the end of the curve remains high.

If younger children are less likely to use strategies like rehearsal, we might expect them to perform worse at the beginning of the serial position curve, which is shown in the results for first-graders and third-graders in Figure 10.3 (Sarver et al., 1976). The clearest pattern in these graphs is that the younger children show only a very limited primacy effect, although they show a recency effect similar to that shown by older children and adults. This pattern suggests that, before age 7, children not only remember less, they seem to use strategies less, leading to qualitatively different patterns of recall.

Children's spontaneous use of other memory strategies, such as clustering items in meaningful ways, associating items with images, and relating the items to one another, shows similar age-related changes (Shin et al., 2007). A large body of research has demonstrated that children under about age 7 do not spontaneously draw on a variety of strategies that might help them encode, store, and recall information (Camos & Barrouillet, 2011). Such a failure to spontaneously use strategies to improve memory has been called a **production deficit** (Kail, 1990; Schneider, 1999). Young children sometimes do show signs of using simple strategies, such as putting an item they need to remember in a prominent position, but they generally do not use memory strategies nearly as effectively as older children.

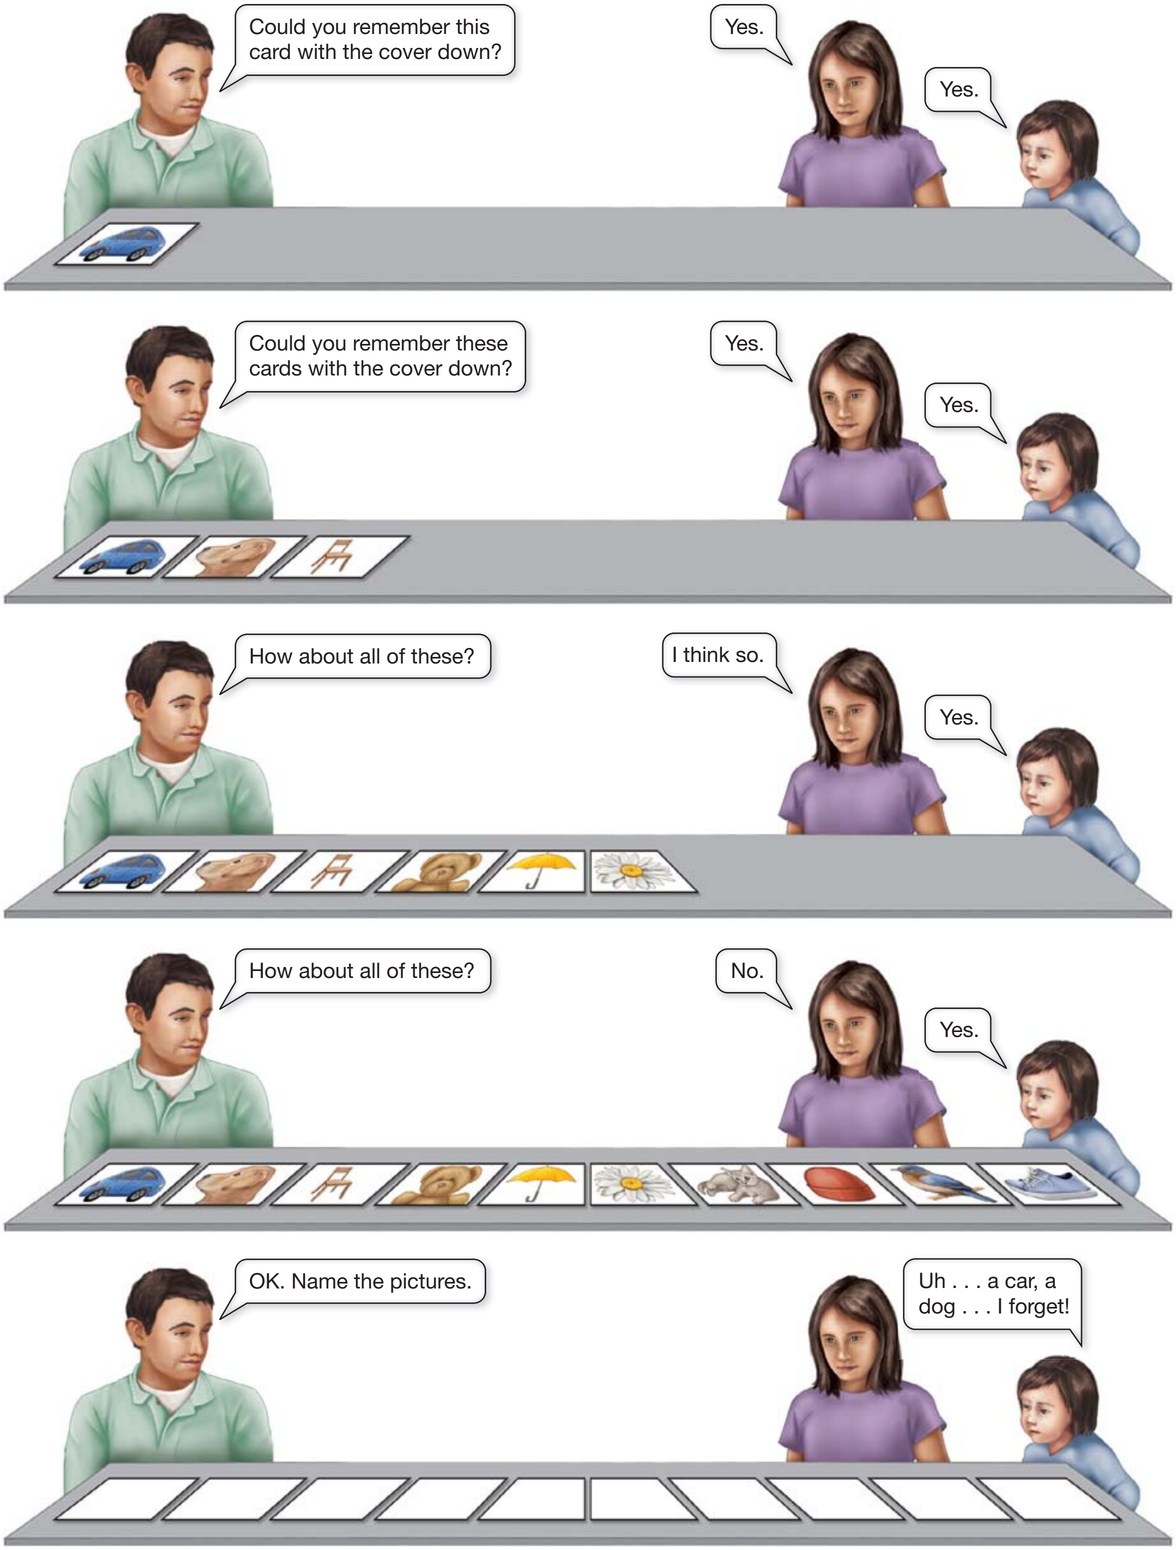
Q: Why do younger children tend to show robust recency effects but only small primacy effects in the serial position curve?

What happens when younger children are shown how to use a memory strategy and told to use it in a particular task? In most cases, younger children's performance does not improve much until they have used the strategy on several occasions (Bjorklund & Harnishfeger, 1987; Miller et al., 1994). This initial lack of benefit from a new strategy, known as a **utilization deficit**, tends to occur only in children younger than about age 7, whereas older children often show more immediate benefits (Coyle & Bjorklund, 1996). Interestingly, even when younger children have benefited from using a particular strategy, they typically will not employ it later when they are asked to do the task on their own. This pattern of results struck early researchers as almost paradoxical. Why wouldn't younger children use the strategies when they had been trained to do so and when doing so made them perform better? It wasn't a motivational problem; the children clearly wanted to do well, and sometimes there was even a large reward at stake. Rather, the children did not seem to understand when it was appropriate to use the strategy.

Development of Metamemory

A closer look at young children's failures to use strategies suggests that one important cause of the problem is that they do not really understand what memory is or have a sense of how their own memory functions (Flavell 1987; Flavell & Wellman, 1977). This awareness of our own memory processes, abilities, and limitations is known as **metamemory**, and it is one facet of *metacognition,* the broad ability to think about our own mind and thoughts, a topic that we will examine later in the chapter. The two aspects of metamemory are: (1) knowing roughly how memory works—that is, how information is encoded, stored, and retrieved, and (2) monitoring how effectively these processes are working to know when to rely on strategies. The two facets of metamemory are interlinked: monitoring the effectiveness of memory processes requires a basic sense of what memory is and how it works.

Many studies have shown that younger children have weak metamemory skills. Consider, for example, how a 4-year-old might approach an experimental task in which she has to estimate how many picture cards she will be able to remember (see Figure 10.4). At first, researchers show the child a paper strip that has just one card with one picture on it, and they ask the child whether she thinks she will be able to remember it when it is covered. Then researchers present the child with a new paper strip that has two cards, and they ask the child whether she thinks she will be able to remember both pictures when they are covered. As this process continues, each new strip shows a larger number of pictures, and the child is again asked whether she thinks she will be able to remember all the pictures when they are covered. Children in



Could you remember this card with the cover down?
Yes.
Yes.
Could you remember these cards with the cover down?
Yes.
Yes.
How about all of these?
I think so.
Yes.
How about all of these?
No.
Yes.
OK. Name the pictures.
Uh . . . a car, a dog . . . I forget!

FIGURE 10.4 **Failure of metamemory in young children.** Through the early elementary school years, children are often quite poor at estimating how much they can remember. They usually are overconfident and think they can remember far more than they can. This mismatch is thought to be caused by a failure to examine their own memory processes, a failure of metamemory. Adapted from Yussen & Levy (1975).

the later elementary school years, like adults, tend to say that their memory capacities have been reached at about five or six pictures, but younger children seem much less aware of the limits of their memory. Many 4-year-olds happily predict that they will remember as many as ten pictures. Yet, when they are asked to recall the pictures later, they typically remember only two or three (Flavell et al., 1970; Yussen & Levy, 1975).

Given that younger children more often think that they will be able to remember without any help, they may not realize when they would benefit from strategies like verbal rehearsal. Furthermore, if they try to use strategies but still fail to remember, they may disregard the strategies without realizing that they can become more beneficial with repeated use. Thus, children younger than about age 7 may show a production deficit partly because of a failure of metamemory—that is, a lack of understanding that many strategies yield more benefits with practice.

Following the pattern we have seen in many other aspects of cognition, young children do not completely lack the ability to use memory strategies or an awareness of what they can remember. Some studies have found that even 2- and 3-year-olds have some capability to use strategies and some basic sense of their own memory functions, but children become far more knowledgeable and effective in these areas as they get older (Bjorklund & Douglas, 1997; Joyner & Kurtz-Costes, 1997; Kail, 1990; Miller et al., 1994). What develops seems to be a group of related abilities, including an understanding of the idea of memory, familiarity with relevant memory strategies, and an awareness that practicing these strategies helps make them more effective. In addition, the capacity to form richer memories with more details and internal structure may help foster metamemory in its own right by providing cues to the quality of the memory and how it was acquired (Ceci et al., 2010). Finally, as discussed next, expertise in a specific knowledge area can strongly influence memory as well.

Q: How is the development of metamemory related to the development of memory strategies?

Memory and Expertise

While young children typically perform worse than adults in experimental tasks that require remembering arbitrary lists, they may have less difficulty learning and remembering information that they find more meaningful and interesting. With practice, some children can gain truly impressive expertise in specific areas of knowledge such as chess. They may then become able to recognize patterns and contexts, which can greatly improve their memory. In these cases, their expertise seems to enhance their memory abilities not only within their knowledge base but in other areas as well. To investigate how and why expertise affects memory development, researchers studied child experts by redesigning some classic experiments that had been used to test adult expertise and memory.

The original studies of adults tested the assumption that the superior chess skills of grandmasters were based on their exceptional memory capacities (De Groot, 1965). Researchers hypothesized that grandmasters excelled at chess because they had a general ability to store far more information than other players. The studies tested both grandmasters and novices in their ability to remember configurations of chess pieces after a brief glimpse at the board. When the pieces were arranged as they would be in the middle of a game, the assumption seemed to hold. Grandmasters often remembered perfectly the positions of 20 pieces after only a few seconds of viewing, whereas novices and intermediate players usually made more than a dozen mistakes. But the crucial experimental manipulation involved testing both groups' memories for chess pieces arranged at random, so that the positions had no possible relation to an ongoing game. In these cases, the grandmasters hardly did better than the novices at remembering the positions of the chess pieces (De Groot, 1965; see also Chase & Simon, 1973).

Thus, grandmasters performed well in the first task because they could use their rich knowledge of chess and of familiar game patterns to store many positions in terms of the meaningful relations between pieces—that is, they could use chunking to remember where the chess pieces would be in a typical game. When the pieces were arranged randomly, the grandmasters could not exploit their background knowledge, and they performed much like novices. These findings revealed that grandmasters' skills are not based on broadly superior memory capacities but on their deep knowledge base, which helps them store information relevant to their area of expertise much more efficiently.

This finding raised the question of whether very young children who are chess experts, some of whom have played over 1,000 hours of chess by age 5 or 6, would show similar memory skills within their area of expertise (see Figure 10.5). A series of studies used memory tasks to compare the memory skills of these precocious chess players with those of other children their age (Chi, 1977, 1978). In fact, the child experts differed from child novices in the same way that adult grandmasters differed from adult novices. Child experts significantly outperformed their peers at remembering arrangements of chess pieces that would be meaningful in a game, but they did the same as child novices when remembering randomly arranged pieces. They also performed at novice level in memory tasks unrelated to chess, including remembering simple strings of numbers or configurations of game pieces on unfamiliar board

FIGURE 10.5 Expertise and memory. When young children have extensive practice in chess, their memory for configurations of chess pieces as they might look in the midst of a game can surpass that of adults with little chess experience. If those same young experts are asked to remember a random arrangement of pieces that could not reflect a real game, they will likely perform worse than most adults. Thus, expertise in a domain can produce precocious memory performance within that area.

games (Chi, 1977, 1978). Thus, like adult grandmasters, these children do not have a larger memory capacity in general, just a better memory for meaningful configurations of chess pieces based on their rich knowledge about chess. As further evidence that expertise, not age, exerted the crucial influence on memory, the child chess experts even recalled far more positions than the adult novices when the board setup came from a real game (Chi, 1977, 1978; Schneider et al., 1993). Moreover, young children who know a great deal about dinosaurs or cartoon characters similarly outperform adults at memory tasks that draw on the children's area of expertise (Chi & Koeske, 1983; Lindberg, 1980).

Expertise may also make it easier for young children to know when to use memory strategies. If a child has extensive experience with chess, perhaps it is easier for her to monitor her knowledge and realize the need for strategies when trying to keep track of moves in a complex game. It might also be easier for her to use words to encode and rehearse the names of pieces and configurations. In fact, expertise not only facilitates the use of memory strategies within a person's area of knowledge (DeLoache et al., 1985), but it also facilitates their use in other areas, bolstering memory in those other areas as well. Thus, to remember particular information, having a strong knowledge base relevant to the information at hand may be more important than either age or the ability to use general memory strategies unrelated to content and meaning. (Such general strategies may be most helpful for remembering arbitrary, meaningless information.)

Memory research on both adults and children has become more focused on how we remember the kind of meaningful and richly structured information that we actually encounter in the world (Neisser & Libby, 2000). In most real-life experiences at any age, items are related to each other through a variety of means, including narrative structures, hierarchical structures, causal interactions, and spatial relations. Often, all of these interrelations may be involved at the same time and may affect what is remembered or forgotten. To appreciate the developmental insights that this more naturalistic approach offers, it is useful to consider a fascinating, long-standing developmental question: How can we explain infantile amnesia?

Q: How do areas of expertise in childhood influence memory?

Infantile and Early Childhood Amnesia

One of the most dramatic developmental changes in memory is the phenomenon of **infantile amnesia** (Howe & Courage, 1993), the inability later in life to recall any memories of experiences prior to about 2½ years of age. If you think back through childhood, your recall probably seems rich and detailed until approximately the preschool years. At this point, the tapestry of memory fades into just a few isolated experiences. Even further back, before about age 2½, there are either no reliable memories or very few. What does this forgetting of early life experiences suggest about memory development?

The phenomenon of infantile amnesia has been remarked on for many years, but only recently has it become better understood. There have been many hypotheses about the reasons for infantile amnesia, but three possible explanations have figured most prominently: (1) The basic memory "code" or format may change with age in ways that make early memories inaccessible later. (2) Early in life, immature brain regions may be unable to preserve memories. (3) Early memories may actually be present and potentially accessible later in life, but they may not be easily retrieved unless the right kinds of cues are used.

Each of these hypotheses points to a different reason for infantile amnesia, and as we will see, all three of them seem to play a role in explaining it. Both the immature brain hypothesis and the cueing hypothesis describe changes in the way long-term memories of childhood experiences are formed. They both seem to correctly describe aspects of developmental change, but they seem to pertain to different types of memories and to changes taking place at separate points in development. The hypothesis of a change in the basic code or format of memory is more difficult to prove, but in a revised form, it may be critical to understanding infantile amnesia.

Q: What are three different accounts of infantile amnesia?

Memory Format Change Hypothesis The first hypothesis is the **memory format change hypothesis**, which says that the memory format or code changes, so that memories formed very early in life become inaccessible to older children and adults. This hypothesis seems to fit well with some of the classic stage theories of cognitive development. Recall that many of these stage theories held that a child's way of thinking undergoes a global shift during the preschool years—for example, from preverbal visual imagery to thought processes embedded in language. Imagine, for example, that a 2-year-old represents the experience of a party in a purely image-like way (for example, remembering a set of images of balloons and clowns and cake at a party) and then as a 4-year-old shifts to more sentence-like thoughts (for example, remembering stories about what happened at a party) as her language skills improve. If development follows this course, then when she is older, she may not be able to use her language-bound way of thinking to recall her early image-based memories, since these images would be stored in a different format that she would no longer be able to access. Indeed, if such a dramatic shift in thought and memory occurs, it could potentially explain amnesia for early experiences. As we have now seen in several chapters, however, children do not seem to undergo the kind of across-the-board mental metamorphoses that earlier theorists envisioned.

Nonetheless, the memory format change hypothesis may still be useful for understanding cases in which memory encoding involves language. Some current theorists argue that language development might bring with it a new way of formatting knowledge and structuring recall and that these new ways of thinking might make preverbal memories extremely difficult to access (Fivush & Schwarzmueller, 1998; Nelson, 1993). This language-based proposal is similar to the memory format change hypothesis, but it does not suggest such an all-or-none shift in recall, especially given that language skills do not develop abruptly, as in a stage change, but become gradually more elaborated over time (Fivush, 2011).

Q: What is the main problem with the original memory format change explanation of infantile amnesia?

Neural Change Hypothesis The second explanation for why we lack memories for early experiences is the **neural change hypothesis**. As described earlier, the hippocampus plays a role in transferring information from working memory into long-term memory, as well as helping set up a system for retrieving and integrating memory traces distributed throughout the cerebral cortex. These processes occur even without explicitly using strategies, and they presumably occur throughout our adult lives. The neural change hypothesis suggests that some brain structures involved in memory, including the hippocampus and certain frontal lobe regions, must mature before they can set up and maintain permanent memory stores, particularly those that support episodic memories. Especially in the first year of life, some hippocampal regions seem to be quite immature and perhaps unable to help form stable memories of conscious experiences (Nelson, 1997; Serres, 2001). This may help explain why there is infantile amnesia for episodic memories before the hippocampus matures.

Frontal lobe development may continue to influence memory functions in children well past the age of 2 because frontal regions are involved in many strategic aspects of memory, such as monitoring the contents of working memory and knowing when to use strategies. The prefrontal regions and other areas of the frontal lobes continue to mature during the elementary school years and even into adolescence. The development of frontal regions during the preschool years may help support source monitoring, narrative language skills, and the ability to focus on relevant cues in ways that create more robust episodic memories that can overcome infantile amnesia.

Q: What role might the frontal lobes play in the development of memory skills?

Cueing Hypothesis The third explanation, the **cueing hypothesis**, emphasizes how the ability to cue, or trigger, memories changes with age in ways that may make very early memories inaccessible. Effective cues often take the same form as the memory itself: verbal memories are generally cued by words, phrases, and stories, while nonverbal memories might be cued by a taste, a smell, or an image. There is ample evidence that young infants register memories of experiences in nonverbal forms and can recall these memories months later if the right cues are present. In one study, researchers assessed infants' long-term nonverbal delayed recall through their deferred imitation of actions they had observed in the past. In the study, 14- and 16-month-old infants observed an actor perform particular actions on four objects and then were presented with these objects (the cues) after a 2-month or 4-month delay. After the delay, the infants spontaneously imitated the actions that the actors had previously performed on the objects (Meltzoff, 1995). Toddlers show striking abilities to remember more than a year later aspects of experiments that they had participated in as infants (Perris et al., 1990), but these memories are nonverbal and often implicit. The children do not act in a way that clearly indicates conscious recognition. Instead, they simply react differently to the stimulus than children who had not been exposed to it in infancy. For example, children who had been in earlier experiments would be more likely to pick up and play with toys that were in those experiments than would children who had not been in those experiments (Hayne et al., 2000; Myers et al., 1987; Perris et al., 1990; Rovee-Collier & Shyi, 1992).

It used to be considered very difficult to recall memories verbally that were initially acquired in a nonverbal manner, but several studies have shown that such verbal recall of preverbal memories can occur. In one study, children who were roughly 2½ years old returned to a laboratory where they had been exposed to specific event sequences when they were as young as 16 months old. After exposure to the same objects (the cues) used in the earlier event sequences, several of the children spontaneously talked about the earlier events, indicating verbal recall of preverbal experiences (Bauer et al., 1998; see also Cheatham & Bauer, 2005). Detailed analyses of these children's responses suggested that their verbal ability to recall the earlier events was not simply a result of unusual verbal skill. Rather, they seemed able to access memories that had initially been encoded without any apparent verbalizations of those events at the time they were experienced. Although these questions are still being debated, this pattern of results suggests that the emergence of language does not cause a radical change that renders earlier, preverbal memories inaccessible. Instead, language may provide additional cues to help recall those preverbal memories (Cheatham & Bauer, 2005). Such results appear to indicate that although there are important developmental changes in the young child's memory system, some aspects of memory remain the same across development. Thus, even the youngest children seem to be sensitive to which events typically occur together. This enables them to pick up on cues that indicate meaningful rather than arbitrary events.

In many cases, the toddlers in these studies were responding to nonverbal cues that triggered early memories. These kinds of cues are most effective for very young children when they are highly similar to the original experience. For example, if a young toddler is taught how to pop open a jack-in-the-box, one way to assess his memory is to give him the toy again and see whether he pops open the box again on his own. In this case, the toy is thought to cue his memory of the action. Compared with using nonverbal cues, verbal cues are harder for toddlers to use to trigger early memories. To cue verbal recall of past events by 18-month-olds, for example, researchers might need to provide the child with more specific prompts and context. Thus, if a young child is asked in general terms about a visit 2 weeks earlier to a petting zoo ("What happened at the zoo?"), the child may provide almost no information. But if the questioner begins to describe the petting zoo and perhaps shows the child pictures of various scenes, the child may then start to blurt out words and phrases, clearly showing that she can recall more information than what is elicited by the cues.

By around age 3, children become much more competent at verbally describing past experiences. Even so, their recall remains somewhat fragmentary and patchy, requiring considerable cueing support until about age 5. The sparseness of their early verbal recall seems to relate to not having well-developed ways of storing information that will aid later retrieval. As children master the ability to talk about past events, this verbal ability influences how they encode the events they experience and how they cue memories of those events later (Fivush, 2011). In addition, since language enables people to communicate what has happened, it becomes a way of embedding memories in a social context, which seems to improve recall (Nelson, 1993; Nelson & Fivush, 2004). Before around 18 months of age, however, children have much more difficulty talking in detail about even recently experienced events. They do not yet have enough control of language to use it to structure or cue their memories of experiences (Mandler, 2004).

By considering the three models of infantile amnesia, we have seen that two of them, the memory format change hypothesis and the cueing hypothesis, view the emergence of a child's language skills as crucial for developing accessible long-term memories of experiences. It seems that by allowing us to embed our experiences in coherent narratives, language may influence how we represent and cue memories of those events. One way of examining the role of language development in memories of early experiences is to see whether cultural differences in children's early exposure to language influence the development of infantile amnesia.

Q: What are three different explanations for infantile amnesia?

Culture, Gender, and Early Childhood Amnesia The accounts of infantile amnesia that stress the influence of language skills on early memories suggest an intriguing question: Do children with earlier exposure to adults' language and narratives tend to have earlier first memories? Researchers investigated this question by comparing the ages at which Koreans and Americans formed their earliest memories (Mullen, 1994; Mullen & Yi, 1995). Because Korean culture traditionally involves fewer parent-child interactions focused on narrating experiences, the researchers predicted that Koreans would have later first memories than Americans. The same study also tested predictions about the effects of birth order and gender. The researchers predicted that firstborns, who receive more undivided parental attention, would develop narrative skills earlier and thereby retain earlier first memories. Similarly, they expected that girls, who tend to have more verbal interactions with parents, would have earlier first memories than boys. The cross-cultural prediction was borne out—Americans' first memories tended to be earlier than those of Koreans—and there was some evidence for the expected birth order and gender differences as well. More recent studies have also supported these cross-cultural and gender differences in the age of earliest memories (Conway et al., 2005; Fiske & Pillemer, 2006; MacDonald et al., 2000; Wang, 2003, 2007; Wang et al., 2000, 2004, 2011). The effects also hold when older children, rather than adults, are asked to recall their earliest memories. Here, too, North American children report earlier memories than Chinese children (Peterson et al., 2009), suggesting that the effects of cultural differences do not arise from changes to early memories in adulthood.

Besides the tendency of American parents to talk with their children in detail about their experiences, a second, broader cross-cultural influence on early memories relates to the ways children learn to see themselves. Western cultures tend to have an individualistic view of identity, emphasizing people's individuality and autonomy more than their group membership. This tendency may make children in Western cultures more inclined to view themselves as autonomous early on and may lead them to pay more attention to their own memory timelines, rather than thinking of themselves first and foremost as members of a larger collective with shared group memories (Cohen & Gunz, 2002; Ross & Wang, 2010). Thus, the greater individualist tendencies in Western cultures may cause an earlier sensitivity to the autobiographical sense of self in memory.

Correlational studies, like the one comparing Koreans and Americans, show that young children with more exposure to adults' narratives also tend to retain earlier long-term memories of experiences, but they cannot explain the reason for the difference. Further evidence from experimental studies suggests that increased exposure to narrative structures can actually *cause* early improvements in memory. These causal effects have been demonstrated in studies that assign young preschoolers' mothers either to an experimental group, in which they are trained to elaborate on their recollections of past events with their child, or to a control group, in which they receive no training. Even when the mothers receive only brief training, they spend more time talking about events with their young preschoolers, who show lasting improvements in their recall of experiences that they had several months earlier (Boland et al., 2003; McGuigan & Salmon, 2004; Reese & Newcombe, 2007; see Scientific Method box). These experimental studies therefore strongly support the idea that cultural differences in the ways parents reminisce with their children contribute to differences in early recall.

Q: How do early interactions with parents affect the development of long-term conscious memory for experiences?

Emergence of Long-Term Autobiographical Memory

Current researchers believe that explaining the emergence of long-lasting episodic memories (and the disappearance of infantile amnesia) requires taking into account multiple factors (Nelson & Fivush, 2004). The best available evidence suggests that beyond the first year of life, the brain is mature enough to avoid imposing absolute limits on episodic memory, rendering the neural systems hypothesis less important (Ceci et al., 2010; Nelson, 1997). Starting at around age 1 and continuing for several years, some closely related neural changes support the emergence of long-lasting episodic memory by influencing the ability to encode and cue memories. As long-lasting episodic memories emerge, they also support stronger autobiographical memories, which incorporate episodic memories of one's journey through life as well as linking those episodic memories to semantic memories to make them more richly textured. Four especially important influences on the emergence of episodic memory and autobiographical memory need to be considered:

1. *Explicit rehearsal of past events.* Between the ages of about 3 and 5, children become more inclined to spontaneously recount past experiences, either to others or to themselves. Such rehearsals are less common in younger children. As children recount experiences more often, they show greatly improved memory for the events they have talked about. In contrast, newly verbal children rarely engage in such rehearsals spontaneously, and this lack could contribute significantly to infantile amnesia.
2. *Development of narrative skills.* In the same time frame, between about ages 3 and 5, children's narrative skills also greatly improve. More specifically, children become increasingly attuned to the three aspects

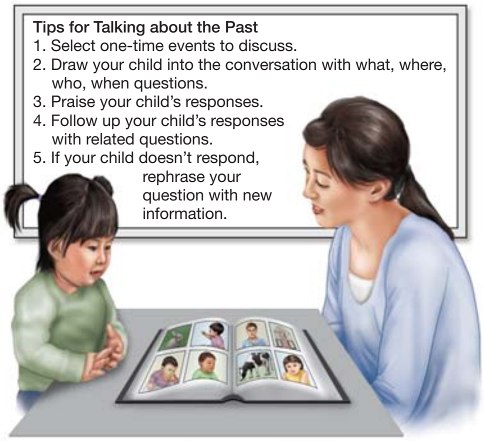
SCIENTIFIC METHOD: Maternal Reminiscing and Children's Autobiographical Memories

Hypothesis:

When parents are trained to engage in elaborative reminiscing with their young children, that process will cause the children to have more detailed autobiographical memories a year or more later.

Method:

1. Researchers recruited 115 families with 19-month-old children.
2. Half the mothers were trained to talk more with their children in structured ways that would help bind memories to situations and sources (see Tips on the board). The other half were controls who conversed normally with their children.
3. When the children were 32 months old and 44 months old, the experimenters visited the families' homes and observed conversations between mothers and their children.
4. Experimenters then asked mothers to have their children talk about past events and to continue to probe for more details.



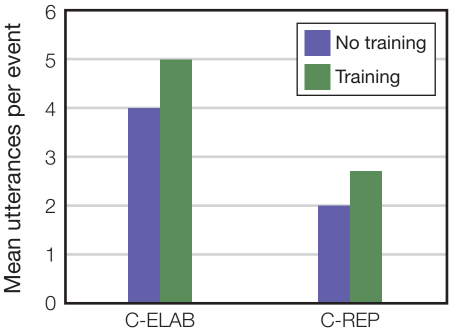
Tips for Talking about the Past
1. Select one-time events to discuss.
2. Draw your child into the conversation with what, where, who, when questions.
3. Praise your child's responses.
4. Follow up your child's responses with related questions.
5. If your child doesn't respond, rephrase your question with new information.

Results:

Children whose mothers were trained to reminisce with them had more detailed memories of events that they had experienced several months earlier both in elaborations (C-ELAB) and in repetitions of key elements (C-REP).

Conclusion:

Correlations have been repeatedly noticed between parent-child conversational patterns and the age at which autobiographical memories first appear. This study helps make the case for a causal relationship between certain conversational styles and the facilitation of earlier autobiographical memories.



Source study: Reese & Newcombe (2007).

of narrative structure shown in Table 10.1 (Haden et al., 1997; see also Fivush, 2011). They become better able to use *orienting information* to provide context, such as where an event happened or who was present. They incorporate more *referential detail*, such as information about the color or size of an object or animal, to describe entities in the narrative. And they include more *evaluative information* that conveys their own responses to events, such as mentioning that an incident was funny or frightening. Using these narrative features to recount an event soon after it happens improves memory encoding, and it also aids retrieval by providing a more elaborate, detailed framework for later cueing.

3. *Social sharing of memories.* Talking about past events with others makes those events easier to recall (Fivush, 2011; Nelson, 1993). Moreover, conversations create another means of cueing, since others can now remind you of the events and thereby trigger more rehearsals and better narrative skills. Social skills for sharing memories develop dramatically between the ages of 3 and 5 as children become more adept at communicating ideas to others.
4. *Development of a sense of self.* A child's emerging sense of self may provide important support for the development of long-term episodic memories and the emergence of autobiographical memory. When children are able to think about their own past as situated on a continuous timeline, they can see how personal events along that timeline relate to each other and to experiences shared with others. Nonetheless, a sense of self like this takes considerable time to develop over the course of the preschool and elementary school years. As we will see in Chapter 13, the development of the self occurs on several interrelated dimensions, rather than as one discrete achievement.

These four influences together support a complex ability: a narrative way of encoding and remembering. These

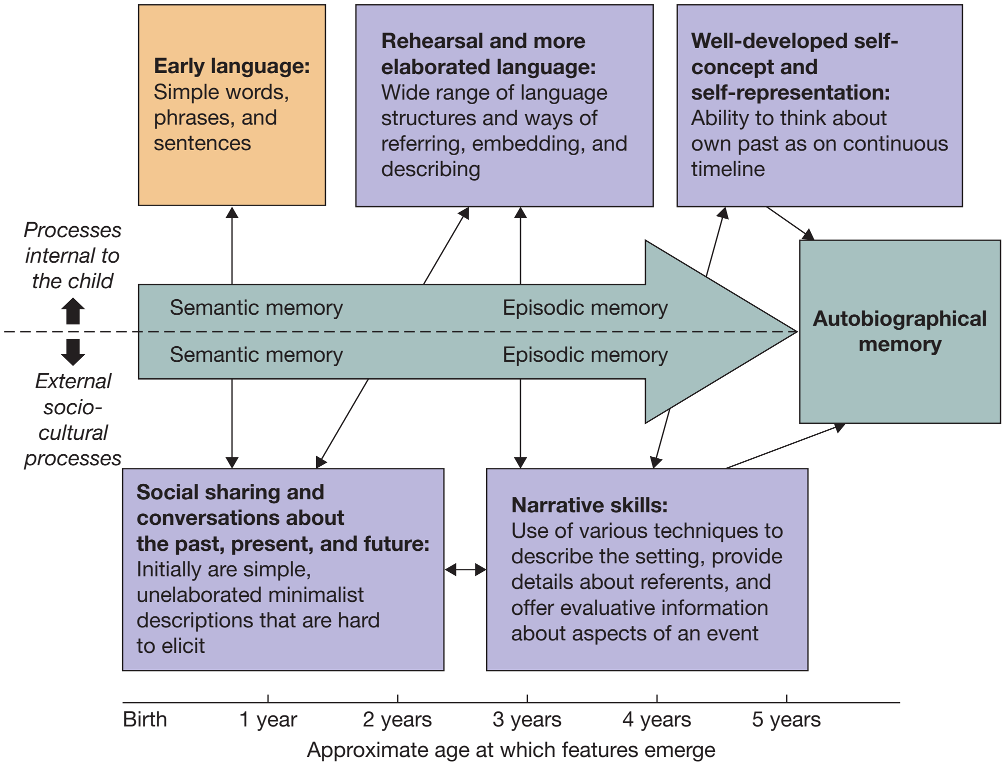
Narrative Feature	Function	Elaborated Examples	Unelaborated Versions
Orienting information	Provides context for where an event happened and who was involved	"I was in the hospital with my parents and my Uncle Bob and saw my sick sister." "I was at the zoo with my preschool group in the morning and saw a monkey."	"I saw my sister." "I saw a monkey."
Referential detail	Describes physical properties of important entities in the narrative	"It was a big black horse covered with sweat." "He had a bright red shiny truck that made a squeaking sound."	"It was a horse." "He had a truck."
Evaluative information	Conveys the narrator's own response to an event	"We walked into a very scary and creepy graveyard." "I saw a very, very funny movie."	"We were in a graveyard." "I saw a movie."

TABLE 10.1 Narrative skills and the development of episodic and autobiographical memories. Older children tend to elaborate much more than younger children when describing their experiences. And when children elaborate, they tend to have much more accurate, detailed recall of the events. Adapted from Haden et al. (1997) and Nelson & Fivush (2004).

and other related processes interact and converge to create long-lasting episodic memories and a fully developed autobiographical memory, as shown in Figure 10.6. The influences can be roughly divided into those that are internal to the child and those that reflect the external, sociocultural environment in which the child develops.

Attention

Any organism that can learn requires not only a memory system but also an attentional system to focus on the most useful information within an environment teeming with stimuli. Attentional skills for gathering information



Early language: Simple words, phrases, and sentences
Rehearsal and more elaborated language: Wide range of language structures and ways of referring, embedding, and describing
Well-developed self-concept and self-representation: Ability to think about own past as on continuous timeline
Processes internal to the child
External socio-cultural processes
Semantic memory
Episodic memory
Semantic memory
Episodic memory
Autobiographical memory
Social sharing and conversations about the past, present, and future: Initially are simple, unelaborated minimalist descriptions that are hard to elicit
Narrative skills: Use of various techniques to describe the setting, provide details about referents, and offer evaluative information about aspects of an event

require coordination between several distinct components. Here we consider the most common elements of attentional processes: drawing attention to salient stimuli, anticipating which patterns of these stimuli are about to occur, and regulating how attention is deployed. We then consider individual differences in attention as well as developmental disorders in attentional abilities. First, however, we need to understand the behaviors involved in attentional tasks.

Attention as an Active Exploratory System

Suppose you walk into a familiar restaurant where you are supposed to meet friends. The room you enter is full of hundreds of voices in various conversations, an acoustic guitar is playing in the corner, a pinball machine is making noises and flashing lights in the background, and unusual decorations are displayed on all the walls and at strategic points on the floor. It is raining outside, your best friend is talking to someone 10 feet to your left, and your worst enemy is talking to someone 10 feet to your right.

Two things are immediately obvious in this situation. First, you cannot attend to everything at once, but you can somehow manage to focus on the most important and immediately relevant information. Second, even as you focus on only some information, you can still at some level notice other potentially pertinent information. Thus, if you are talking with a friend but someone says your name 10 feet away, you will likely notice it amid the other conversations and track what is said next. A full attentional skill set requires the ability to notice novel information, to be vigilant for particular patterns (such as one's name), and to develop strategies for allocating attention in an optimal way. The dynamic interplay between these key components frames most theories of attention (Duncan, 1996, 2006).

Earlier theorists conceived of attention as a set of filters. The British psychologist Donald Broadbent hypothesized that we erect perceptual filters that allow only certain kinds of information to enter the main information processing channel of the mind (Broadbent, 1958). We can change which filters are used and even switch between filters fairly rapidly, but the filters prevent some sort of information from ever entering the mind. With respect to the development of attention, it was normally assumed that younger children (for example, those in kindergarten) have more difficulty staying on task and not being distracted than do older children (for example, those in fifth grade). Many assumed that as children get older, they become better able to filter out irrelevant information. Classic studies of children's attention, in which they had to either track a message delivered in a noisy context or pick out one type of picture (for example, animals and not vehicles) from a set of images, seemed to support this notion. Thus, children showed large developmental improvements in the ability to notice relevant information and to ignore the irrelevant (Hagen & Hale, 1973).

Yet, younger children are not always more distractible than older children. One important developmental change involves becoming better able to monitor our surroundings and to disengage quickly from an absorbing stimulus, like a favorite TV show, when appropriate (Anderson, 2002). Thus, the poor "filtering" and general distractibility that these early studies highlighted may be less important to understanding young children's attention than questions about how children actively select and track meaningful information in everyday tasks, including those that require monitoring several things at once. Along these lines, an alternative model for understanding the development of attention emphasizes the idea that children actively seek out certain information patterns to guide their thoughts and actions.

Children can be seen as employing **attentional schema** suited for particular forms of important information (Neisser, 1976). Attentional schemas are cognitive structures that are learned through experience in response to a particular set of stimuli in a specific task and that form a framework for organizing information and responses to that information. Because those schemas are tuned to noticing particular patterns of information, they will, in effect, "filter" out irrelevant information. In this view, focusing on some stimuli and ignoring others is an active, exploratory process. Consider a child learning to play a favorite video game in which the player's character must avoid certain hazards that appear on-screen. If the hazards tend to appear in certain ways, such as popping out from behind walls or vegetation, the child will start to develop an attentional schema tuned both to how the hazards look and how they tend to pop up in the overall context of the game. As the child becomes good at noticing and reacting to hazards, she may also get better at filtering out distractors that fly by on the screen. Children have learned these same skills for millennia while growing up in environments with familiar recurring patterns and sets of events.

Three Components of Attention

Across the many studies on the development of attention, three distinct components of the attentional system show their own developmental trajectories: the attentional networks for *orienting*, *alerting*, and *executive functioning* (Mezzacappa,

DEVELOPMENT AND SOCIAL POLICY

Children as Witnesses

Some crimes involve children, either as victims or as witnesses. In both cases, the child may have memories of the event that either the defense or the prosecution may want to use to support their case. To what extent are these memories reliable? Are young children's memory abilities so different from those of older children and adults that they should be prevented from testifying in court? These are high-stakes questions for anyone who takes part in legal proceedings involving children (Ceci & Bruck, 1995; Klemfuss & Ceci, 2012).

One crucial question concerns children's suggestibility. How easily can adults alter children's memories or even implant false ones? A child's responses may be based on either compliance (when faced with an interviewer who engages in very directive or forceful questioning) or on the creation of false memories (Fivush, 1994b). For example, in response to questions that are directed toward eliciting particular answers, a child might say something happened simply to please an interviewer without having any new memories of what happened. Later, in a less stressful setting, the child might indicate that the story she agreed to earlier was not what she really remembered. In contrast, it is possible to implant truly novel false memories, so that a child believes that she has had an experience that she never actually had.

In various studies, researchers have demonstrated this implantation effect (Brainerd & Reyna, 2005; Ceci & Bruck, 1993; Ceci et al., 1987; Goodman & Clarke-Stewart, 1991; Principe & Schindewolf, 2012).

In one study, the way in which 5-year-olds were asked about their visit to the pediatrician for a tetanus shot led them to develop false memories of the encounter (Bruck et al., 1995). Children who were told that the shot hurt were more likely to falsely remember experiencing pain and engaging in actions that never actually occurred, such as crying after the shot. Misleading information about what the pediatrician and the office assistant did during the visit also resulted in false memories. Similar effects of suggestibility happen in more casual, everyday circumstances as well. Thus, as a group of preschoolers start to talk among themselves about a recent experience, their conversations may suggest false events that lead to distorted memories (Principe & Ceci, 2002). Children ranging from preschool age to adolescence are therefore often quite susceptible to the implantation of false memories (Bruck et al., 2002; Ceci & Bruck, 1993; Goodman & Melinder, 2007; Holliday et al., 2002). Interestingly, in at least some instances, memories created by suggestions can be more detailed and elaborate than real memories (Bruck et al., 2002). Such differences in detail, however, are only somewhat more likely for false memories, so the amount of detail should not be used to discount or accept the validity of any particular memory in the courtroom.

2004; Rueda et al., 2004). These three networks show different developmental patterns, are based in different parts of the brain, tend to use different neurotransmitters, and are related to different loci on the human genome (Fosella et al., 2002; Rueda et al., 2004; see Figure 10.7). We will briefly consider orienting and alerting first, before looking in more detail at the complex developmental story of executive functioning.

Orienting Drawing attention to a particular region is called **orienting**. Thus, orienting occurs when a baby moves her eyes and turns her head to look at a blinking light or stays oriented in that direction in anticipation of another blink. Orienting appears to be the most primitive attentional network and the earliest to develop. The orienting network involves a large number of brain regions at both the cortical level (the superior parietal lobes and the frontal eye fields) and the subcortical level (the superior colliculus and the pulvinar nucleus). It is associated with the neurotransmitter acetylcholine. Developmentally, the orienting network is fully operational in infancy and changes little thereafter.

Alerting Arousing the attentional system through a cue that both indicates that a target stimulus is about to occur and that gives some information about the target is known as **alerting**. Alerting occurs, for example, when a child notices that a changing traffic light predicts when and where certain cars will start to move and then looks to that location in anticipation of the move at an appropriate time. The alerting network tends to be more prominent in the brain's left hemisphere, especially in the frontal and parietal areas of the cortex, and in the thalamus (Petersen & Posner, 2012). It is associated with the neurotransmitter norepinephrine.

The alerting system is present in infancy, but it undergoes considerable refinement during the early elementary school years, with corresponding improvements in a range of alerting tasks (Ahissar, 1999). In one study, children were

It might seem that younger children would be more susceptible than older children to suggestions that can implant false memories or distort real ones. In reality, the situation is more complex and depends on how the false memory is induced. Even in young children, the effects vary depending on the nature of the suggestion and how it relates to the child's prior knowledge. A child is much more likely to incorporate a false suggestion presented in a context consistent with what she already knows. If the context seems to contradict this knowledge, she is more likely to resist the suggestion (Roberts & Powell, 2006). Thus, if an interviewer asks a child about a (false) trip to a relative's house while providing details about the house that are at odds with what the child knows, the child will resist the suggestion much more than if the interviewer presents it along with accurate, familiar details. In addition, not all young children are equally suggestible; they show large variations that are correlated with personality traits such as impulsivity. In particular, more impulsive children tend to be more suggestible, whereas more reflective children tend to think more before accepting new information (Goodman & Melinder, 2007).

In some cases, it is easier to implant false memories in older children (for example, those who are age 11) than in younger children (for example, those who are age 5). These seemingly surprising developmental reversals in false memory are most often found in a type of study in which a participant hears a large list of related words (for example, violin, cello, mandolin, banjo, viola, bass) and forms a strong "gist category" (in this case, stringed instruments). Because of this sense of category, participants often mistakenly include other stringed instruments, such as a guitar, when recalling the list. If older children have an easier time than younger children creating a strong gist for a particular category, and if their precise memory is not that strong, they can show higher incidences of false memories (Brainerd et al., 2008). By carefully manipulating the stimuli to change the strength of the gist memories in ways that favor either younger or older children, it is possible to make such developmental reversals appear and disappear (Holliday et al., 2011). Clearly, if younger children have less familiarity with a category, they will be less able to extract a gist and then less likely to infer a false member of that category. Similarly, if children do not have a gist about what is likely to occur in a particular kind of event, they are less likely to insert a false memory about that event.

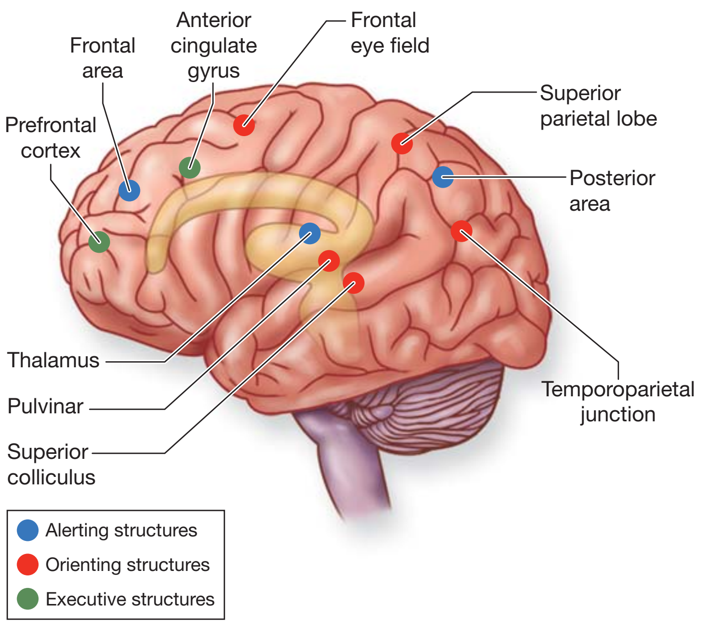
Developmental research on false memories has important implications for the courtroom. Researchers once believed that the younger the child, the less reliable the memory and the more likely that false memories might intrude. We now know that the pattern is more complex and that the courts should not assume that young children are less reliable witnesses than older children. The nature of giving testimony and the memories involved can sometimes make young children's memories less reliable, but in other cases older children's memories are less reliable. Thus, no constant, age-based rule of reliability applies (Brainerd et al., 2011). In practical terms, lawyers and judges need to carefully monitor how children are interviewed, the content of the interview, and the ways in which the content and method of the interview interact with basic developmental research on memory.

presented with a cue that indicated the location where a target figure would appear. The researchers then measured children's speed at detecting the object when it appeared. When there were valid cues indicating where a target would appear, such cues speeded up performance equally well in both 8- and 10-year-olds. The ability to shift attention when cued seemed to emerge during the early elementary years and to heavily involve the parietal cortex, which matures relatively early in development (Goldberg et al., 2001). By the time children are 8 or older, the cueing system seems to be functioning very effectively, although the ability to ignore distractors takes longer to develop.

Q: What are three distinct components to attentional abilities that seem to show their own developmental trajectories?

Executive Functioning In its broadest sense, **executive functioning** is defined as the collection of cognitive activities involved in goal-directed tasks and problem solving. Descriptions of executive functioning often emphasize three component processes: inhibitory control, error correction/shifting, and working memory. All three work together in the development of attention, but inhibitory control and error correction/shifting are especially important. The executive functioning network tends to involve frontal areas and the middle of the brain, including such areas as the anterior cingulate cortex and the lateral prefrontal cortex, as well as including the basal ganglia. The relatively late maturation of the prefrontal cortex is thought to explain the later development of executive functioning (Goldman-Rakic et al., 1997). It is associated with the neurotransmitter dopamine.

Executive functioning develops significantly during the elementary and middle school years (Best & Miller, 2010; Diamond, 2013; Garon et al., 2008; Klenberg et al., 2001,



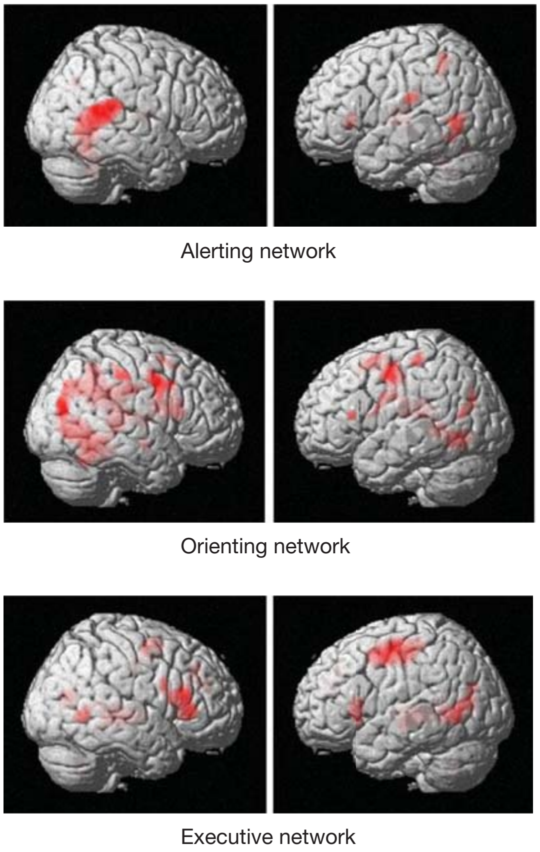


FIGURE 10.7 Three attentional networks in the brain. (A) The anatomy of the orienting (red), alerting (blue), and executive functioning (green) networks, as shown in a left view of the brain. **(B)** These three networks show different developmental trajectories, different neurotransmitter usage, and different patterns of brain activation, as shown in these fMRI scans of the brain. Adapted from Posner & Rothbart (2007) and Fan et al. (2005).

Zelazo & Mueller, 2002). We can see the influence of executive functioning most clearly in studies on the development of attentional strategies. For example, in tasks that require judging whether two complex visual patterns are identical, it is useful to divide each pattern into subregions and then compare corresponding subregions sequentially. But sometimes a strategy may be simple, such as turning our head so that a distracting display is no longer in view. As with memory, using these strategies effectively partially depends on an increasing awareness of how our own mind works—in this case, learning what attention is and how it can be overwhelmed.

In one classic study of the development of attentional strategies, Elianne Vurpillot asked children to compare two pictures of houses and to say if they were identical (Vurpillot, 1968). The two houses had similar layouts, but they had different features in some windows. Vurpillot monitored the children's performance by tracking their eye movements. With development, children showed strong improvement in both their speed and accuracy in performing the task. Most interesting, however, was the difference in children's use of planning strategies for examining the pictures. Younger children did not systematically search corresponding windows on the two displays, which made them much less efficient and more error-prone. Older children quickly realized that it was best to look at one pair of corresponding windows at a time, and their eye movements revealed this strategy. This study provides interesting information about the development of attention as well as the planning skills that are often a key part of attention.

These sorts of attentional tasks often show dramatic developmental changes; indeed, younger children seem to have a much weaker understanding of what attention is and how to monitor it (Miller & Bigi, 1979; Miller & Weiss, 1982; Miller & Zalenski, 1982). In contrast, older children and adults know that certain distracting environments are poor places to do challenging work. They also can usually tell when their attentional capacities are being taxed too heavily and will change the task or use strategies, if possible, to reduce the load. With age, children develop a richer understanding of the aspects of their mind that attention involves. As they gain this understanding, their use of attentional strategies also advances (Welch-Ross & Miller, 2000).

Q: Name an attentional strategy that undergoes developmental change.

Other attentional development studies ask children to ignore a distractor while directing their attention toward a target stimulus. In one such study, even 10-year-olds had more trouble ignoring distractors than adults did (Goldberg et al., 2001). One factor that may contribute to this difficulty is the relatively late development of certain frontal cortical regions, which may not fully mature until late adolescence (Huttenlocher, 1979, 1990). When these brain areas mature, they help the child to increasingly disengage attention from stimuli that seem to capture their initial attention and then to redeploy their attention elsewhere. In Chapter 7, we saw that this ability to disengage from a stimulus and change focus may also relate to developmental and individual differences in temperament. For example, some children may be more fussy and reactive than others because their prefrontal cortical regions are less mature, making the reactive children less able than calmer children to direct attention away from upsetting stimuli.

The growth of more sophisticated executive functioning can have very real consequences in children's lives. Consider the common and potentially dangerous activity of crossing the street. Thousands of children are injured or killed each year because they apparently fail to notice an oncoming vehicle. Crossing safely makes multiple demands on attention, especially executive functioning. A pedestrian must strategically shift attention to monitor traffic from all directions, must maintain a working memory of the physical layout and objects recently seen, and must inhibit any interest in distracting objects.

To investigate how developments in executive functioning might affect children's behavior while crossing the street, one research team created clearly marked pretend crosswalks next to a real, active road and used a clear plastic partition to prevent their young participants from actually entering the road (Barton & Morrongiello, 2011). Children between ages 6 and 9 were asked to monitor the traffic on the real road to decide when to "cross" at the pretend crosswalk. The researchers measured several aspects of executive functioning, including inhibitory control, monitoring and shifting between skills, and overall efficiency of handling this complex attentional task. Children who showed higher levels of executive functioning, especially in the overall efficiency measures, showed safer pedestrian behaviors. All areas of executive functioning seemed to contribute to street crossing and, in general, older children showed considerably better executive functioning and safer pedestrian behaviors (see Figure 10.8).

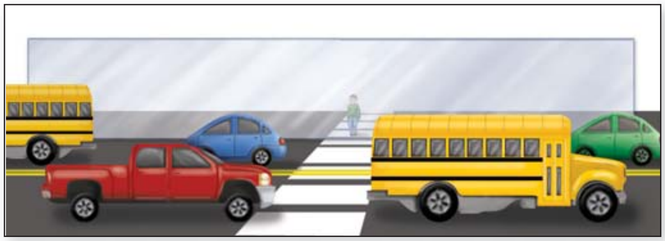

FIGURE 10.8 Executive functioning at the street corner. Children who score lower on tests of executive functioning also tend to show riskier behavior when crossing the street. In this study, a plexiglass panel prevented them from actually crossing the street.

All three components of executive functioning are involved in attentional strategies. Inhibitory control helps suppress tendencies to look at distracting stimuli; error correction/shifting involves monitoring attention and learning to allocate it effectively, as in Vurpillot's picture scanning task; and working memory helps keep track of performance and build links to metacognitive understanding. A large and growing amount of research on executive functioning has shown substantial developmental changes occurring not only in infancy and the preschool years but through middle childhood and beyond (Miyake et al., 2000). In the later years, the largest changes occur in working memory, skill shifting, and planning (Best et al., 2009; Diamond, 2013).

The three attentional networks of orienting, alerting, and executive functioning also interact with each other throughout development. Given that many tasks draw heavily on all three networks, explanations of children's performance will often involve understanding the complex interactions between these networks as well as the developmental patterns of each attentional network in its own right. As we will see shortly, these patterns of interaction create major challenges in trying to understand why some children have more attentional difficulties than other children at the same age.

Q: Describe how two different brain regions might be involved in the development of attentional skills.

A Developmental Disorder in Attention: ADHD

In 1845, the German doctor and author Heinrich Hoffmann wrote "The Story of Fidgety Philip," a poem about a "naughty, restless child" who "won't sit still." The poem was later published and translated into many languages and is often regarded as the first published description of what is now called **attention-deficit/hyperactivity disorder (ADHD)**. In Hoffmann's poem, Philip ignores adults' scolding as he "wriggles and giggles" at the dinner table, "swings backwards and forwards and tilts up his chair" until it starts to fall over, then "catches at the cloth" and crashes to the floor, pulling the tablecloth and the glasses and dishes down with him (Hoffmann, 1845/1995; see Figure 10.9). The uncanny resemblance of these behaviors to those observed by modern clinicians suggests that ADHD may have a long history, especially among young boys (Barkley, 1998b). Yet, diagnoses of ADHD have greatly increased only recently, as has the use of drugs to treat it. Today in North America, ADHD is diagnosed more often than any other childhood psychological problem, and by some accounts, more than all other childhood psychological problems combined. In some communities and groups, more than 20 percent of children have this diagnosis (Carey, 2003). ADHD is most often diagnosed as children progress through the early years of schooling (ages 5 to 10), but it is also diagnosed in older children and adults. In fact, the College Board, which prepares the SAT, reported that the number of high school students diagnosed with ADHD—who thereby qualified for extra time on standardized tests—doubled in one year (Gross, 2002; Vatz & Weinberg, 1994).

ADHD is defined by several clusters of behaviors that may begin as early as infancy and can continue into adulthood. The core symptoms are inattention, hyperactivity, and impulsivity. The child is fidgety, often running around the classroom, and seems to have poor impulse control. He is more likely to speak without thinking and to interrupt others. Teachers often consider him to be problematic, very messy, "all over the place," and difficult to handle. He typically has trouble doing well in class, even though teachers may feel that he is quite bright. He seems unable to concentrate on the task at hand or to stop himself from looking elsewhere (American Psychiatric Association, 1999; Barkley, 1990). Along with these difficulties in paying attention, children with ADHD may also have trouble moderating or managing their attention. In some cases, a child who usually has trouble focusing may become too obsessively focused on a task and may be unable to disengage to respond to parents or teachers (Barkley, 1990; Neuwirth, 1994). ADHD is normally classified into three subtypes: inattention, hyperactivity, or combined—a combination of symptoms of the first two types (Dalsgaard, 2013; Frick & Nigg, 2012). ADHD is diagnosed if the symptoms are impairing and occur in two or more settings. Children need not have every possible symptom of inattention or hyperactivity to be diagnosed into a subtype, but they must display a substantial and sustained set of symptoms (at least six out of nine possible symptoms) to be so classified. Many studies have repeatedly found evidence for the two subtypes of inattention and hyperactivity, as well as evidence that they are often correlated in a manner that suggests a common core deficit (Toplak et al., 2012; Wilcutt et al., 2012). Distinct genetic pathways also seem to be associated with the two subtypes (Nikolas & Burt, 2010). Both boys and girls are diagnosed with ADHD, but the core behaviors and the diagnosis are more common in boys than in girls (Gershon, 2002; Rucklidge, 2010).

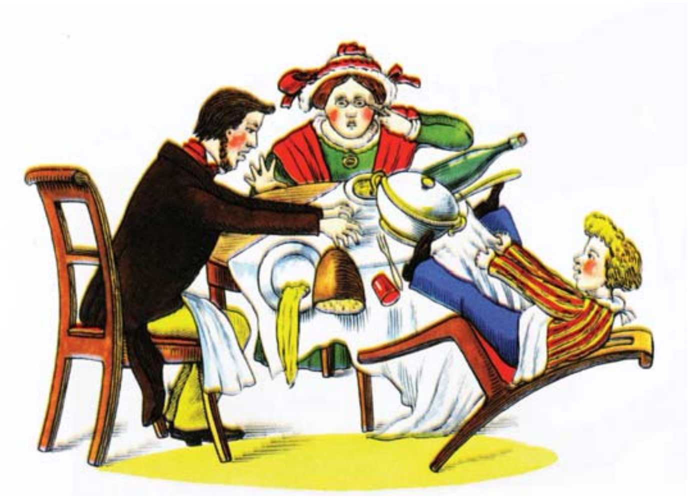

FIGURE 10.9 **An early illustration of ADHD.** This drawing shows the consequences of Fidgety Philip's hyperactivity, as described in the poem by Heinrich Hoffmann. From Hoffmann (1845/1995).

Q: What are the typical characteristics of a child with ADHD?

Researchers have described potential precursors of ADHD, including links to some aspects of infant temperament (see Chapter 7). For example, it has been reported that children with ADHD are more likely to have been "difficult" infants who had irregular daily routines and sleep habits, strong emotional responses to events, and high levels of activity (Nigg et al., 2004; Olson et al., 2002). The neurological bases of this relationship are not yet clear, although it has been noted that children with ADHD have had higher instances of birth trauma and serious illnesses, including high fevers, during their infancy (Banaschewski et al., 2005; Coghill et al., 2005).

As toddlers, children with ADHD are highly distractible and have difficulties with self-regulation, including problems inhibiting impulsive behavior and related problems with executive functioning (Barkley, 1997). But these behaviors are usually less problematic for the child in the less structured environment of home or day care than they will become in the more structured setting of elementary school. Many people who are diagnosed with ADHD as children seem to outgrow it by adulthood, but others continue to have difficulty accommodating to life's more structured demands (Lie, 1992; Weiss & Hechtman, 1993). This can be seen in the higher incidence of ADHD in people in prison populations (Eyestone & Howell, 1994). It is also correlated with depression, schizophrenia, other personality problems, dyslexia, asthma, and the symptoms of fetal alcohol syndrome (Cotugno, 1995).

Biological Bases of ADHD What causes ADHD? Most researchers in the field believe that its roots are biological, but they vigorously debate what the specific causes are. Some researchers speculate that the deficit may arise from delayed or impaired brain development, particularly in the frontal and prefrontal cortical regions that help regulate attention, as well as in subcortical regions such as the nucleus accumbens and the striatum. Others have proposed that deficits in neurotransmitters, especially dopamine, which affects neural circuits connecting those regions, may also be involved (Russell et al., 1995). Some researchers even suggest that ADHD may be linked to deficits in the immune system (Warren et al., 1995).

Evidence for ADHD's biological bases has been found in numerous studies. One of these studies used magnetic resonance imaging to measure the brain volumes of 152 children with ADHD and 139 control children over a 10-year period (Castellanos et al., 2002). Overall, the children with ADHD had brain volumes about 3.5 percent smaller than those of the control children, and this difference remained constant throughout the study. Among the children with ADHD, smaller brain volumes were also correlated with stronger symptoms. Although reduced brain volumes in children with ADHD have been found in the prefrontal cortex, other parts of the brain and circuits connecting brain regions are also affected, making it difficult to pinpoint which specific regions are associated with specific deficits.

In light of the complex interactions between the three attentional networks described earlier, it is not surprising that researchers have not localized ADHD to a single brain area. It may be that numerous brain regions are involved and that there are actually multiple related disorders rather than one single disorder. Analyses of brain networks and their role in ADHD have indeed led some to call for a return to a distinction between cases in which there is a proposed deficit in working memory and cases in which there is a deficit in response inhibition (Diamond, 2005). Moreover, researchers are now investigating which attentional networks are likely to be associated with specific facets of ADHD. For example, the orienting network has not been linked to ADHD, but both the alerting and executive functioning networks have been implicated in some cases (Johnson et al., 2008; Nigg & Casey, 2005). Thus, executive functioning deficits might cause problems with ignoring distractors while deficits in alerting might lead to challenges in anticipating a stimulus in a specific, expected location.

As mentioned earlier, ADHD is known to be highly heritable, but genetic research is now going beyond the well-documented finding of a high heritability to show how differences in specific alleles may affect particular networks in the attentional system (Bellgrove et al., 2005; LaHoste et al., 1996; Levy & Hay, 2001). For example, individual differences in alerting ability and in executive functioning seem to be influenced by alleles associated with the activation of neural networks involving two different neurotransmitters (norepinephrine in alerting and dopamine in executive functioning; see Fan et al., 2003, 2005; Parasuraman et al., 2005; Posner, 2012; Posner & Rothbart, 2005; Posner et al., 2007). This new line of research promises a more fine-grained analysis of the different cognitive deficits that may be bundled under the global heading of ADHD. Eventually, this more detailed understanding may allow clinicians working with children who have ADHD to precisely target each child's deficits and to train the child in cognitive skills likely to bring real improvements (Posner & Rothbart, 2005).

Q: What attentional networks seem to be involved in ADHD?

Drugs such as Ritalin (methylphenidate) are frequently prescribed for children with ADHD, and they can have positive effects, such as making it easier for these children to stay on task. Because Ritalin can increase levels of the neurotransmitter dopamine in neural circuits, some have argued that low levels of dopamine cause ADHD, but this evidence is not compelling. Ritalin, which has pharmacological similarities to amphetamines, not only helps many people with ADHD to focus, but it can also improve how people without ADHD perform on certain tasks. Simply showing that Ritalin enhances performance by influencing certain neural pathways does not mean that those pathways are different in people with ADHD. Only with more sophisticated analyses of Ritalin's effects on attentional networks will it be possible to learn whether it acts on the brain regions that have been linked to ADHD.

While some researchers feel that Ritalin is uniquely effective in treating ADHD (Sonuga-Barke et al., 2013), many other researchers have found very good results from programs that focus on either parent behavioral change or on direct behavior change in children (Hinshaw, 2009). Parent behavioral training usually takes the form of learning to positively reinforce prosocial behavior and negatively reinforce (through giving time-outs or taking away privileges) or ignore inappropriate behavior (Lee et al., 2012). Child behavioral training generally focuses on developing conflict management skills and problem-solving skills (Webster-Stratlon et al., 2011). The younger the child, the more effective behavioral interventions seem to be, whereas pharmacological interventions often are not effective and increase the likelihood of adverse effects in younger children (Charach et al., 2013).

Misdiagnosis of ADHD ADHD is not a single problem. Rather, this label is often applied to a number of related problems that have different underlying causes (Weinberg & Brumback, 1992). Some people diagnosed with ADHD may have smaller working memories; others may have trouble transferring information from working memory into long-term memory; still others may have more limited metacognitive skills, making them less efficient at using attentional strategies. Each component of attention, including the subcomponents of executive functioning, is a potential source of attentional difficulties. Moreover, when there is hyperactivity, it may arise from a huge number of variables that lead to high levels of activity and not just from ADHD. Thus, there is great potential for misdiagnosis of ADHD because some factors that really should not be considered part of an attentional deficit can cause problems similar to those associated with ADHD. At the cognitive level, for example, a child may process information slowly, leading him to fall behind in class and then have trouble focusing because he does not understand the material. Thus, even with well-functioning attentional systems, he may still fail to attend to information presented in class. Misdiagnosis of ADHD can also arise from social and emotional factors. A child who is having problems at home may be preoccupied and distractible in school. Any of these difficulties (and many others) can cause children to exhibit behaviors that may result in their being classified as having ADHD.

A final reason that ADHD may be misdiagnosed is that a child with this diagnosis may qualify for special considerations that would not be available if he were simply having academic problems (Horowitz et al., 1993; Reid & Katsiyannis, 1995). One such case involves special accommodations for high-stakes tests. For example, between 1987 and 2001, there was a 300 percent increase in the number of students who qualified for extra time on the SAT, even though the number of students taking the test increased by only 18 percent (Franek, 2006; Freedman, 2003). In many cases, the extra-time requests were granted for learning disabilities far broader in nature than ADHD, even though ADHD was most often listed as the problem (Lerner, 2004). The extra time also resulted in higher scores, especially on the mathematics part of the test (Mandinach et al., 2005; Wainer et al., 2004). This makes sense, given that students with learning disabilities may require extra time during testing to demonstrate their true capabilities with the material. But receiving extra time on a large set of mathematics problems seems to benefit control children (those who were not diagnosed with ADHD) just as much as those diagnosed with ADHD (Lewandowski et al., 2007). This finding raises questions about whether granting some students extra time really addresses their specific deficits (Franek, 2006; Freedman, 2003; Leong, 2005; Lerner, 2004). Research has also shown higher rates of diagnosis of ADHD and other learning disabilities in wealthy communities compared with other communities (Allen, 2006; Getahun et al., 2013; Leong, 2005; Lerner, 2004). These data are cause for concern, especially considering that large-scale assessments of young children have not shown higher incidences of ADHD in the children of more affluent families. In fact, the incidence of ADHD in younger children is usually higher in poor communities and among disadvantaged minorities (Biederman & Faraone, 2005).

The many potential causes for the misdiagnosis of ADHD should not be taken as arguments against the existence of real neurocognitive and attention-related deficits that make it much more difficult for some children to function effectively in cognitively challenging settings. And children with these deficits typically need quite different interventions than children who are having problems for other reasons. It is essential not to leap to one diagnosis, such as ADHD, without closely examining the evidence and other possible causes. Interventions can then be tailored to be more sensitive to the needs of each child.

Reasoning and Thinking about Knowledge

Improving at a particular cognitive task often depends on mastering its unique features. Developing a chess strategy, for example, requires learning to apply the rules of the game in ways that help anticipate an opponent's moves. Similarly, in the development of reasoning and the ability to think about our own knowledge (that is, metacognition), domain-specific properties of the information involved can also have important cognitive effects. Nonetheless, there are some broad, general principles that apply to the development of reasoning and thinking about knowledge in many different domains. We will explore both the broad principles and some domain-specific knowledge here, focusing on analogical reasoning, scientific reasoning, and judgments about the nature of knowledge.

Analogical Reasoning

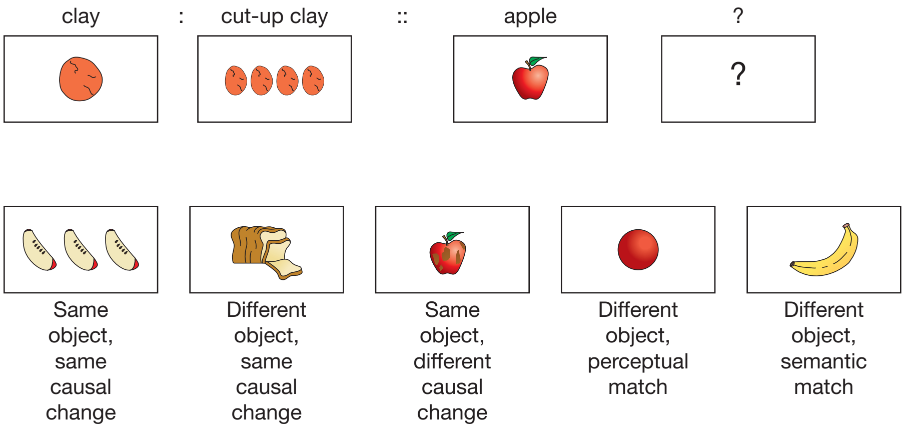
Analogical reasoning is a way of comparing things that on the surface seem quite different in order to see deeper-level similarities between them. For example, analogies likening the atom to the solar system or the world economy to a marketplace can often reveal new correspondences and relationships. Analogical reasoning, then, can involve using information known about one domain to understand corresponding information about another domain. Analogies can reveal similarities between the two domains and can thereby shed light on patterns in the new domains that may have otherwise escaped notice. Indeed, analogical reasoning has been described as making "mental leaps" from one domain to another (Holyoak & Thagard, 1995). Young children often seem to lack this ability. They may fail to see analogies that older children and adults consider obvious. If you say that an animal doctor's relation to pets is like a mechanic's relation to cars, most adults immediately recognize that the analogy is based on both parties' concern with proper functioning and repair. In contrast, a preschooler, even one who understands the words "animal doctor" and "mechanic," might look at you blankly, wondering what the similarity could be.

Piaget believed that young children fail to grasp such analogies because their minds lack certain *logical operators*. As discussed in Chapter 9, in Piaget's theory of cognitive development, these operators serve as a kind of mental toolkit that makes it possible to think about certain kinds of properties and relationships. He argued that analogical reasoning requires several sophisticated logical operators that most children do not acquire until early adolescence (Inhelder & Piaget, 1958). But as we have seen in earlier chapters, recent research has cast strong doubts on Piaget's claims that children are unable to think in certain ways.

Research has indicated that younger children can, in fact, use analogical reasoning under certain conditions in both the laboratory and in the real world. Rather than lacking certain logical operators or ways of reasoning, younger children may fail to understand some analogies simply because they do not know enough about the relevant topics. For example, children may miss the higher-order similarities between doctors and mechanics because they have limited knowledge of what these jobs involve, making their similarities much less obvious.

If this explanation is correct, then it should be easier for preschoolers to use analogies that describe relationships between things they understand well and that rely on clear structural similarities. In one study, researchers showed 2- and 3-year-olds a picture of a tree with a knotty trunk and asked, "If a tree had a knee, where would it be?" The children seemed to understand the tree-body correspondence, as they picked a protuberance on the tree that was roughly on the bottom third of the trunk (Gentner, 1977). Another study examined children's understanding of analogies that were based on actions such as burning, melting, and cutting (Goswami & Brown, 1990). For example, researchers might show a child a ball of clay next to cut-up pieces of clay and then show him an apple, followed by a question about what should go with the apple: cut-up apple pieces or various distractors (see Figure 10.10). The distractors were designed to show the correct object with the wrong relation (for example, a bruised apple), an incorrect object with the right relation (for example, sliced bread), an object that visually resembled the original apple (for example, a small red ball), and finally an object semantically associated with the original object (for example, a banana; Goswami & Brown, 1990; see also Goswami, 2001).

Even 3-year-olds are capable of understanding analogies about familiar objects and relationships and can pick up on the correct causal relation with the correct object and can ignore the more superficially similar object. When asked which display went best with the whole apple in the study just described, 4- and 6-year-olds (and some 3-year-olds) didn't simply find the display that was most similar to an apple, but they looked for a display that showed a similar relation to that between the whole ball of clay and the cut-up pieces of clay—namely, a cut-up apple. These results were interpreted as evidence that, in familiar domains of knowledge, very young children are able to think beyond simple surface similarities to consider deeper causal relations. In laboratory experiments, even children as young as 20 months take knowledge they learned in one situation and use it in another situation in a way that suggests



clay
:
cut-up clay
::
apple
?
?
Same object, same causal change
Different object, same causal change
Same object, different causal change
Different object, perceptual match
Different object, semantic match

FIGURE 10.10 Analogical reasoning in preschoolers. When shown a ball of clay next to cut-up clay, even young preschoolers will draw the correct analogy between the cut-up clay and the cut-up apple by picking the cut-up apple from the choices shown here.

analogical thought. For example, after being shown how to use a "pulling" tool to bring an attractive object to hand, the children would use that knowledge in a new setting to choose a new, similar "pulling" tool from a large set of possible tools (Brown & Kane, 1988).

Children's analogical reasoning ability is strongly influenced by their knowledge base, and they are much better able to draw analogies in familiar domains and between different domains if both domains are familiar. Their analogical ability is also influenced by the level of complexity and abstraction that the analogies involve. One proposal suggests that younger children can grasp familiar objects' typical properties in a domain and the relationships between those properties, but they tend to have trouble seeing how certain kinds of relationships correspond across different domains—that is, how relations in one domain resemble those in another (Rattermann & Gentner, 1998). Thus, younger children tend to pay more attention to simple, perceptual properties than to higher-order relationships when both are in competition (Andrews & Halford, 2002; Halford et al., 1998). For example, in the scenario modeled in Figure 10.10, many 3-year-olds will choose an object that is visually similar to the apple, like the red ball, rather than choosing an object based on the relationship between the first two objects, as older children and adults would choose. Nonetheless, young children can sometimes see such relationships and make correct choices based on analogies, as was done by some 3-year-olds in the study.

As this example shows, reasoning analogically about a less familiar domain can involve pitting obvious perceptual similarities (for example, between the apple and the red ball) against children's still-developing knowledge of cause and effect and other abstract relations. In many of these situations, children younger than about age 6 seem more likely to fall back on the clear perceptual similarities. Interestingly, in scenarios like the study just described, children seem to have more trouble seeing the correct relational similarity when the options include a distracting perceptually similar object. In a study designed to examine this difficulty, researchers showed the children the pairs of pictures in Figure 10.11 and asked the children what the pictures in each pair had in common. In pair A, the children said that the dog was watching the cat chase the mouse, just like the mother was watching a girl chase a boy. But in pair B, when a stationary mouse like the one in the first picture was added to the second picture, many preschoolers were distracted and no longer saw this relational similarity. Instead, they focused on the obvious perceptual similarity, saying that both pictures had a mouse, whereas older children still saw the relational similarity in pair B despite the distracting mouse (Richland et al., 2006). Thus, younger children can see relational similarities, but they seem to have more difficulty noticing such similarities when they are in competition with obvious perceptual similarities.

Q: How might knowledge in the relevant domains facilitate the emergence of analogical reasoning between them?

Scientific Reasoning

Scientific reasoning can be thought of as the ability to develop hypotheses about some aspect of the world and then efficiently test those hypotheses with relevant data.

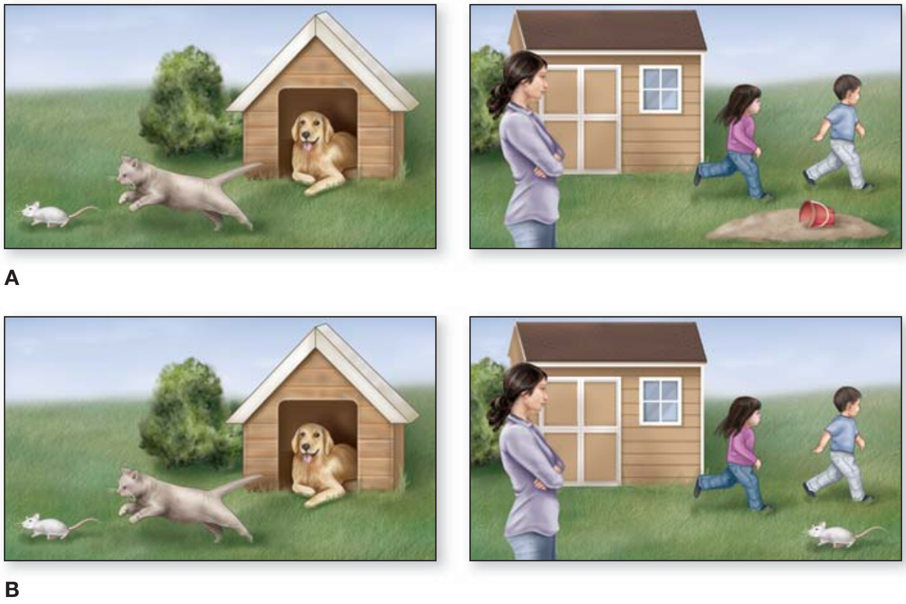


FIGURE 10.11 Analogical reasoning in the face of perceptual distractors. Younger children can see the relational similarity of an observer watching a chase in the two panels in pair A, but they have much more difficulty recognizing this similarity when both panels in pair B contain a prominent, perceptually similar object—in this case, the mouse. Rather than focusing on the structural similarity between the events in pair B's panels, young children tend to focus on the perceptual commonality. Adapted from Richland et al. (2006).

In the past, some researchers believed that in the course of normal experience, children approached the world much like scientists, using scientific reasoning to develop and test hypotheses about how things work (Carey, 1985). Yet, much more often, developmental researchers viewed children as incapable of true scientific reasoning because they believed that children did not have logical capacities (Inhelder & Piaget, 1958) or could not connect isolated pieces of knowledge into a systematic set of beliefs (diSessa, 1988). While scientists' reasoning processes were thought to be logical, consistent, objective, flexible, and open-minded, children's reasoning was considered to be quite the opposite: illogical, inconsistent, subjective, rigid, and dogmatic (Brewer & Samarapungavan, 1991). Moreover, scientific theories were thought to be abstract, global, internally consistent, and universal, while children's theories were thought to be concrete, fragmentary, inconsistent, and context-bound. These differences fit well with some theorists' broader ideas about how children's thinking differs from that of adults, including Piagetian views of children as illogical, concrete, and inconsistent.

As we have seen with some other aspects of cognitive development, however, comparing the thought patterns of children and adults shows that it is difficult to find any of these differences consistently. For example, one line of research examined children's intuitive beliefs about cosmology—that is, about the earth, sun, moon, and stars and their relationship to each other (Brewer & Samarapungavan, 1991). Even children as young as 6 could give explanations that were surprisingly abstract (rather than perceptually bound) and internally consistent and could integrate and explain new information. Furthermore, when researchers directly compared children's and scientists' reasoning, both children and scientists seemed to depart from consistency and logic in similar ways—that is, *neither group* conformed to the stereotype of how scientists work (Dunbar, 1999; Salmon, 1989).

Some researchers have argued that young children's theories lack true explanatory power because they cannot integrate and explain new information, a capability that would expand the reach of their theories. Yet, a closer look at children's theories reveals that two key explanatory processes are quite common. The first process, *explanation application*, refers to the ability to answer questions about how a thing works or why it is the way it is by referring to relationships and dynamic patterns. The second process, *explanation expansion,* is the process of elaborating a simple explanation into a more complex one in response to further queries. For example, after being given several three-dimensional models of the earth and selecting a model in which the sun, moon, and stars can move in and out of a hollow sphere in which we live inside, a 7-year-old gave the following explanation of the day/night cycle:

Experimenter: Does the earth move?

Child: Yes.

Experimenter: Show me how it moves.

Child: It spins around. (*She demonstrates by rotating the hollow sphere she had selected as the best 3-D model of the earth.*)

Experimenter: Does the sun move?

Child: It moves from outer space into the sky and to space again.

Experimenter: Does the moon move?

Child: Yes.

Experimenter: Show me how it moves.

Child: Just like the sun and the stars, too. They go where the moon is.

Experimenter: (*He hands the child the set of models she previously selected.*) Now, with your models of the earth, sun, and moon, show me how it changes from day to night for this little boy here on earth.

Child: See here is the sky half of the earth. (*She cups her hands in a dome over the sphere.*) During the day the sun comes down from far in outer space to the sky part and we get light on earth. And then slowly the sun moves back up into the outer space part and the moon and the stars come down from space into the sky part. . . . So it will be night for the boy. (*She indicates that outer space is a region above the sky dome that covers the earth.*) (Brewer & Samarapungavan, 1991)

Without having been taught anything about cosmology, this child has constructed a set of intricate spatial and dynamic relations that work quite well to explain the day/night cycle as well as many other celestial phenomena, an instance of explanation application (Brewer et al., 2000). She also uses explanation expansion when the experimenter asks how the earth moves, and she realizes the need to demonstrate how spatial relations change over time. When prompted for further information, she easily builds on her first explanation. Other children construct different models that also capture many spatial and dynamic relations. Figure 10.12 shows the full range of models offered by children.

If children reason and construct theories about the world similarly to the way scientists do, why do people remain so focused on the differences? Brewer and Samarapungavan suggest that one important reason actually has more to do with misunderstanding science than underestimating children's reasoning abilities. They point out that people have a tendency to confuse the institution of science with the way an individual scientist works. Individual scientists benefit from a large body of accumulated knowledge, which allows them to far surpass what any isolated individual engaged in scientific inquiry could do. In contrast, the child can be considered a "universal novice" working

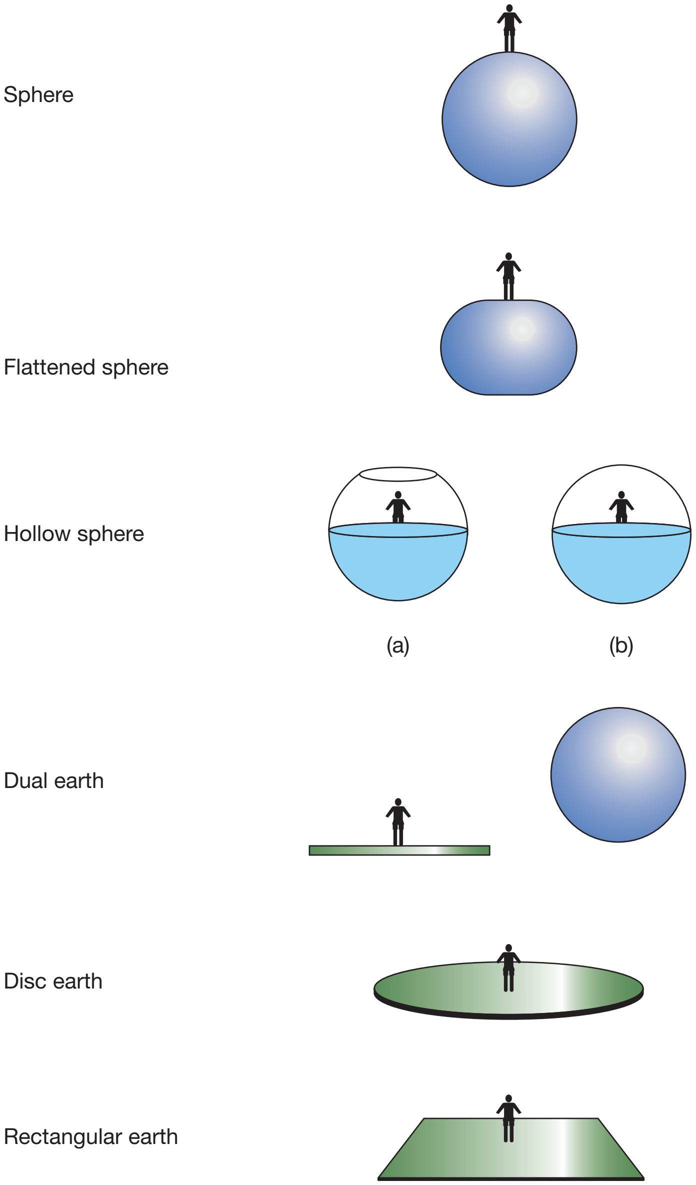

FIGURE 10.12 Children's models of the earth. Children often develop models of the shape of the earth that are quite different from the standard adult model seen in developed cultures. All of the models shown here were selected as the best model of the earth by different children and were used as the basis of their explanations for phenomena like the day/night cycle. One of the models depicted the earth as a hollow sphere in which we live and which is covered by a kind of sky dome in which the sun, moon, and stars move in and out. Versions of this hollow sphere model were surprisingly common among young elementary school children. Adapted from Vosniadou & Brewer (1992).

largely on her own. The young child's independent inquiry and her small knowledge base may better explain the many developmental differences in scientific reasoning than do the accounts that claim that there are intrinsic differences in children's and adults' reasoning abilities.

Even young schoolchildren show parallels in their thinking to the ways individual scientists reason, and these aspects of children's scientific reasoning show a degree of developmental consistency across different scientific domains (Keil, 2011). What, then, distinguishes adults' scientific reasoning from children's? One important change may involve the ability to integrate information across different domains. For example, consider how children reason about two related domains: how model sailboats and model cars move best (Kuhn et al., 1992). In repeated sessions over the course of several weeks, children became better at isolating the critical variables that improve a model boat's mobility (for example, its hull size or weight). Interestingly, over the course of the study, their reasoning about how model cars move improved in parallel to their increased understanding of how boats move. Each small insight in one domain (here, model boats) increased the likelihood of a similar insight in another domain (here, model cars). The two domains were linked by more general, higher-order insights, so that what initially happened within one domain then generalized to the other domain.

Moreover, gaining knowledge in each domain seemed to foster general improvements in the children's scientific reasoning strategies. Such strategies include considering multiple causes and outcomes, determining which comparisons to include in an experiment, thinking of appropriate experimental controls, and recognizing when an experiment's outcome is indeterminate (Siegler & Jenkins, 1989; Sodian et al., 1991). By adopting more efficient strategies, the children became increasingly skilled at generating hypotheses and testing their predictions. And in doing so, children are not so different from adults. Thus, domain-specific knowledge and causal understanding play crucial roles in the development of more domain-general scientific reasoning strategies (Kuhn et al., 1992, 1995).

Q: How is a young child's scientific reasoning similar to and different from that of a scientist?

Metacognition and Accessing Knowledge

Another critical set of cognitive skills that develops in childhood concerns **metacognition**—that is, the ability to think about our own mind and what we know and to think about knowledge in terms of its quality, depth, and relevance. Metacognitive skills involve the ability to think about and evaluate our own knowledge and to consider what others know (Schneider & Lockl, 2002). These capabilities are quite sophisticated, and they emerge only gradually during the elementary school years. A related set of skills involves evaluating others' knowledge and learning various indirect pathways to knowledge.

Illusions of Knowing As described earlier in the chapter, children younger than around 6 years of age have limited metacognitive abilities; they fare poorly at evaluating their own capacity to memorize information or pay attention to a complex display. Young children also have difficulty assessing whether they have understood a paragraph they have just read or a story they have just heard or whether they have learned how to do a task (Markman, 1979; Pressley et al., 1987; Schneider et al., 2000). In all of these situations, young children tend to overestimate their abilities, often assuming they have learned far more than they really have. Although adults sometimes make similar misjudgments, younger children usually make more of these kinds of errors.

To investigate how children become aware of the limits of their own knowledge, researchers have focused on another aspect of metacognitive understanding: assessments of knowledge acquired gradually through life experience and for which any specific learning episodes may long be forgotten. For example, how well do you know how a can opener works? You probably don't recall learning this information, but you still may have a strong sense of your own understanding. In fact, adults are often surprisingly inaccurate at assessing their own knowledge of how things work. They are said to be under an "illusion of explanatory depth," initially thinking they have a fairly detailed understanding of how a device works but then downgrading their ratings of what they know after attempting an explanation and realizing how little they do know (Rozenblit & Keil, 2002). One developmental question this raises is whether asking children to explain their knowledge will similarly help them to recognize what they don't know. This issue is important for getting a better sense of how children know the limitations of their own knowledge and decide when to seek out further information.

One study examined the extent to which kindergartners, second-graders, and fourth-graders could recognize the limits of their explanatory knowledge (Mills & Keil, 2004). While kindergartners seemed to have a fragile ability to recognize the limits of their knowledge, most second-graders clearly recognized the mismatch between what they thought they understood and what they really understood, and fourth-graders responded much like adults. In addition, even after attempting to explain how various devices worked, kindergartners still gave the highest average ratings of how much detail they knew, followed by second-graders, who gave the next highest average ratings, then by fourth-graders, whose ratings were lower still and more like those of adults. Thus, younger children more significantly overestimated what they knew, while actually knowing less. After attempting to provide explanations, they realized their initial ratings were too high, but they did not reduce them nearly as much as they should have. This pattern of results suggests that younger children can be guided to realizations that their understanding is incomplete, but even when they have some insight into the limits of their knowledge, they will likely remain overconfident about their level of understanding. This confidence may help them feel competent and motivate them to continue learning.

Q: In what ways do both children and adults share certain biases about how they assess the quality of their own understanding?

Evaluating Others' Knowledge In addition to evaluating their own knowledge, children need to learn to evaluate what others know and who the experts are on particular topics. These abilities to think about the knowledge in other people's minds are crucial for figuring out whom to believe and whom to consult, affecting children's social interactions as well as their developing systems of knowledge. To some extent, even 3- and 4-year-olds can evaluate other people's knowledge to decide whether to trust what they say. Preschoolers are less likely to believe an adult's statements if they know that on prior occasions that person has made mistakes in labeling familiar objects (Koenig et al., 2004). Children also evaluate a speaker's reliability in terms of whether he shows a consensus with others—that is, how compatible his views are with the views of experts in the dominant culture (Harris & Corriveau, 2011; Koenig, 2010). By the time they are 5 years old, children take into account multiple factors, such as weighing both speakers' intentions (good versus bad) and their prior performance in deciding whether to trust them (Liu et al., 2013).

In their preschool years, children start to understand the idea of expertise as a "division of cognitive labor"—that is, they realize that particular people are likely to have in-depth knowledge about different areas (Lutz & Keil, 2002). When children of various ages were asked about what kinds of things doctors and car mechanics would understand, children as young as 4 years of age understood that a mechanic would be more likely than a doctor to understand problems with simple devices, even those unrelated to cars. Similarly, these children saw doctors as more likely to understand biological phenomena, even those not directly relevant to medicine (Erickson et al., 2010; Lutz & Keil, 2002). Thus, even preschoolers have some sense of how knowledge can be clustered in ways that roughly correspond to disciplines like physical mechanics and biology.

Early on, however, this sense is quite fragile and can be overwhelmed by other ways of clustering knowledge, such as around common goals. For example, a shoe seller might amass expertise on everything that supports the goal of selling more shoes, including fashion trends, costs of different kinds of leather, and advertising rates in different media. Young children can find this type of goal-centered expertise category more obvious and compelling than discipline-based ways of clustering knowledge (for example, around physical mechanics, biological processes, or psychological processes). That is, if both ways of sorting are available to young children, they may find the goal-centered ones more salient, even though they are also able to use discipline-based categories—and this is especially true if the goals at hand seem familiar and sensible. The discipline-based view of fields of knowledge starts to more clearly dominate children's thinking only late in elementary school (Danovitch & Keil, 2004; Keil et al., 2008).

Children also learn a great deal more about the nature of knowledge during their elementary and middle school years (Markman, 1979). For example, children come to understand the uncertainty involved in acquiring new knowledge, and they realize that a central goal is to become more certain about whether something is true. It now appears that even preschoolers may have a crude sense of this uncertainty, which becomes more elaborated and effective in later years (Metz, 2004). School experiences can also foster (or hinder) a child's developing awareness of the nature of knowledge. Teaching children about the nature of evidence, certainty, and multiple perspectives can help them understand the continuously evolving nature of knowledge (Smith et al., 2000).

Many children in their early school years tend to have a view of knowledge known as absolutism, in which they think that there is only one true explanation or way of characterizing a situation. As they enter middle childhood, they often become relativists, thinking that any explanation or theory is just as likely to be true as any other. Finally, they move toward an evaluativist perspective, in which they view some explanations and theories as closer to the truth while still rejecting absolutist views (Hofer & Pintrich, 1997). These shifts likely relate to their increasing understanding of uncertainty, evidence, and ways of justifying beliefs or explanations (Kuhn, 2009).

Three Specific Skills

In tackling the broad topics of memory, attention, reasoning, and metacognitive skills, we have seen that developing expertise in specific domains of knowledge can affect how these broader domain-general skills are manifested in each domain. In this section, we will consider the development of reading skills, mathematical skills, and the skills for understanding symbolic representations such as maps, models, and drawings. Detailed analyses of these specific cognitive skills draw on several themes mentioned in prior sections—for example, the changes that come with increasing expertise, the importance of cognitive strategies and their interactions with metacognitive awareness, and the interplay between explicit and implicit aspects of cognition. But there are also specific factors unique to each cognitive skill. With this in mind, we will first consider the emergence of reading and mathematical skills and then examine how symbolic representations come to be used.

Reading

Most of us remember learning to read early in elementary school. For the vast majority of children, learning this skill requires some guidance from teachers and caregivers. Yet, for most literate adults, reading seems effortless. How does a cognitive skill progress from being a real challenge in elementary school to being a skill seemingly as basic as walking?

Learning to Read Learning to read requires integrating several skills over an extended period from the late preschool years to early adolescence. At least five major component skills are involved: (1) understanding the idea of the alphabet and learning the letters; (2) developing an understanding of how letter patterns correspond to sounds; (3) learning to read aloud fluently; (4) expanding vocabulary; and (5) learning to extract meaning from a passage and comprehend it (National Institute of Child Health and Human Development, 2000; Paris & Paris, 2006). Although these components can be considered separately, they also interact. Thus, a child with a larger vocabulary and better comprehension skills can often use those skills to infer words and thereby read aloud more fluently.

Given these component skills, it is possible to broadly characterize the development of reading as a prereading stage followed by a series of five reading stages (Chall, 1983). According to Jeanne Chall, children typically master reading skills in the following way:

- *Stage 0: Prereading (birth to approximately age 6).* Children begin to acquire foundational skills for reading during this period. They start to get a sense that printed words relate to sounds, and they begin to recognize a small number of words. They understand how a book represents a story sequentially and can "read" picture books by turning the pages while telling a corresponding story. Their spoken vocabulary at this point is many thousands of words.
- *Stage 1: Initial reading and decoding (usually ages 6 and 7).* In this stage, children start to master the idea that each

letter has a sound and that letters can be combined to create all possible words. In addition, they learn that they can often figure out the sound of a word from the sounds of its letters and how they blend together. Taken together, this process is described as *decoding*—that is, learning to convert strings of letters into sounds and words and then link those words to their stored meanings. Developing decoding skills first requires learning the *alphabetic principle,* which is simply knowing that words are built up out of letters and letter combinations that stand for particular sounds. Decoding skills then require gaining the ability to hear, recognize, and manipulate the smallest sound units that can change a word's meaning (such as recognizing how "b" creates a different meaning for "bat" than "p" does for "pat"). Children in this stage are just starting to be able to read words, and their reading vocabulary may be quite small, often less than 10 percent of their spoken vocabulary.

- *Stage 2: Confirmation and fluency (approximately ages 7 and 8).* Children in this stage are "confirming" what they have learned in stage 1 and becoming more rapid, fluent readers. They also start to use the context of a sentence or passage to help decode words. For example, if a child has figured out that a sentence begins, "The cat said m . . . ," this context can make it much easier to read "meow." Children's spoken vocabulary in this stage still far exceeds their reading vocabulary.
- *Stage 3: Reading to learn (approximately ages 8 to 13).* Children now start to reap more benefits from reading and come to see it as a valuable way to acquire new information. During this stage, reading also adds to the child's vocabulary, and the child's oral and reading vocabularies start to converge. Stage 3 children become more like adults in starting to heavily rely on the comprehension component of reading, and they will use several comprehension strategies to understand a text, such as predicting typical story structure and anticipating how one event will likely follow from another. Having mastered more basic reading skills, children can start to focus more directly on understanding what they have read and the broader narrative structure of a set of sentences.
- *Stage 4: Multiple viewpoints (approximately ages 14 to 18).* During this stage, adolescents acquire a complex reading skill that involves interpreting text from different viewpoints, such as thinking about how the author's point of view differs from the reader's or how the characters in a novel construe the same set of circumstances very differently.
- *Stage 5: Construction and reconstruction (approximately age 18 and older).* During this final stage, readers acquire the ability to evaluate and selectively read information from many sources and to integrate it to create new insights, perhaps through their own writing. Most readers are not thought to attain this level of proficiency.

These stages of learning to read involve perceptual identification of letters, awareness of individual sounds, awareness of syllables, familiarity with the layout of text, and a grasp of authors' and readers' intentions and goals, among many other components (Crowder & Wagner, 1992; Gibson & Levin, 1975; Rayner et al., 2001). To learn to read, a great deal of practice is required, and some threshold levels of proficiency in all components must be met. Nevertheless, different children often show strikingly different ways of putting together and relying on these components. Children might stall in any one of the stages of learning to read, and when they do so for an extended period, especially in the early stages, they may be seen as having a reading disability that needs corrective action. All of these factors come into play in trying to understand the best ways to teach reading.

Q: What must a person learn to do to be able to read?

Teaching Reading Two approaches to teaching reading have become widely used in many different contexts. Both have a long history and strong supporters and yet they differ enough to have sparked a heated controversy over which is best. The first one is often known as the **whole language approach**. Rather than having children memorize letters and then isolated words, this approach favors teaching them to comprehend and produce small stories in a variety of formats (Crowder & Wagner, 1992). To do this, children are exposed to sentences in the context of narratives, accompanied by supporting pictures. Proponents of the whole language approach argue that reading has to be connected to broader communicative competencies so that it will be engaging and meaningful for the child. If reading-related activities are made sufficiently engaging, they supposedly will motivate children to develop the necessary component skills, such as decoding (Weaver, 2002).

A second way of teaching reading, known as the **phonics approach**, advocates teaching children about *phonics*, the rules for combining the sounds of letters into words as a foundation for early reading skills. Since most languages have only about two dozen letters in their associated writing systems, learning to associate the letters with sounds and then put the sounds together seems to offer an efficient way to begin to understand the written word. The challenge in learning to read phonetically, however, is that the sounds of each letter, when run together, often do not sound much like the word they represent. As readers, we somehow learn many complex patterns of correspondence between letter sequences and sounds. As a result, we can usually sound out novel words correctly, but not by simply blending the sounds of each letter (Gibson & Levin, 1975;

Rayner et al., 2001). When one of our sons was 5, he objected vigorously to his teacher's method of having the children say the sounds of each letter in a word, then having them repeat the sounds faster and faster together to read the word. As he insisted, no matter how fast he said "buh" "oh" "tuh" "tuh" "ull" "ee," it did not sound like "bottle." An additional complication is that in many languages, there are a larger number of distinct sounds than there are letters. For example, English has only 5 vowels but over 12 distinct vowel sounds. Consider the sound of the "a" in "baby," "bat," "about," "saw," and "car." Moreover, two different vowels can also have the same sounds, like the "a" in "across" and the "u" in "circus."

Despite the complexities of mapping sound sequences onto letter sequences, phonics approaches are critical to early reading. When phonics approaches are compared with those like the whole language approach, which downplays the memorization of letter sounds, there seem to be clear drawbacks to omitting phonics instruction (Adams, 1990; Hulme & Snowling, 2013; Rayner et al., 2001, 2002; Vellutino, 1991; Williams, 1980). At the same time, many students and teachers hate the rote-drill aspects of some phonics approaches. Whole language approaches, which emphasize learning in context, tend to be much more fun. For that reason, it can be helpful to draw on some of the excitement and pleasure of whole language approaches while also teaching children about letter combinations and sound patterns. Today, most reading experts recognize the need for both basic phonics instruction and comprehension strategies, since they know that the many components of reading require several different forms of instruction for optimal development of reading skills. In addition, it is becoming increasingly clear that the best teaching involves customizing how much emphasis is placed on each reading skill based on a particular child's strengths and weaknesses. Individualized instruction, in which first-graders with lower vocabularies work more on phoneme decoding while those with more advanced vocabularies work more on comprehension strategies, seems to result in greater improvement for both groups (Connor et al., 2007, 2011).

In the process of learning to read, most children reach a point at which they seem to suddenly catch on and start reading at a much higher level. These apparent surges in reading skill have often been seen as evidence that children learn to read by progressing through a series of discrete stages, each of which corresponds to a particular strategy for decoding strings of letters (Gough et al., 1983). Others, however, have argued that decoding strategies actually undergo more incremental changes, so that reading develops smoothly, without stage-like transitions (Perfetti, 1999). Theorists from both camps agree that one of the most critical developmental processes for reading is **phonological awareness**, which refers to the child's understanding of the sound units and structures of spoken words. Thus, a phonologically aware child is able to discern the number of sound units in a spoken word and compare sound units between words by engaging in phonological processing.

There are a wide variety of tests for phonological awareness (Anthony et al., 2002; Goswami & Bryant, 1990; McBride-Chang, 1995). These include asking children whether pairs of words rhyme or start or end with the same sounds and asking them how many distinct sound units a word has. In these tasks, children hear the questions aloud and answer the same way; there are no written words involved. Yet, in many different languages, a child's grasp of spoken words' sound structures is a powerful predictor of how easily he will learn to read (Anthony & Francis, 2005; Ehri et al., 2001; Hulme & Snowling, 2013; Rayner et al., 2001).

At the same time, some developmental differences in children's phonological awareness are related to the extent to which their language has correspondences between spelling and sounds. Thus, exposure to writing in Spanish and Dutch, which have much more regular correspondences than English, helps advance children's phonological awareness more rapidly than does exposure to written English (De Jong & Van der Leij, 2003; Ziegler & Goswami, 2005). In addition, among speakers of more phonologically regular languages, problems with phonological awareness tend to disappear in adulthood, whereas for speakers of irregular languages like English, those problems often persist into adulthood (Anthony & Francis, 2005; De Jong & Van der Leij, 2003).

Q: How is phonological awareness involved in the development of reading?

When Reading Is a Challenge: Dyslexia Some children have enormous difficulties learning to read, and in some cases, reading difficulties can persist throughout adulthood. One cause of these problems is **dyslexia**, a learning disability that typically involves a deficit in phonological processing despite normal intelligence, a good motivation to learn to read, and ample early exposure to environments that normally foster reading (Shaywitz & Shaywitz, 2003). A child with dyslexia may end up falling behind peers academically because the dyslexia causes the child to have much less experience practicing and mastering the art of reading by actively decoding words and sentences. Most children spend thousands of hours reading and becoming more efficient processors of text, but since children with dyslexia have such difficulties in phonological processing, they may read less and fail to build up expertise without very intensive tutoring

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

The Genetics of Dyslexia

For over a century, it has been noted that dyslexia seems to run in families (Smith et al., 1983). Twin studies and other methods have found high heritability rates (DeFries & Gillis, 1993). In addition, as children progress from learning to read to increasingly using reading to learn, shared genotypes are by far the strongest predictors of levels of reading ability (Harlaar et al., 2007). With advances in our understanding of the human genome, it has been possible to find specific gene loci that are significantly correlated with dyslexia.

The genetic studies clearly indicate that there is not a simple gene locus for dyslexia. As in almost all cases of genetic influences, several gene loci and their interactions seem to be implicated. In general terms, the finding that multiple gene locations are involved in dyslexia offers some biological support for the idea that there are several distinct types of dyslexia, as well as several interacting biological components that support normal reading (Castles et al., 1999; Scerri et al., 2010; Shaywitz et al., 2003; Shaywitz & Shaywitz, 2005). One key question is how closely various reading problems—such as problems with phonological awareness, short-term verbal memory, or rapid naming of pictures, colors, and letters, among others—are associated with specific genetic signatures.

In the search for genes associated with dyslexia, researchers have found one especially prominent locus in a gene called *DCDC2* on chromosome 6. This gene seems to influence how new neurons move to their target locations during brain development. A *DCDC2* variant that causes abnormal neuron migration in which neurons end up in inappropriate cortical locations is unusually common among people with dyslexia (Kere, 2011; Meng et al., 2005; Schumacher et al., 2006). A second gene known as *KIAA0319* also seems to affect neural migration during brain development (Fisher & Francks, 2006; Schumacher et al., 2007). The story becomes more complicated, however, as the involvement of genes on several other chromosomes has also been suggested (Gayán et al., 1999; Giraud & Ramus, 2013; Grigorenko et al., 1997; Hannula-Jouppi et al., 2005; Kere, 2011; Nopola-Hemmi et al., 2001; Scerri et al., 2010). It is too early to tell whether these different genetic loci correspond to different subtypes of dyslexia or whether different combinations of genetic loci produce the subtypes.

Of course, the involvement of specific genes in dyslexia does not mean that everyone with these genes has dyslexia; many do not. Nor does it mean that people with dyslexia cannot learn to read well. With the right instruction, most people with dyslexia can develop strategies that help make reading easier and more fluent (Shaywitz et al., 2003). Interestingly, many people with dyslexia seem to recruit brain regions other than the ones used by nondyslexic readers to compensate for their reading difficulties. For example, reading processes and dyslexic deficits usually occur in the left hemisphere, but in some people with dyslexia, right hemisphere areas may be used during reading to compensate for the deficits (Gabrieli, 2009). Certain approaches to reading instruction may help accelerate this neural compensation process (Shaywitz et al., 2003). Some researchers hope that specific genetic signatures will correspond closely enough with particular reading difficulties that these genetic differences may even provide guidelines for tailoring individualized approaches to teaching reading.

and instruction. By one estimate, a fifth-grader who does not have dyslexia may read outside of the classroom in 2 days as many words as a fifth-grader with dyslexia reads in a year (Gabrieli, 2009).

A large proportion of children with dyslexia do especially poorly on phonological awareness tasks (Snowling, 2001; Ziegler & Goswami, 2005). Some people with dyslexia may have difficulty correctly perceiving sounds that occur close together in time, as they have deficits in detecting rapidly changing sensory stimuli (Tallal, 2000). But in most cases, the problem on phonological awareness tasks does not seem to be with initial perceptual processing of sounds, but with translating sounds into the efficient linguistic codes that correspond to letters and words (Snowling, 2001; Ziegler & Goswami, 2005). Children and adults who have such difficulties may have less-developed capacities in the left dorsolateral prefrontal cortex. This region shows no increased activation in people with dyslexia when they engage in word rhyming tasks, while the same region does show more activation when typically developing children engage in the same tasks (Kovelman et al., 2012). As the New Directions in Developmental Research box describes, genetic and neuropsychological models of dyslexia are starting to support the idea that there may also be distinct types of dyslexia that arise from different mechanisms.

Mathematical Reasoning

In earlier chapters, we examined two aspects of the development of children's mathematical thought. First, we considered infants' ability to sense numbers through estimations and perform simple "addition" and "subtraction" (see Chapter 5). Second, we saw how toddlers and preschoolers develop concepts of number through counting and other means (see Chapter 9). Here we will consider how more complex mathematical skills develop, especially those concerned with calculations.

Growth of Mathematical Skills The late preschool and elementary school years bring many advancements in children's mathematical skills. Three of the most important changes concern an understanding of mathematical concepts, skill in carrying out mathematical procedures, and the ability to solve math problems strategically (National Research Council, 2001).

First, a child has to develop a conceptual understanding of mathematical concepts. In Chapter 9, we touched on the child's early, intuitive grasp of counting. As a child's broader mathematical abilities develop, her conceptual understanding can greatly amplify her mathematical skills. For example, knowing that addition is commutative—that numbers can be summed in any order without affecting the answer—allows a child to know some arithmetic facts without having to be taught them. Thus, a child who learns that $2 + 5 = 7$ and knows that addition is commutative, also knows that $5 + 2 = 7$ without having to learn that sum separately. Similarly, a student who conceptually understands the number line will find it much easier to understand fractions as intermediate values between the familiar integers.

A second major development in children's mathematical abilities during elementary school has to do with skill in carrying out mathematical procedures, or *procedural fluency*. This ability involves being able to perform calculations efficiently and appropriately. An important component of procedural fluency is a highly practiced knowledge of sums and "times tables," usually for all pairs of numbers between 1 and 12. These memorized facts then form the basis for rapidly and accurately carrying out more sophisticated procedural skills, such as subtracting or multiplying three-digit numbers. In some cases, while learning a procedure, a child may unwittingly acquire a mistaken procedure that then has to be "unlearned." Thus, a child might assume that subtraction always involves subtracting the smaller number from the larger. When the child moves on to subtracting two-digit numbers, she might erroneously subtract the smaller digit in each place value from the larger, such that $84 - 67 = 23$ (instead of 17). Richer conceptual understanding often helps children avoid such procedural errors.

The third mathematical advancement during elementary school affects children's ability to solve problems strategically. These skills include the ability to set up a "story problem" appropriately and then solve it to attain a goal, such as figuring out how to divide bills and coins equally among friends. One key skill here is determining how to use the available information to represent a question mathematically rather than simply calculating with the first numbers encountered. Consider a problem in which five friends sell lemonade from 9:00 a.m. until 3:00 p.m. and make $24 in bills and $12 in coins. How much money does each person get if the earnings are divided equally? A child who fails to set up a careful model of the situation might start to inappropriately do calculations on numbers that seem to go together, such as dividing five friends into a time. Children who have good procedural fluency but lack strategic skills will often rush through calculations that do not make sense in terms of what the problem is really asking (Clark et al., 2010; Geary, 2013; Van der Ven et al., 2012).

Teaching Mathematics Children need plenty of instruction and practice in all three of these facets of mathematical skill. Unfortunately, in the history of teaching mathematics, educators have sometimes gone to extremes, stressing one facet of instruction to the point of neglecting others (Schoenfeld, 2004, 2007). Some schools may overemphasize procedural fluency to such an extent that children's understanding of what the problems mean (that is, conceptual understanding) and how to approach them (that is, strategic knowledge) are neglected, making the children more prone to applying procedures inappropriately. Other schools may emphasize math concepts and some broad strategies but neglect procedural fluencies. Their students may have a better sense of what the problems are asking but may then struggle with the computations. Perhaps considering the history of these opposing trends in math teaching will lead future educators to favor a more balanced approach.

Developing Problem-Solving Strategies As children's mathematical skills develop in middle childhood, they often choose different strategies to solve problems (Siegler, 2003). These developmental changes in strategy choice are among the most prominent changes in children's mathematical thought during the elementary and middle school years. Children might use several distinct strategies to perform arithmetic. For adding, children's most common strategies include: (1) *counting all*, which means counting up all the numbers in the sequence to reach the total, often using the fingers; (2) *counting on*, which means knowing that in a sum such as $7 + 5$, the first number means you start with *seven things* and the second number means you count *five more things*, either mentally or vocally saying "8, 9, 10, 11, 12"; (3) *reconstructing* the sum by comparing it with a known answer, such as knowing that 5 + 5 = 10 and then adding 2 to that sum to solve 7 + 5; and finally, (4) simply *retrieving* the sum from memory, the way many adults do for sums of single digits.

For multiplying, children use similar strategies, such as (1) *counting up* by one of the numbers being multiplied, such as solving 3 × 7 by counting 7, 14, 21; (2) *repeated addition*, such as solving 7 × 3 by adding 7 + 7 + 7; (3) *reconstructing* by comparing with a known answer, such as knowing that 5 × 3 = 15 and then adding two more 3s to get 21; and finally, (4) *retrieving* a known product from memory (Baroody & Ginsburg, 1986; Hopkins & Lawson, 2002; Miller & Paredes, 1990).

How do children's mathematical strategies change with development? Broadly speaking, children use increasingly efficient strategies as they get older—although there are also large individual differences, and even adults sometimes use earlier strategies (Lemaire & Lecacheur, 2011; Lemaire & Siegler, 1995; Siegler, 1989, 1995). At most ages, children know several strategies, and different ones emerge as the most efficient at different points in development (see Figure 10.13). More broadly, this can be seen as part of a larger effort to choose increasingly efficient strategies from among alternative solutions to a problem.

To study the development of problem-solving strategies, researchers often use microgenetic analysis of cognitive development. This is a method of repeatedly assessing children every few days or weeks rather than over multiyear intervals (see Chapter 1). This approach enables researchers to document children's shifts in strategy use as they happen and to refine their models accordingly.

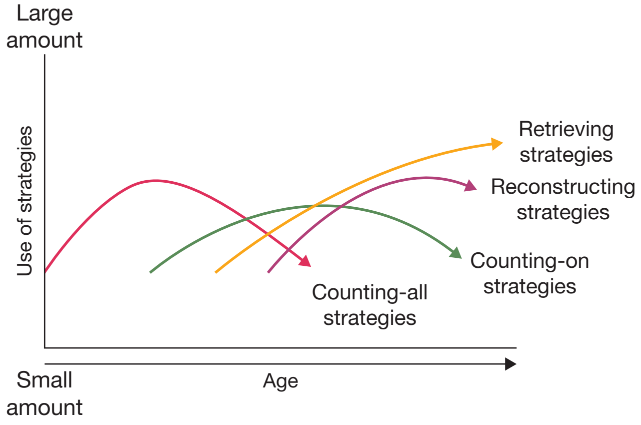

FIGURE 10.13 Mathematical strategies in development. As a child develops mathematical problem-solving strategies, several possible approaches to any given task are available in his repertoire. Here we see different strategies for addition problems. The child uses a series of overlapping strategies on any given problem, but the tendency to use particular approaches or strategies changes with age, typically shifting toward more efficient strategies. Nonetheless, even adults sometimes use early-developing strategies, such as counting-on strategies. Adapted from Hopkins & Lawson (2002).

This kind of research into strategy development has also inspired new instruction methods that focus on teaching children multiple strategies to solve certain kinds of problems. The assumption is that if children have a larger repertoire of strategies to choose from, they will be able to more easily and adaptively find the most efficient strategies for each problem (Torbeyns et al., 2005). Critics have pointed out that one disadvantage of these approaches is that they can sometimes neglect to foster children's deeper conceptual understanding. Children may simply learn to associate some strategies, and not necessarily the most efficient ones, with more success than others. In such cases, children do not necessarily have to think about what their strategies actually "mean" conceptually, so long as they produce the right answer.

This associative view of strategy development also seems incomplete, which has caused others to ask pointed questions about the developments in conceptual understanding that underlie changes in strategy use. For example, how do children begin using a new strategy in the first place? And when will they abandon a successful strategy for a new one that is conceptually more coherent? In addition, the associative accounts of strategy development have difficulty explaining broad changes that seem to involve reorganization of conceptual knowledge. For example, when children who have become proficient at adding start to multiply, the new multiplication strategies often temporarily disrupt the addition strategies, causing a drop in performance (Miller & Paredes, 1990). The drop seems to happen because the acquisition of new knowledge causes a reorganization of older knowledge rather than changing the strengths of associations to particular strategies.

Q: How do children's strategies tend to change with development in the area of mathematical reasoning skills?

As we have seen, the development of mathematical reasoning involves the emergence of several different component skills, and the best math teachers must address all these components at the same time. Even within a single component skill, such as choosing between problem-solving strategies, teachers can foster understanding at several levels, ranging from rote strategy performance to more sophisticated conceptual understanding of the different approaches to a problem. Teaching math well is challenging, and there are considerable variations in teacher effectiveness, not only across schools, but also across countries.

Over the past few decades, multiple studies have found that students in the United States do not perform as well on math competency tests as children in many other countries do (Beaton et al., 1996; Conway & Sloane, 2006; Kelly et al., 2000). Although scholars disagree on the best explanations for these differences, a few important reasons are widely acknowledged. First, mathematics instruction in countries where students have higher-ranking scores often involves richer conceptual explanations together with more mathematical drills, while instruction of children in lower-scoring countries often involves less conceptual exposure and less practice with drills (Askew et al., 2010; Hiebert et al., 2003; Stigler et al., 2000). Second, math teachers in high-scoring countries often have a deeper understanding of mathematics than U.S. math teachers do, often because they have more mathematics education (Conway & Sloane, 2006; Hiebert et al., 2003; Stigler et al., 1987). Finally, in many countries, such as Japan, mathematical skill is viewed as the result of a student's efforts, whereas in the United States, it is common to think of being good at math as a kind of inborn ability (House, 2006). This cultural difference may lead students in Japan and in other countries that emphasize improvement through effort to be more persistent in the face of failure. It may also spur families to invest in more tutoring, based on the belief that with enough practice and effort, most children can become quite skilled in math. These cultural differences can have job-related consequences. As technology becomes more sophisticated, even economically powerful countries may find themselves at a disadvantage if their workforce is less advanced in mathematical skills.

Using Symbolic Representations

Letters and numbers are some of the most common symbols used in advanced cultures, but the more ancient and universal uses of symbols involve drawings, maps, and models. It takes children many years to become skilled users of these kinds of symbols. We will consider how children learn to interpret symbols made by others—namely, maps and models—and then how they create their own symbols through drawings.

Using Maps and Models Almost all cultures use representational systems to illustrate spatial relations in the world (Gladwin, 1970). Unlike in reading and mathematics, the symbols in these representations are structured so that they directly correspond to spatial relations in the real world. On a road map, for example, the three-dimensional world is transformed into a two-dimensional rendering in which spatial relations are reproduced in miniature. To adults, the correspondences between these representations and their real-world counterparts may seem obvious, but interpreting them is not at all easy for younger children. These relations can even be difficult for adults to understand on less familiar kinds of maps, such as topographic maps, which show elevations along with other spatial information.

One important aspect of understanding maps and models involves learning which aspects of the representation correspond to which real-world counterparts. Colors are often irrelevant, for example, as are the materials that make up the maps or models. Children have to learn which correspondences are relevant and how the relevant representations map onto the real world (Flavell et al., 1990; Perner, 1991; Zaitchik, 1990). As we examine the developmental changes in children's use of maps, models, and pictures of the world, we can once again ask whether a special capacity for information processing emerges over the course of childhood, perhaps a spatial/geometric visualization ability. We can also ask about the role of more domain-general developments, such as the ability to conceive of different ways of representing the same physical systems in the real world. Some of the most provocative and intriguing studies in this area have investigated children's abilities to understand and use small-scale models and pictures of scenes (DeLoache, 2004). The developmental changes in these abilities can be quite large and can occur over very short intervals.

Between ages 2 and 3, children go from low levels of performance at using models and pictures to excellent performance. One way this change has been documented is by testing young children's understanding of the way a model represents the world. This understanding involves an awareness that models serve as **dual representations** in which they can be both physical objects in their own right and also symbols for other objects. In one series of tasks, an experimenter shows a child a small model of a room, "hides" an object in the model room while the child watches, and then asks the child to find the object in a corresponding, full-size room. For 2½-year-old children, such a task is extremely difficult and they often fail, but for 3-year-olds, the task is easy and they succeed admirably (DeLoache, 1987, 1989, 1991). The younger children can easily retrieve the hidden miniature object from the model room, showing that they do remember its location. They just do not seem to spontaneously connect the model to the full-scale room in a meaningful way. They also fail to realize how the scale sizes of some objects, such as chairs, require comparably scaled other objects, such as dolls that sit in those chairs (Ware et al., 2006).

Interestingly, when using pictures of rooms instead of small three-dimensional models, children show a shift in their mapping ability at an earlier age, failing at 2 years old but succeeding at 2½ years old (DeLoache, 1987). There are several possible explanations for children's success in mapping between pictures and the real world at an earlier age (DeLoache, 2004; DeLoache et al., 2003). One theory speculates about difficulties with dual representations and keeping them separate (Leslie, 1987). The child is trying not to confuse the model with reality and not to blend the real object and the model together. Perhaps the confusion occurs more often with three-dimensional models than with pictures, where the differences are more obvious. Another explanation may involve practice. In our culture, at least, children have far more experience early on with pictures than with three-dimensional models of spatial layout (Uttal, 2005).

What ultimately causes the shift in children's understanding of maps and models? One line of insight came from a study in which the experimenter explained to the child that the three-dimensional model was the "real" room but it had been shrunk by a magic "shrinking machine" (DeLoache et al., 1997; see Figure 10.14). Then, after the child watched the researcher hide the miniature object, the model was removed and said to be "enlarged," and the child was asked to find the object in the full-size room. In this case, 2½-year-olds did much better at finding the hidden object in the real room. One likely reason that the children did so much better in this case is that the "shrinking room" description provided a causal account of how to link the model to the full-scale environment. It made clear what sort of relations between the model and the real room were important and therefore made much clearer how the model could be used as information to guide a search. This research implies that strategy and knowledge are important components of children's understanding of spatial relations (Liben, 1999).

Finally, the development of mapping and modeling skills is not an all-or-none affair in which children under a certain age simply cannot use a map or a model to guide their actions (Newcombe et al., 2013). Instead, children show a gradual increase in their appreciation of increasingly subtle aspects of maps and models. Moreover, using these kinds of representations may help support other kinds of developments in spatial cognition, just as the broader developments in spatial cognition may help foster increased mapping and modeling skills (Uttal, 2000).

Q: How do young children differ from older children in their abilities to use models?

Children's Drawings Some time after children come to understand symbolic representations such as maps and models, they develop the ability to create their own representations. The drawings that many parents save provide a record of changes in a child's symbolic skills from the early preschool years into elementary school. Regardless of an individual's artistic talent, these drawings reveal some general patterns in the development of symbolic skills.

Before age 3, most children simply scribble, and each new scribble looks very much like the last (Golomb, 2004). Yet, even in these early drawings, children show some grasp of the way the artist's intentions link the artist, the drawing, and the drawn object. In one study, 2-year-olds watched an adult who was looking at a balloon make a simple drawing. When asked what the drawing was, the children declared that it was of the balloon, even though it was just a circle with a line coming down from it. If the adult instead was drawing while looking at a lollipop, the children described the same picture as a lollipop (Preissler & Bloom, 2008).

In their third year, children start to draw simple figures that crudely represent the objects that they see. Thus, they might

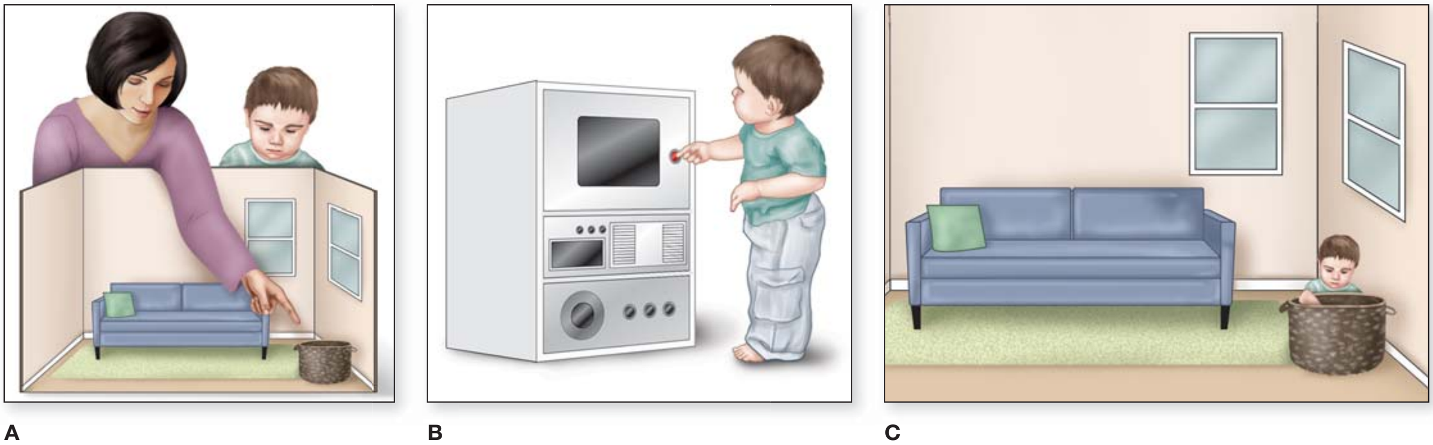

FIGURE 10.14 **Studying model use with the "shrinking room." (A)** After observing an object being hidden in a small model of a room, children younger than about 3 often have difficulty locating a corresponding object in the real room. When 3-year-old children are told that the model is the real room after it was "shrunk" by **(B)** a "shrinking machine," they can better understand the relation between the model and the real room and locate the object in the real room **(C)**.

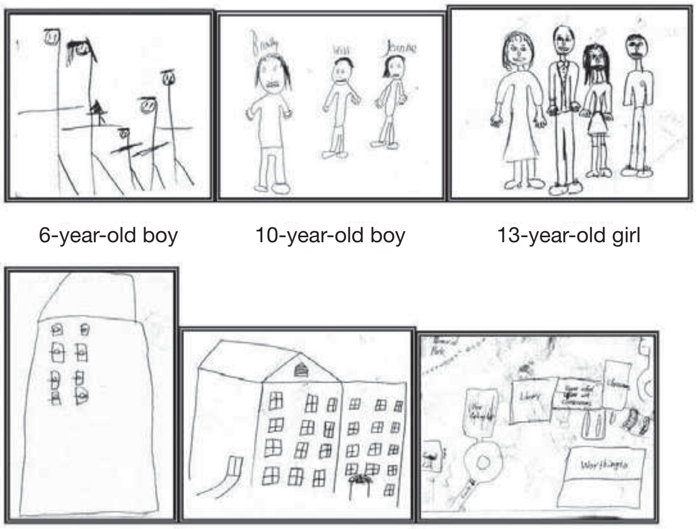
depict a person as an oval with lines coming out of it. The crudeness of these drawings stems from several factors. First, their motor skills are limited and not precisely controlled. (As a parallel, imagine how you would fare at drawing a figure with a pencil between your toes.) Second, their understanding of how to translate a three-dimensional object into a two-dimensional picture may be limited, resulting in more distortions and simplifications, such as not taking into account the effects of distance on perceived size (Golomb, 2004). Third, their attention to the properties of an object is limited, and so they may fail to depict various features of an object or scene; as their knowledge of the objects in the world grows more complex, however, they may use that knowledge to make sure that their drawings have the right features, such as five fingers on a hand and five toes on a foot (Goodnow, 1977). Finally, children may not be aware of particular cultural conventions that affect the way they should portray objects and their relations; as they learn these conventions, however, their drawings will become more detailed (Cherney et al., 2006). For example, children in North America learn to draw more smiles on people than Japanese children, who in turn learn to draw more details on each person. Similarly, different groups may vary in whether they tend to draw aerial views of a scene such as a playground or a ground-level horizontal view, and this will affect how children in those cultures learn to depict a scene.

Children seem to be especially fond of drawing human figures and buildings. As a result, there have been many studies of their evolving skills in drawing these two kinds of objects. As shown in Figure 10.15, there is a clear elaboration of detail and accuracy as children grow older. In addition, the spatial arrangements of objects, such as family members or a group of buildings, become more accurate as children seem to develop a sense of depicting a coherent scene rather than simply a collection of individual objects. One fascinating aspect of children's drawing is that most children are strongly motivated to draw, suggesting a drive to create pictorial representations that goes beyond parents' and teachers' encouragement.



6-year-old boy 10-year-old boy 13-year-old girl

5-year-old girl 10-year-old boy 13-year-old boy

FIGURE 10.15 Drawing skills and age. Children's drawings improve greatly with age in terms of the accuracy, detail, and spatial layout of objects, as shown in these drawings of family and school by children of different ages. The children's emerging skills represent a convergence of increasing motor skills, growing understanding of drawing techniques, growing knowledge of objects and their properties, and expanding awareness of cultural conventions for representations. From Cherney et al. (2006).

Conclusions

There is no single story about how cognitive skills develop, but from the vast amounts of research in this area, some powerful themes emerge. First and foremost is the extraordinary importance of expertise. When we consider abilities such as memory and attention, the dramatic developmental changes that occur with respect to those skills cannot be understood without considering the contributions of expertise itself, independent of age. Having a thorough knowledge of a given topic improves people's memory for information in that area to such an extent that expertise often influences memory performance more than age does. Within a given area, child experts can remember more than adult novices. Expert-level reading involves automatic, effortless decoding of letters into meanings, which requires enormous amounts of practice. Mathematical skills, likewise, do not develop as flashes of insight but rather require surprisingly large amounts of practice.

In addition to these effects of expertise within specific domains, there are also some broader, cross-domain effects on the development of cognitive skills. For one, being a "universal novice," as most young children are, puts the child in a very different state from an adult, who is a novice in some areas but an expert in others. To develop a new area of knowledge, an adult can tap into other knowledge bases for strategies, relationships, and metacognitive insights to apply to the new learning. The child has far fewer resources of this sort and as a result is less able to apply previously successful strategies, draw analogies, or step back and consider what it means to have a high level of skill in a particular area. Yet, as children gain understanding in several related domains, as with the development of scientific reasoning skills, they start to see relationships between these domains and common higher-order patterns.

Children's increasingly effective use of strategies—to improve memory, manage attention, and solve problems—is another theme that pervades many aspects of cognitive development. Although young preschoolers rarely use strategies spontaneously, they are capable of doing so, especially for fairly simple tasks that draw on very familiar domains of knowledge. Moreover, like adults, young children are more likely to use strategies within their areas of expertise. For many kinds of tasks, children are often capable of using a huge array of strategies. In these cases, development consists of choosing between strategies in increasingly efficient and effective ways. Careful microgenetic analysis of skill development has shown the evolution of patterns of strategy choice, although it has been less successful in explaining how strategies originate in the first place and why certain ineffective strategies persevere.

One important influence on children's ability to use cognitive strategies is their developing understanding of how the mind works. Children become increasingly competent at metacognition, learning more about what memory and attention are and how they are used in daily life. Their metacognitive understanding is part of their emerging theories of mind and is linked to their ability to use strategies. More sophisticated metacognition helps children see more clearly when and why they need to use particular strategies. In addition, increasing executive skills can build on metacognitive awareness of such things as distracting stimuli and the need to inhibit attention to those stimuli.

Finally, research on the development of cognitive skills has uncovered important differences in the ways that children apply cognitive skills to information they find meaningful rather than arbitrary. Going forward, the most productive ways of studying the development of cognitive skills will invariably be concerned with how children remember, pay attention, reason, and perfect specific cognitive skills in the real world, focusing on sensible goals and naturalistic bodies of information. Such an ecological approach to the study of these cognitive skills has been increasingly championed in adult cognitive science, but its successes in developmental research are even greater and more obvious.

STUDY AND REVIEW

SUMMARY

Memory

- Memory at all ages requires encoding, storage, and retrieval, and each process is associated with specific neural systems. In addition, information is first represented in high-capacity, very rapid sensory memories, then in more limited capacity working memories, and finally in high-capacity long-term memories. Information held in working memory creates a temporary storage platform that can support reasoning, problem solving, and many other cognitive tasks.
- The memory system can be broken down into various components, most notably implicit and explicit memory. While implicit memory, which is memory for information or behavior that is outside of conscious awareness, may be evolutionarily more ancient and perhaps more dominant in the young child, at least some explicit memories, which are memories for information or behavior that is consciously recalled, may also be from quite early in life and from well before the onset of spoken language. There is also a contrast between declarative memory, which is the memory for events or facts, and procedural memory, which is the memory for how to perform actions or procedures. And there is a contrast between semantic memory, the memory for knowledge about the world, and episodic memory, the memory for specific events experienced at a particular time and place, including autobiographical memories, which are memories of an individual's own life journey.
- A major change in the development of memory involves improvements in the use of strategies for storing and retrieving information. Developing metamemory, or having a sense of what memory is and how it works, seems to foster the use of strategies. Expertise in a specific domain also improves memory performance for domain-relevant information. Quite young children with expertise in a particular local domain can far outperform adults on memory tasks in that domain, while doing poorly relative to adults in other domains.
- Early episodic memories, which are usually autobiographical in nature and consist of memories of discrete events that an individual experiences prior to 2½ years of age, seem to be inaccessible to older children and adults, a phenomenon called infantile amnesia. People's earliest accessible memories are from their early preschool years, about the same time when the ability to embed specific memories in larger narrative structures significantly improves. The reasons for infantile amnesia are still not fully understood, but they likely relate to changes in specific brain regions, changes in how memories are encoded and linked to information about context, and changes in how children are able to use memory-triggering cues.

Attention

- Attention is an active exploratory system. Its development during the elementary school years involves the increasing ability to track information of interest and not be distracted by irrelevant information.
- Attention involves the interacting processes of orienting, alerting, and executive functioning. Each of these processes tends to be associated with different neural systems, developmental time courses, and genetic correlates.
- Executive functioning consists of the cognitive activities involved in goal-directed tasks and problem solving. Its three major components are inhibitory control, error correction/shifting, and working memory, which work together in an integrated fashion. Dramatic developmental changes in executive functioning take place during the preschool and elementary school years.
- Attention develops with considerable support from the growth of strategies. These in turn are fostered by an increase in metacognitive awareness—namely, the ability to understand a situation's attentional demands and the ways of manipulating internal and external factors to facilitate attention. Executive functioning also helps direct strategy choice and use.
- Attention deficit hyperactivity disorder (ADHD) consists of behaviors involving inattention, hyperactivity, and impulsivity, and commonly includes difficulties with staying on task and/or disengaging appropriately from activities. Although ADHD diagnoses have increased significantly in recent years, the cognitive and biological bases for the deficit are not yet well understood. There is no question that some children and adults have biologically based attention-related disorders, but because of the many reasons that ADHD may be misdiagnosed, there may be considerably fewer people with the disorder than the number currently diagnosed and medicated for it.

Reasoning and Thinking about Knowledge

- Many kinds of reasoning abilities undergo important developmental changes during the elementary and middle school years. These changes do not cause qualitative differences in the types of reasoning children can use. Instead, development seems to proceed more on a domain-by-domain basis, as increasingly sophisticated knowledge in one area can then support more advanced forms of reasoning.
- Early views held that young children could not reason in terms of analogies, but later studies showed clear evidence of analogical reasoning skills in preschoolers when they were asked about areas in which they had well-developed knowledge. In contrast, when children (or adults) know very little about a particular area, they will be unable to reason about it by using analogies, a skill that depends on understanding important relationships between different domains and using information about one domain to understand corresponding information in another domain.
- Scientific reasoning involves several related abilities, including the ability to consider hypotheses and evaluate evidence for them and the ability to build coherent theories and models about the world. This kind of reasoning continues to develop for much of the lifespan, but it is not completely outside the grasp of young children. When sufficiently simple, familiar domains are involved, and when the theories and structures are simplified as well, young children are able to make hypotheses, consider evidence, and show some coherence in their explanations for the patterns they observe.
- Metacognition is the ability to think about cognition—to think about memory, attention, and the nature of knowledge. Metacognitive skills develop considerably during the elementary school years, often more rapidly in areas where children have high levels of expertise.
- Children get better at seeking out information and closing the gaps in their own understanding and knowledge as they gain an understanding of what others know and who their culture's experts are in particular domains. Even preschoolers are sensitive to this "division of cognitive labor" in a community. Children become more inclined to think about fields of knowledge in terms of different disciplines during the elementary and middle school years. As they grow older, they also tend to improve at estimating how much they know, but even adults retain some illusions about what they know.

Three Specific Skills

- Learning to read depends on phonological awareness developed through extensive exposure to the links between the sound patterns of a language and the visual symbols that represent those patterns.
- Deficits in phonological processing, despite normal intelligence, good motivation to read, and early exposure to reading, account for most cases of dyslexia. But many children with dyslexia can learn to read well, even though they typically find the process more difficult than do children who do not have dyslexia.
- The development of mathematical reasoning seems best understood not as a series of stages of mathematical ability, but as the development of more flexible and adaptive ways of using mathematics-related strategies.
- The ability to use maps and models as representations of layout develops a great deal during the preschool and early elementary school years. Younger children seem to have trouble understanding how a small model of a room can represent the room and yet be different from it.
- Children's drawing ability also undergoes major changes during the preschool and elementary school years. Improvements depend on developments in children's motor abilities, sense of how to represent three-dimensional images, detailed knowledge about the things they draw, and sense of cultural norms.

THOUGHT QUESTIONS

1. Imagine that you are employed by the court system in a large city as an expert on child witnesses. Your task is to design interview techniques that are most likely to yield accurate information. Given what you know about the development of memory, how might you design interviews for children who are 3, 5, and 7 years old?
2. Two parents disagree about whether their 7-year-old son's difficulties in school justify long-term usage of Ritalin, as suggested by one pediatrician but not by another. What considerations would be most helpful in attempting to resolve their disagreement?
3. Young children may be more prone to trust the testimony of others. In what ways might this higher level of trust make sense for younger children? As children start to be more discriminating in what and whom they trust, in what areas might this increased skepticism first appear?
4. Many young children have extensive exposure to video games in which they learn to navigate a virtual space and engage in various actions. Would this kind of experience help their developing ability to learn how to use maps and models to represent the actual world, or would it be of no help and perhaps even a hindrance? Consider concrete examples and reasons to support your view.
5. In Chapter 8, we considered theories of how the acquisition of language might influence the nature of thought. Comparable arguments have been made for how the acquisition of literacy influences the nature of thought. Consider some ways in which emerging literacy might change the nature of thought, and then evaluate their plausibility.

KEY TERMS

alerting (p. 360)
analogical reasoning (p. 366)
attentional schema (p. 359)
attention-deficit/hyperactivity disorder (ADHD) (p. 364)

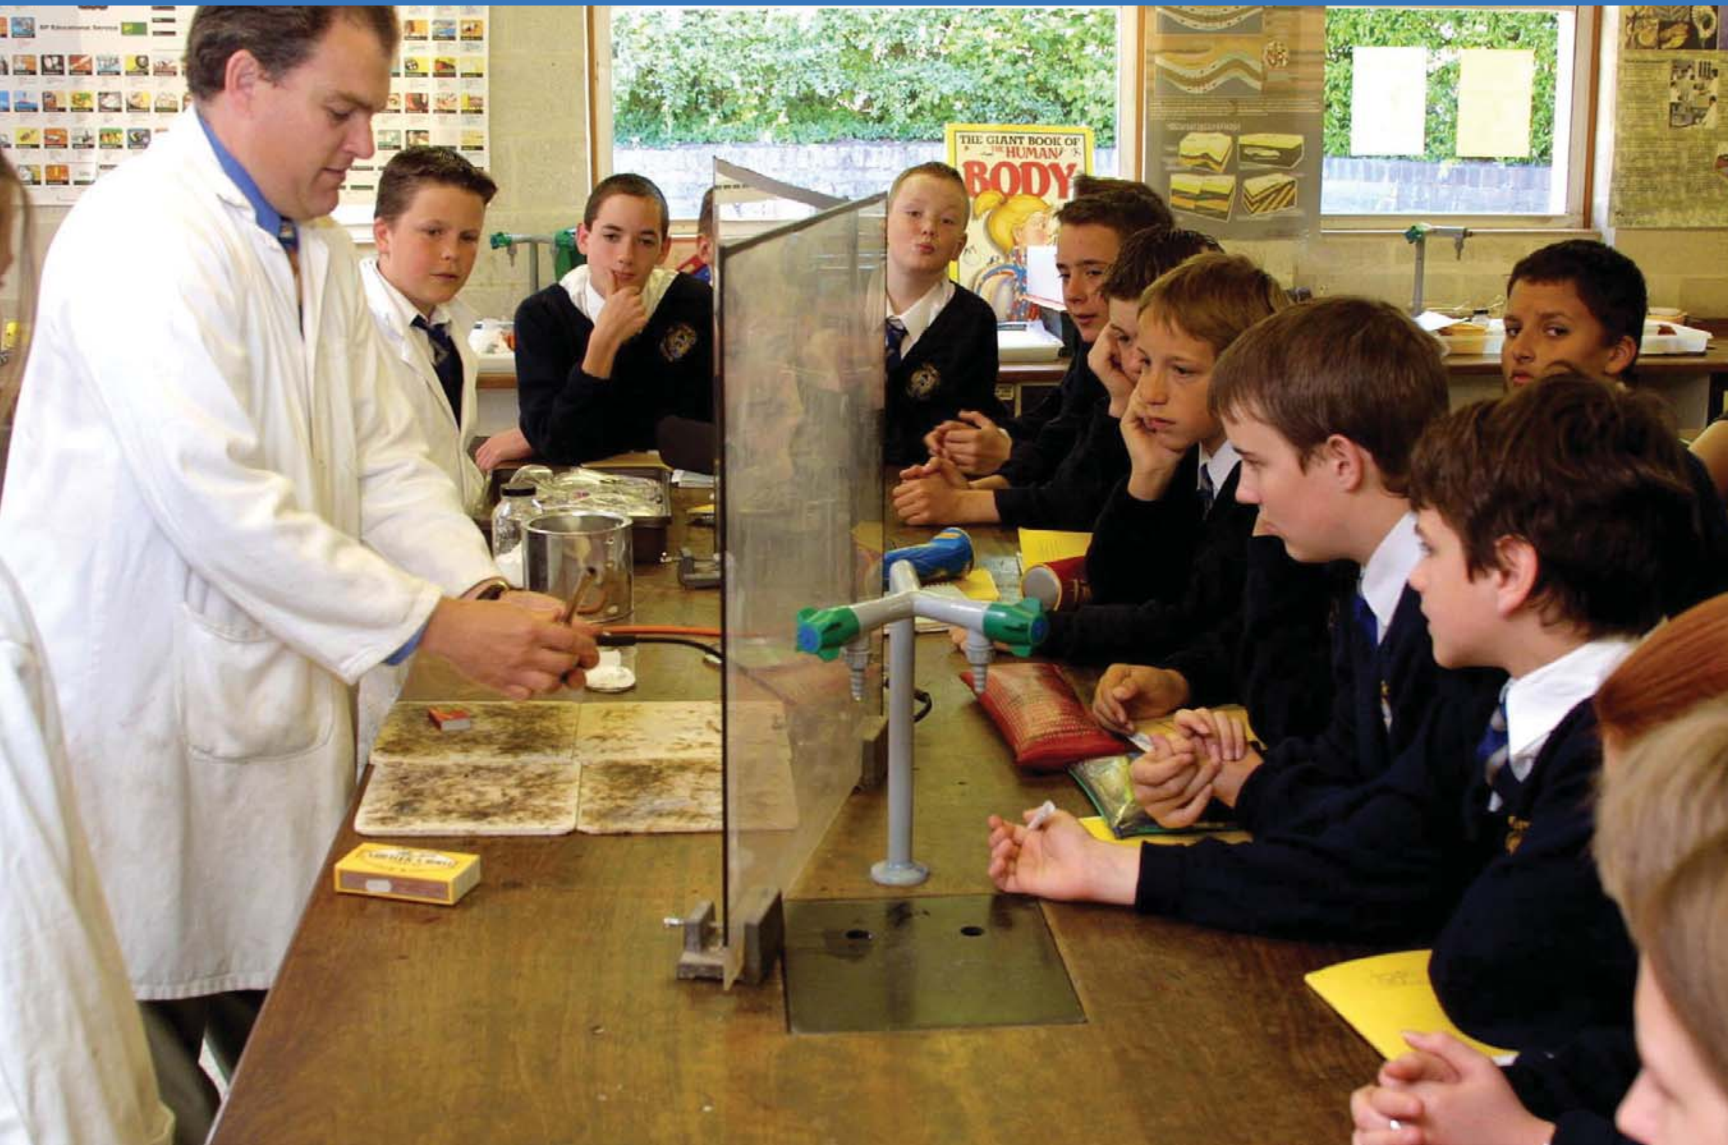
Conclusions

Summary



THE GIANT BOOK OF THE HUMAN BODY

Beginning in 1944, the British government's Eleven Plus exam provoked waves of anxiety in generations of 11-year-olds until its widespread use was discontinued in 1976. The Eleven Plus exam was a screening test used to determine what kind of school a child would attend thereafter (see Figure 11.1). Moreover, it was clearly meant to be a test of intelligence. One of its chief designers, the British educational psychologist Cyril L. Burt, was obsessed with the idea of measuring intelligence to identify people of different intellectual abilities. Burt was accused of fabricating data to support his views that intelligence is inherited (Gould, 1981; Kamin, 1974), an accusation that was subsequently contested (Mackintosh, 1995).

The Eleven Plus worked much like a real-life version of the Sorting Hat used in Harry Potter books. The test could heavily influence a child's future even before the child entered middle school. Depending on test scores, children were "streamed" either into an elite educational track or into tracks leading toward much less prestigious futures. Children who scored in approximately the top 20 percent on the Eleven Plus were sent to grammar school—the first step leading to a top university and a high-ranking profession. The other 80 percent of children soon came to be seen as having "failed" the Eleven Plus, and from age 11 on, they were likely destined for blue-collar or other nonprofessional jobs. Although it was possible for a child who "failed" the Eleven Plus but performed exceedingly well in school to be moved up to the grammar school track after age 11, this rarely happened.

FIGURE 11.1 The Eleven Plus exam. For these young students in 1950, the Eleven Plus exam, which had many of the hallmarks of intelligence tests, could have an enormous influence on their future school choices and careers.

Opposition to the Eleven Plus grew over time, and people began to question whether it provided an equally accurate measurement of the abilities of children from different socioeconomic classes and minority groups. Some also worried that the test favored children who matured early over those who did not hit their stride academically until their teen years. As a result of this opposition, the Eleven Plus was scrapped as a national test in the United Kingdom in 1976. Since then, the distinctions between types of British schools have become less rigid, and most British school systems now use a variety of measures to assess children over a longer period.

The Eleven Plus story is not over, however. The test is still used in several UK counties and in much of Northern Ireland. Many countries that were members of the British Commonwealth, such as those in the Caribbean, also still give most students a version of the Eleven Plus, often under different names, such as the Common Entrance Examination. When members of those communities are polled about whether the test should be discontinued, as it was in the United Kingdom, many people favor its preservation. They argue that it helps identify talented children, regardless of class or background, and guides them toward needed educational resources (*Times of London*, 2005). The Eleven Plus story powerfully demonstrates how views of intelligence can be translated into public policies that influence the education and intellectual development of millions of children.

In several earlier chapters, we considered cognitive development primarily in terms of common developmental patterns, focusing on how all children come to understand and think about the world. Similarly, in this chapter, we will consider some common patterns that theorists have proposed about how intelligence develops. Some of these ideas, like the notion that children's intelligence increases continuously with age, often turn out to be misleading. Others, such as ways of encouraging active learning in the classroom, seem to yield impressive results. For much of this chapter, however, we will shift emphasis to the development of thought and knowledge, with a focus on the differences between individuals. Individual differences are central to the study of intelligence, as the very notion of intelligence assumes that people have different levels or kinds of intelligence. In developmental research, there are two ways to compare the intelligence of different individuals. We can ask how age groups as a whole differ in terms of facets of intelligence, and we can ask how differences in intelligence between individuals within any age group occur. We will consider both questions but will tend to focus on the factors that are associated with differences among children in the same age group. This focus, however, raises further questions about the developmental processes that lead to such differences, both within the child and because of external influences. As we will see, the study of intelligence is also intimately linked to the broader social context and culture.

We will begin by examining the nature of intelligence and some of the theories developed to explain it. Among these theories, the psychometric approach has been most prominent. It focuses on designing ways to measure and quantify forms of analytical intelligence closely related to academic success. We will consider how some of these traditional measurements work, the kinds of developmental outcomes that often correlate with test performance, and some of the reasons behind these relationships. Alternative views of intelligence highlight different facets of intellectual ability as well as the possibility of multiple types of intelligence.

We will then consider some of the ways researchers have attempted to measure intelligence in infancy and what their findings imply about the early origins of intelligence and the extent to which there is a genetic basis for intelligence. We will examine findings that certain infant measures correlate strongly with intelligence test scores many years later and ask what such correlations might mean. We will also look at the heritability of intelligence and how it changes with age, with the seemingly surprising finding that heritability can often rise in late childhood and adolescence rather than drop, as might be predicted from simplistic views of there being more environmental effects the older a child is and hence lower heritability.

Next we will explore the highly controversial area of possible group differences in intelligence and what bases there might be for such differences. We will see that group differences certainly do occur on intelligence tests, but that such differences may mean something very different from intrinsic differences in intellectual abilities. A related topic concerns the nature of environmental influences on intelligence. What sorts of environments, ranging from intellectual experiences to social threats, seem to have an influence on the development of intelligence? Moreover, what is the best explanation for the apparent dramatic rise in intelligence test scores throughout the world for much of the second half of the twentieth century?

In the context of intelligence research, we will turn to a discussion of the many ways that schooling affects children's development. We will consider useful ways of characterizing the wide variety of school types, the roles that schools serve in a society, and how the strengths and weaknesses of individual students interact with specific kinds of teaching; this is an academic version of the idea of "goodness of fit" between a child and his environment, previously encountered in Chapter 7. Finally, we will consider how the highly valued trait of creativity relates to the study of intelligence and cultural institutions such as schools.

What Is Intelligence?

Although people routinely judge other people's intelligence, there is no simple way to describe what intelligence is. Some people emphasize quantitative skills, others stress literacy, while still others focus on creativity and the ability to deal with novelty. Even among academic psychologists, who might seem likely to show some consensus on the matter, definitions of intelligence vary as much as they do among laypeople (Sternberg & Detterman, 1986).

The definitions become even more diverse across a wider range of groups and cultures. One group favors speed of thinking while another favors accuracy. Still others favor cultivating extraordinary skill in one special area, while others value having a wide range of above-average abilities or adeptly handling novel situations (Super, 1983). Definitions of intelligence may also stress different types of abilities, with one group emphasizing verbal skills and another emphasizing spatial, artistic, or mathematical skills (Heath, 1983). This range of views illustrates the need to develop ways of measuring and quantifying intelligence to describe how it varies across individuals. In psychology, this has traditionally been done by adopting the psychometric approach.

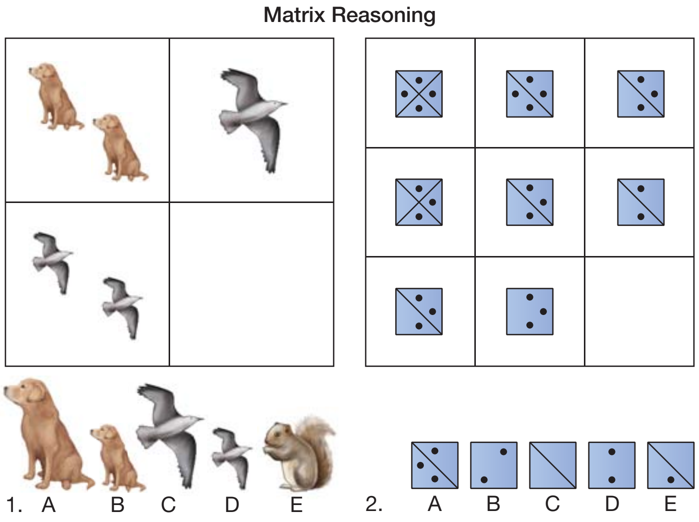
The Psychometric Approach

The **psychometric approach** emphasizes cognitive skills closely linked to success in school and focuses on developing quantitative measures of intelligence through such means as intelligence tests. Although the psychometric approach will occupy most of our discussion, researchers have also proposed other views of intelligence.

Psychometric tests were originally designed at the beginning of the twentieth century by the French psychologist Alfred Binet. He designed his tests to distinguish mentally retarded children from other children of the same age, including those with other behavioral problems (Binet, 1903). Schools considered the tests immensely valuable for figuring out which children to place in remedial education. Moreover, the tests seemed to work well in the sense that teachers and parents felt that the tests were identifying roughly those children who were indeed in need of remedial education.

Binet's tests were based on the idea of quantifying children's intelligence in terms of an **intelligence quotient**, or **IQ**. The term originally referred to a test score based on the following calculation: a child's intellectual abilities were tested to determine her "mental age," and this score was divided by her chronological age. The answer was then multiplied by 100. Thus, a 10-year-old with a "mental age" score that was average for 10-year-olds would have an IQ of 100 (because 10/10 × 100 = 100), and a 10-year-old with a score that was average for 12-year-olds would have an IQ of 120 (12/10 × 100 = 120), and so on. This notion that intelligence increases continuously with age proved to be a very crude way of describing its development, and current measures no longer divide mental age by chronological age. The terms *IQ* and *IQ test* have persisted, however.

Q: For what purposes were psychometric tests originally designed?



Number Series
3. 2, 4, 6, 8, __, __
4. 3, 6, 3, 6, __, __
5. 1, 5, 4, 2, 6, 5, __, __
6. 2, 4, 3, 9, 4, 16, __, __

Analogies
7. brother: sister ⟶ father: __________
A. child B. mother C. cousin D. friend
8. joke: humor ⟶ law: __________
A. lawyer B. mercy C. courts D. justice

FIGURE 11.2 Psychometric tests. The examples shown here are similar to the items used on standardized tests for analytical intelligence. From Gottfredson (1998).

Today, the most common intelligence tests are the Wechsler Intelligence Scale for Children (WISC), the Wechsler Adult Intelligence Scale (WAIS), and the Stanford-Binet Intelligence Scales. Traditionally, the Stanford-Binet Intelligence Scales were so broad that they could be used on populations ranging from 2-year-old children to adults. When the tests were tailored for children, the children's versions were quite similar to the adult versions but contained obvious simplifications to make them appropriate for children. Table 11.1 illustrates the sorts of items used on children's tests. The sample questions in Figure 11.2 are similar to test items on common intelligence tests. As these examples show, distinct parts of the tests assess different kinds of intellectual abilities. Taken together, the scores on the various subtests are meant to provide an overall assessment of intelligence.

The latest version of the WISC, the WISC-IV, has four major components: the verbal comprehension index (VCI), the perceptual reasoning index (PRI), the processing speed index (PSI), and the working memory index (WMI). The **verbal comprehension index** measures both comprehension of language-based materials and the ability to solve problems posed in words. It includes questions designed to measure vocabulary, general knowledge about the world, and some questions that require abstract reasoning about similarities. The **perceptual reasoning index** uses pictures and other visual materials and largely avoids using language. It includes items testing the ability to (1) complete missing details in pictures, (2) arrange pictures to form a reasonable sequence of events, and (3) use blocks to re-create abstract designs. The **processing speed index** measures how quickly a child seems to process information in tasks ranging from time spent searching for a target shape among a much larger set of shapes to tasks identifying all instances of a target image—for example, an animal or a specific number—in a very cluttered field of diverse objects. The **working memory index** assesses performance on tasks that draw on working memory. It includes doing simple arithmetic tasks and remembering strings of digits either backwards or forwards. These subtests yield separate scores on components such as language, mathematics, and visual/spatial ability. The subscores are used to calculate an overall test score, colloquially known as the IQ.

Verbal Comprehension Index (VCI)	Perceptual Reasoning Index (PRI)	Processing Speed Index (PSI)	Working Memory Index (WMI)
What is a taxi used for?	What is wrong with this picture [*of a girl combing her hair with a comb that has no teeth*]?	Look through these two pages with images of different objects and animals and tell me how many times you see a lion.	Bill is 3 years older than Bob and 6 years younger than Fred. If Fred is 12, how old is Bill?
A shoe is to a foot as a glove is to what?	Can you put these 4 pictures [*showing a person getting a flat tire and fixing it*] in the correct order?	Here is a shape. Is there another shape [*from a sheet with many different shapes*] like this one?	Mary won 10% more marbles than Sue. Sue won 30 marbles. How many marbles did Mary win?

TABLE 11.1 Items like those on the WISC-IV test. These items are similar to items used to assess children's performance on the four components of the WISC-IV.

Q: What is the intelligence quotient, or IQ? How does the modern measurement differ from the one invented by Alfred Binet?

Interpreting Test Scores Intelligence test scores are often interpreted in terms of where they fall on a **bell curve**, or **normal distribution curve**, representing the range and distribution of scores in the population. Figure 11.3 (gold numbers) shows a curve for intelligence test scores and how such scores would be ideally distributed in a large population. The highest part of the curve at the center represents the most common score in the population. Because the normal curve illustrates the outcome with an ideal sample population, the most common score falls right in the middle, at the mean. Tails on the far ends of the curve represent the least common scores.

To understand the normal curve, imagine a plot of the weights of 1,000 male college freshmen (green numbers). The average (mean) weight in the group might be around 158 pounds. But all men aren't exactly the average weight. Their weights are distributed around the mean in a pattern that can be plotted as a bell-shaped curve. Most men in the group will weigh close to the mean, and as we move farther from the mean, we will find an ever-declining number of students. Approximately 68 percent of them (680 men) will weigh between 137 pounds and 179 pounds. About 95 percent of them (950 men) will have weights between 116 and 200 pounds. The downward sloping sides of the normal curve represent the steady decline in the number of students at each weight as we move away from the mean. Thus, in this distribution, only 25 students out of 1,000 will weigh more than 200 pounds. If claims of gaining the "freshman 15" are true, then the whole curve will shift to the right 15 pounds for sophomore men, resulting in a new mean of 173 pounds.

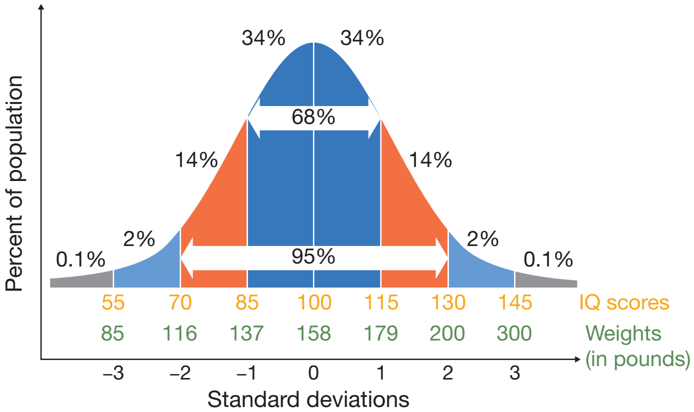


FIGURE 11.3 The normal distribution curve, or bell curve. The bell curve shown here is an idealized model showing standard deviations from a mean. The numbers in gold indicate IQ scores, and the numbers in green indicate the weights of a group of college freshman.

In our example of freshman weights, as in any data set, the **standard deviation** is a way of measuring how much the values tend to vary from the mean. On any normal curve, 68 percent of the scores fall within one standard deviation above or below the mean, and 95 percent of the scores fall within two standard deviations of the mean. In the weight example, the standard deviation is 21 pounds, but it could be larger or smaller in a different population. For example, if the population was made up of male athletes ranging from divers to linebackers, the standard deviation might be larger—say, 30 pounds. If the population was limited to divers, the standard deviation might be only 10 pounds.

Let us now look at standard deviations in the intelligence test scores shown in Figure 11.3. The vertical lines correspond to the standard deviations; as you can see, these tests are designed to have a standard deviation of 15 points. Therefore, roughly 68 percent of people tested will have scores between 85 and 115 (within one standard deviation of the mean), 95 percent will have scores between 70 and 130 (within two standard deviations of the mean), and 99.7 percent will have scores between 55 and 145 (within three standard deviations of the mean). Put differently, a score of 131 would put someone in the upper 2.5 percent of the population for which the test was designed.

Q: What percent of people have IQ scores above three standard deviations?

Correlates of Intelligence Test Scores Infant habituation scores partially predict later intelligence test scores, and from age 5 on, intelligence test scores are increasingly good at predicting later intelligence test scores. But if early test scores correlated only with later ones, they would be of little importance. What other aspects of behavior are related to these scores? In fact, intelligence test scores seem to correlate with many other measures over the lifespan and in many cases provide more accurate predictors than any other available measures. As always, "prediction" simply refers to a population-wide correlation over time. It should not be confused with cause, since many other variables are also at work.

One of the driving forces behind the development and use of intelligence tests has been the desire to predict individual success in school. Intelligence tests predict academic success, measured in terms of grades, with a correlation of approximately .50 (McGrew & Knopik, 1993; Neisser et al., 1996; Sternberg et al., 2001). Although this correlation is significant, it still means that most of the individual variation in school grades is accounted for by factors—for example, degree of self-control (Duckworth et al., 2012). Nonetheless, no other measure, such as assessments of students' motivation or anxiety, is as strong a predictor of school performance. At all ages, intelligence test scores and academic performance are roughly correlated (Chamorro-Premuzic & Furnham, 2005; Frey & Detterman, 2004; Richardson et al., 2012).

We all know of some glaring exceptions to these broad patterns: the high school student with perfect SAT scores who goes on to earn below-average college grades, or the student with low SATs who excels in every college course. Given the .50 correlation between scores and grades, the differences in test scores can explain only about 25 percent of the variance in grades, so such outcomes should not be surprising. Still, if you had to pick a single factor with which to predict academic performance, you would be hard pressed to find a better one than intelligence tests.

Closely related to their correlation with grades, intelligence tests also tend to predict the number of years of schooling that a child will receive. It makes sense that students who do better in school are more likely to stay in school because they find it rewarding. The correlation between IQ scores and years of schooling is normally about .55 (Neisser et al., 1996). Intelligence test scores are also statistically significant, though somewhat weaker, predictors of level of employment and wealth (Jencks, 1979; Sternberg et al., 2001). In Western industrialized cultures, however, some degree of relationship between intelligence test scores and level of employment should not be surprising. If those scores also correlate with grades and the number of years of schooling, then better grades and more years in school may more directly explain certain professional achievements and associated higher income levels. In cultures without such tight links between school performance and high-paying jobs, intelligence test scores do not predict high-status jobs or wealth (Sternberg et al., 2001).

Finally, IQ scores also correlate with success in the workplace. Almost any positive measure of workplace performance, whether it is peer or supervisor ratings or productivity, is correlated with IQ score (Hernstein & Murray, 1994). In addition, those who score exceptionally well on IQ tests by age 13 (the top 1 out of 10,000) do have a higher tendency to have outstanding career achievements 30 years later (Kell et al., 2013). Many find this relationship disconcerting, but the correlation does not mean that IQ tests measure the most important factors in determining workplace success. Almost everyone who has studied the workplace is convinced that social and interpersonal skills are more important. These skills include leadership, conflict resolution, consensus building, risk assessment, and persistence, among many others. But with more than 100 years of concerted efforts at constructing the best possible intelligence tests and far fewer years spent developing tests for these other kinds of abilities, it is not surprising that no other strong predictors are yet available. This may well change as tests for these other abilities become more refined (Boyatzis et al., 2012; Rosete & Ciarrochi, 2005; Sternberg et al., 2001).

Q: What aspects of behavior are at least partially correlated with intelligence test performance?

Psychometric Theories of Intelligence

Is there one particular thing that makes people do well on intelligence tests, or is it a cluster of factors? To answer this question, researchers have conducted many sophisticated statistical analyses of overall scores and relations among the subtest scores. Scores on more specialized tests, including measures of vocabulary (Peabody), nonverbal reasoning (Ravens Progressive Matrices), and spatial abilities (Leiter Performance Scales), have also been compared with performance on the broader, more common intelligence tests. These analyses have revealed intriguing patterns of correlations. They have also fueled major controversies about how to interpret these relationships and what the correlations imply about how intelligence is organized.

Spearman's Theory of General Intelligence After more than 50 years of intensive analysis, at least one reliable finding is a matter of consensus: no matter what pairs of mental abilities we pick, they tend to be positively correlated. Thus, if a person is better than average at mental rotation tasks, she typically will perform better than average on vocabulary tasks as well. If another person is weaker than average on rotation skills, he is also more likely to have a lower than average vocabulary score.

The finding that individuals tend to show consistent positive correlations in their levels of different cognitive abilities does not fit with common intuitive ideas about mental abilities. Many believe that a person who is a wiz at math and computer programming and loves playing with numbers and equations is likely to have below-average verbal skills. Although these intellectual stereotypes are widespread, they do not hold true. Excelling at math does not necessarily come at the expense of verbal skills, or vice versa.

Rather, some have argued that the pattern of positive correlations between different mental abilities supports the existence of **general intelligence**, commonly known as ***g*** (Gould, 1981; Spearman, 1927; Thurstone, 1938), although it remains controversial among intelligence researchers who take a psychometric approach. Charles Spearman originally put forth the theory of a general intelligence, or *g*, in a hugely influential article that appeared in 1904. This article is often seen as the seminal piece in the psychometric approach. Proponents of *g* believe that there is a single, underlying essence to intelligence that affects all kinds of intellectual performance (Spearman, 1904). Seeking precise ways to describe and measure *g*, they have tried to determine what basic aspect of the mind best accounts for most of what we think of as intelligence. That search continues, with researchers arguing for conceptions of *g* based on neural processing speed (Coyle et al., 2011; Jensen, 1993, 1997; Reed & Jensen, 1992), working memory capacity (Cole et al., 2012; Tuholski et al., 2001), and brain myelination (Miller, 1994), for example. Moreover, many proponents of *g* have tended to view general intelligence as intrinsic to each individual and unchangeable. Later in this chapter, we will explore further whether anything like *g* is either intrinsic or unchangeable.

The concept of *g* continues to figure heavily in discussions of intelligence (Glascher et al., 2010; Jensen, 1998; Kaufman et al., 2011; Nisbett et al., 2012; Sternberg & Wagner, 1993). As noted earlier, those who favor it also tend to explain individual and group differences in intelligence in terms of genetic and neurobiological differences. As a hypothetical example, if differences in intelligence were mostly accounted for by differences in neural processing speed, these variations would influence each mental ability. On the other hand, researchers who discount *g* often focus more on how people differ in their individual ranges of intellectual strengths and weaknesses rather than on how their abilities might differ in general. The anti-*g* camp more often emphasizes the many ways in which individuals can excel intellectually. Such groups tend to discount straightforward biological and genetic explanations of intelligence and instead emphasize the influences of culture, class, and experience.

Q: What is *g*? What have proponents of this view of intelligence used as evidence to support the theory?

Carroll's Three-Stratum Theory of Intelligence

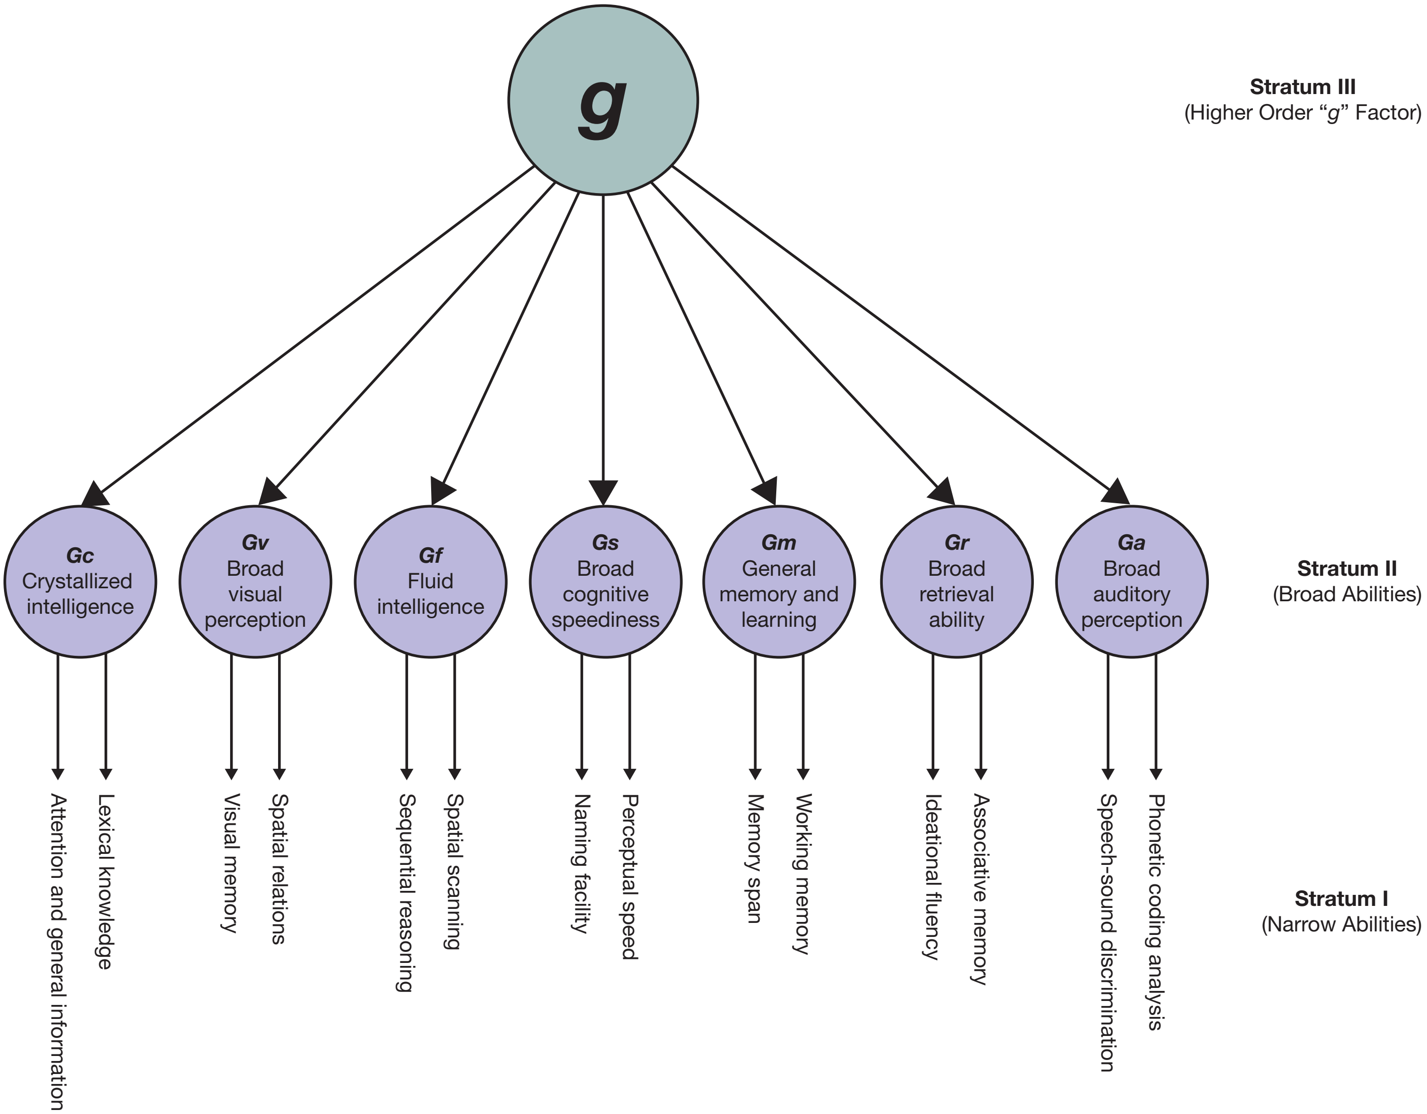
Although a positive correlation between abilities is extremely robust across a wide range of studies, and although a statistical method known as *factor analysis* reliably yields a factor corresponding to general intelligence, some argue that too much weight is assigned to *g* in terms of its role in accounting for intelligence. As an alternative, in 1993 John Carroll proposed the "three-stratum theory." In essence, this is a hierarchical array of abilities with *g* as a single factor at the apex, the third stratum. Nested within *g* is a second stratum of roughly 7 to 10 broad abilities, followed by a first stratum of roughly 70 narrow abilities. One such example is shown in Figure 11.4, although the first level pictured here does not show all the possible abilities.

The key point behind Carroll's approach, as well as a broader family of approaches known as the Cattell-Horn-Carroll (CHC) theory of cognitive abilities, is that factor analysis reveals three levels, each of which makes important contributions to understanding intelligence. According to this account, *g* is a real ability, but it is only part of the full explanation of how abilities vary across individuals. The second broad stratum contains equally important abilities relating to such skills as crystallized and fluid intelligence (discussed shortly), quantitative reasoning, reading and writing skills, memory skills, auditory and visual skills, and skills related to speed of processing. Finally, the first stratum contains more specific abilities, such as distinct verbal skills in the broader area of verbal ability.

In studies of children (Keith & Witta, 1997; Tucker-Drob, 2009) and adults (Alfonso et al., 2005; Schneider & McGrew, 2012), the family of CHC theories have become the dominant way of thinking about the abilities that cause differences in intelligence test scores. Scholars continue to debate whether *g* is real or whether it is a statistical side effect that does not represent a mental ability per se as much as the aggregation of lower-level abilities.

For many years, researchers believed that *g* could simply be the result of real-world tasks "sampling" different combinations of narrow abilities in a manner that made it look like there was a common *g* factor, when in fact it was just the intersection of these lower-level skills (Mackintosh, 1998; Sternberg & Grigorenko, 2002; Thorndike et al., 1927). Thanks to factor analysis, it is possible to create a "virtual *g*" when we can be sure that a true *g* is not really present. Such factor analysis has been accomplished via computer simulations of a model in which reciprocal positive causal interactions between lower-level cognitive abilities—that is, elements causing positive correlations with each other—created a higher-order *g*. This *g* emerged over the course of simulated cognitive development rather than being a latent ability modeled to be present from birth (van der Maas et al., 2006). Thus, it is possible in principle to observe *g* through statistical factor analysis, even when it is clear that there is no general intelligence component actually built into the model. This fact supports those researchers who question the utility of *g*. The debate will continue until further studies are able to carefully isolate cognitive and neural components that are uniquely associated with *g* and that do not originate from narrower abilities.

Q: What is the three-stratum (hierarchical) model of intelligence? What is this model's alternative explanation for general intelligence (*g*)?



g
Stratum III
(Higher Order "g" Factor)
Gc
Crystallized intelligence
Gv
Broad visual perception
Gf
Fluid intelligence
Gs
Broad cognitive speediness
Gm
General memory and learning
Gr
Broad retrieval ability
Ga
Broad auditory perception
Stratum II
(Broad Abilities)
Attention and general information
Lexical knowledge
Visual memory
Spatial relations
Sequential reasoning
Spatial scanning
Naming facility
Perceptual speed
Memory span
Working memory
Ideational fluency
Associative memory
Speech-sound discrimination
Phonetic coding analysis
Stratum I
(Narrow Abilities)

FIGURE 11.4 **Carroll's three-stratum theory.** In Carroll's theory (CHC theory) and in related approaches, *g* is simply a part of a larger system of three levels of abilities. Only part of the narrowest level is shown here. Adapted from Keith & Witta (1997).

Cattell's Theory of Fluid and Crystallized Intelligence Cognitive abilities that make up intelligence can also be divided into the categories of fluid intelligence and crystallized intelligence (Cattell, 1963). As originally proposed by the personality psychologist Raymond Cattell in the early 1960s, **fluid intelligence** refers to the ability to think flexibly and solve novel problems. It is thought to be largely independent of acquired knowledge. In contrast, Cattell described **crystallized intelligence** as the ability to use specific skills and knowledge gained through experience. Hierarchical models often treat both of these forms of intelligence as parts of *g*. On traditional intelligence tests, fluid intelligence is considered more closely related to test items such as novel math problems and puzzles (not simply memorized procedures or tables), while crystallized intelligence relates more to vocabulary items and questions that test general knowledge (Carroll, 1993).

Fluid intelligence and crystallized intelligence reflect distinct types of abilities, but they are not completely independent. Someone with a high level of fluid intelligence is likely to learn factual information rapidly and figure out fairly quickly how to do various tasks. Hence, he is also likely to have a high level of crystallized intelligence. This close relationship between the two has led some to argue that the distinction is unnecessary (Johnson & Bouchard, 2005). But from a developmental perspective, it can be useful for describing how intelligence changes over a person's lifespan (Blair, 2006). Fluid intelligence is thought to develop earlier than crystallized intelligence, as the young child has not had enough time to gain specific skills or acquire much knowledge. From about the late 20s onward, fluid intelligence starts to diminish, while crystallized intelligence continues to develop well into the sixth decade of life and often longer (Blair, 2006). These changes are considered in more detail in Chapter 17.

Alternative Views of Intelligence

Although the psychometric approach to defining and measuring intelligence predominates, several theorists have attempted to move away from this view. Many of these researchers believe that success in everyday life requires other sorts of intelligence beyond those uncovered by traditional IQ tests. If we think of intelligence as a mental ability that allows us to succeed in some arena, then we must take into account the mental abilities that allow some people to outperform others in an enormous range of situations. These mental abilities include many interpersonal skills, including negotiating, managing groups, forming and maintaining friendships, and dealing with superiors of much greater power. Outside the interpersonal domain, these skills also include oral communication (for example, giving a speech to a group), physical-mechanical tasks (for example, being able to fix devices), and spotting styles and trends (for example, recognizing which new electronic device will become the new must-have). All of these abilities and many others that contribute to everyday success are only now beginning to be considered.

Gardner's Theory of Multiple Intelligences One way to ask about the ways in which people cognitively excel focuses on areas of genius and precocity. Howard Gardner (1997) has argued that people of extraordinary talent can offer insights into a different way of understanding distinct kinds of intelligence (Gardner, 1983, 1993). We have all heard of musical and mathematical prodigies whose extraordinary abilities in early childhood surpass those of most adults. Most of these individuals go on to excel in their own area. Based on his study of early-achieving geniuses in various fields, Gardner developed his theory of **multiple intelligences**, a model that divides intelligence into distinct modalities that often have strong links to sensory or motor skills**.** This theory argues that people possess eight separate types of intelligence: linguistic, mathematical, musical, spatial, bodily/kinesthetic (for example, easily picking up complicated dance moves), intrapersonal (self-understanding), naturalistic (a special grasp of animals, plants, and ecosystems), and interpersonal (understanding others). Gardner also suggested that each of these eight intelligences has its own unique developmental path (Gardner, 1983; see Table 11.2).

Gardner's theory raises difficult questions. What do the special abilities of child prodigies tell us about intelligence and its development in all people? Do these domains truly represent separate intelligences that all of us have to varying degrees? Or do these areas of achievement actually draw on a number of more fundamental skills? Along with his case studies of geniuses, Gardner found other evidence for multiple intelligences in the cognitive effects of brain damage. In some cases, patients' impairments seemed to selectively

Form of intelligence	Characteristics	Best way to learn	Related careers/activity
Linguistic	Good with words, language play, linguistic patterns	Through verbal discussions, reading and writing, debates	Author, trial lawyer, journalist
Mathematical	Good with mathematics, logic, discovering formal patterns	Through quantitative tasks, experiments, classification systems	Accountant, scientist, computer programmer
Spatial	Good with visualization, maps, 3-D models	Through diagrams, images, maps	Architect, artist, cartographer, filmmaker
Musical	Good with melodies, rhythms, complex musical patterns	Through musical media, song	Musician, singer, music critic
Bodily/kinesthetic	Good with complex motor skills, manipulating objects	Through manipulating objects, acting out relations physically, hands-on learning	Dancer, athlete, martial arts performer, stage performer
Interpersonal	Good at sensing others' thoughts and feelings, resolving conflicts	Through rich social interactions, cooperation, sharing information	Community organizer, politician, manager, salesperson
Intrapersonal	Good at recognizing own abilities and accomplishments, setting reasonable goals	Through setting individual goals, pacing oneself, often working alone	Therapist, author, philosopher
Naturalistic	Good at understanding plants, animals, ecological relations in nature	Through situations involving living things, nature webs, ecological systems	Park ranger, biologist, conservationist

TABLE 11.2 Multiple intelligences. Gardner's eight forms of intelligence. (Based on Gardner, 1983, 2006).

affect particular types of intelligence, causing focused deficits in language skills, musical skills, motor skills, or interpersonal skills (Gardner, 1983).

The theory of multiple intelligences has been highly influential, especially in educational circles, where teachers see it as supporting the idea of tailoring curricula to meet the distinct aptitudes of different groups of children. In addition, if individuals can excel in different kinds of intelligence, there is less of a tendency to rank people's "intellectual worth" based on a single scale, a practice that can be disheartening for those at the lower levels of such scales. For the most part, however, the argument for eight distinct intelligences is not based as much on empirical evidence and experimental studies as it is on intuitions about how people might differ (Waterhouse, 2006). While there may be distinct cognitive systems for spatial reasoning, aspects of language, and face perception, for example, it is not clear that these different areas would easily map onto multiple intelligences or correspond to the way we categorize people of exceptional intelligence. Similarly, it is important to be careful in inferring that any early area of exceptional performance represents a core mental ability. People show early and extraordinary ability not only in math, music, and other domains discussed by Gardner, but in many other areas as well. These are abilities that can arise from unusually enriched environmental experiences, motivational factors, or even limits on alternatives. But for an extraordinary skill in such an area to count as a separate kind of intelligence, there must be evidence that the skill arises from cognitive aptitudes linked specifically to that skill.

Consider, for example, someone who shows outstanding skill at a particular video game. Is that excellence the consequence of a blend of high kinesthetic and spatial intelligences—or is it a result of extraordinary social competitiveness plus a lack of opportunity to manifest competitiveness in other areas, such as sports? People can achieve great levels of expertise relative to their peers for many reasons, only some of which reflect intrinsic differences in cognitive skills. Thus, connecting case studies of extraordinary precocity and skill to general principles of intelligence is a difficult task. It seems that there should be important relations, but without more detailed models of the cognitive bases for specific areas of genius, convergence between these two ways of studying individual differences is unlikely to occur.

Sternberg's Theory of Successful Intelligence A narrower view of multiple intelligences argues that three types of abilities are important to *successful intelligence* (Sternberg, 1996): analytical abilities, creative abilities, and practical abilities (see Figure 11.5). This view holds that successful, intelligent people tend to have either a balance of all three of these abilities or the insight to recognize which of these abilities are their strengths and which are their weaknesses and to adjust accordingly. The first category, analytical abilities, closely resembles the kind of skills that traditional intelligence tests measure, including comparing, computing, analyzing, and evaluating. The second category, creative abilities, includes the ability to invent, discover, and combine information in novel ways. The third category, practical abilities, includes the ability to use and act on information. These skills often involve knowledge that is difficult to articulate. Thus, someone could be strong both analytically and creatively but so weak in practical skills as to have great difficulty putting those strengths to use. Some proponents of multiple or alternative views of intelligence argue that intelligence tests focus too much on analytical talent. Consequently, their neglect of creative and practical talents makes them only weakly able to predict success in most real-life circumstances (Sternberg, 1996). There is a continued strong interest in developing new tests to assess these other forms of intelligence and to provide a more well-rounded understanding of cognitive ability.

FIGURE 11.5 Successful intelligence. Sternberg's successful intelligence is often characterized in terms of the ability to achieve practical goals, usually in cooperation with others, where leadership and interpersonal skills may be central. Even some quite young children can excel in this area.

When these alternative measures of intellectual ability are taken into account, the general pattern of positive correlations between different kinds of cognitive skills can start to break down. As noted earlier, all the skills that are part of analytical intelligence tend to be positively correlated. In contrast, some researchers have found analytical abilities to be negatively correlated with practical and creative abilities. For example, in one study in Kenya, children were tested both for their knowledge of the local environment, in terms of practical, adaptive skills, and for the more analytical abilities that intelligence tests normally measure (Sternberg et al., 2001). To measure the children's practical knowledge of the local environment, the researchers measured their informal knowledge of

NEW DIRECTIONS IN DEVELOPMENTAL RESEARCH

A *g* for Emotional Intelligence?

As researchers look for intellectual abilities that are not measured by traditional intelligence tests, they have shown great interest in **emotional intelligence** (Brackett et al., 2013; Mayer et al., 2008; Salovey & Mayer, 1990). Emotional intelligence is the ability to evaluate both our own emotions and the emotions of others and to use those evaluations to guide our thoughts and actions. Although emotional intelligence is a relatively recent concept, it has quite old roots. In 1920, the American psychologist Edward Thorndike argued that a broad view of intelligence must include the notion of **social intelligence**, the ability to smoothly manage social interactions (Thorndike, 1920). As Thorndike noticed, developing tests for social intelligence was much more difficult than developing tests for more analytical thinking (Thorndike, 1936; Thorndike & Stern, 1937). This difficulty has persisted (Kihlstrom & Cantor, 2000), but there are now more attempts to develop reliable and valid tests of both social and emotional intelligence.

As with analytical intelligence, researchers have devised different ways of subdividing emotional intelligence into more specific abilities. In one prominent view, emotional intelligence has five distinct components that fit into two larger categories of **intrapersonal intelligence** and **interpersonal intelligence** (Salovey & Mayer, 1990). Here are the components of intrapersonal intelligence:

- *Self-awareness.* Keeping track of our own emotions and emotional states as they occur.
- *Ability to manage emotions.* Knowing how to handle our emotional states in an appropriate manner and understanding the factors that give rise to our emotional states.
- *Motivation.* Using our emotional states to help achieve our goals and deal with impulses; may involve knowing when to delay gratification for larger, long-term gains.

Here are the components of interpersonal intelligence:

- *Empathy.* Having a sense of how others might feel in a situation, especially when their feelings might be quite different from our own; requires the ability to put ourselves in their shoes.
- *Ability to handle relationships.* Understanding the emotional tenor of a social situation and being able to respond in a manner that manages emotional states in others in an effective and useful manner.

A second view subdivides emotional intelligence into four levels of increasing complexity (Mayer & Salovey, 1997): (1) the ability to perceive and identify emotions, (2) the ability to use emotions to aid thought processes, (3) the ability to understand how conflicting emotions can lead to other emotions, and (4) the ability to use emotions to achieve social goals. This description of emotional intelligence carries with it a developmental hypothesis that younger children have mastered only the less complex levels. In a broad sense, younger children do seem much less adept at understanding the nuances of social situations and knowing how to act appropriately. Nonetheless, controversy remains over the best ways to break down the components of emotional intelligence in children and over how to describe their developmental trajectories (Mathews et al., 2003; Zeidner et al., 2003).

As noted earlier, for most individuals, intelligence test scores show a significant positive correlation between different analytical abilities, which some have cited as support for the existence of *g*, or general intelligence. This raises the question of whether the distinctive abilities that make up emotional intelligence would also be positively correlated. Is there a *g* factor for emotional intelligence analogous to that proposed for analytical intelligence? One research project examined scores on a wide range of tasks related to emotional intelligence, looking for positive correlations (Mayer et al., 1999). These ranged from perceptual tasks, such as the ability to recognize emotions in faces, to cognitively complex tasks, such as the ability to think about how emotions combine and lead to new emotions. When the scores of hundreds of adults and adolescents were analyzed, there was a clear positive correlation of all the abilities. This analysis also suggested that a single underlying factor was responsible for most of the patterns in the data. This evidence suggests a *g*-like factor, raising the possibility of an "essence" for emotional intelligence that manifests in a wide range of tasks (Mayer et al., 2001, 2004).

Just as in the case of analytical intelligence, controversies remain about the extent to which these positive correlations definitively indicate a single, general emotional intelligence (Goldenberg et al., 2006; Palmer et al., 2005; Pérez et al., 2005; Roberts et al., 2010). Nonetheless, that possibility highlights a developmental story in which there could be powerful individual differences in emotional intelligence from an early age, perhaps arising from a core skill like identifying emotional states, which then influences all other emotional intelligence tasks in the course of development. The early roots of emotional intelligence, as well as the way it develops; are likely to be an exciting area of research in future years.

the use of herbal medicines to fight infections. Although earlier studies had often found no significant correlations between practical and analytical intelligence, in this case they showed a strong negative correlation. Overall, the higher a child scored on the practical intelligence test of herbal medicines, the lower his score on the traditional intelligence tests.

A major cause of the negative correlation may be that the two groups of Kenyan children had parents with very different values. Parents who encouraged their children to develop practical intelligence through knowledge of local customs and practices also tended to look down on analytical intelligence and more Western approaches to problem solving. Consequently, their children were rarely exposed to analytical intelligence tasks. The other children's parents favored analytical forms of thought while neglecting the practical forms. In this case, different parenting practices and value systems seemed to nourish a high level of one kind of intelligence while discouraging the development of another kind. These findings raise intriguing questions about the ways that many, if not all, cultures may implicitly encourage one kind of intelligence at the expense of another.

Q: Describe some forms of intelligence other than the analytical sort. What evidence is there for these other forms as distinct types?

Origins of Intelligence

How do differences in intelligence arise? Researchers have debated the extent to which doing well on intelligence tests results from schooling and exposure to a literate, technological society and the extent to which it depends on an innate intelligence that remains fairly stable throughout development. To investigate these questions, many researchers have focused on how accurately assessments of intelligence in infancy can predict a person's intelligence test performance as they mature. If cumulative educational experiences are the sole predictors of intelligence test scores, then tests of infants are not likely to predict later test performance. The infants simply would not have been around long enough to benefit from experience. But if intelligence is an intrinsic ability that we always have and exhibit in any environment, perhaps it can even be seen in the early months of life. Not surprisingly, those who expect to find infant predictors of intelligence have often also adopted some form of the *g*-based view of intelligence.

Infant Indicators of Intelligence Test Performance

Almost since the beginning of intelligence testing at the turn of the twentieth century, researchers have been interested in whether measures of functioning in infancy might predict later intelligence test differences. Early assessments of infants' capabilities showed large individual differences between infants. These differences seemed to indicate infants' capacities and abilities to engage in important behaviors, such as motor action or language use. Psychologist Nancy Bayley developed the most widely used set of such scales, the Bayley Scales of Infant Development (Bayley, 1949, 1969, 1993, 2005). These scales measured intelligence in terms of a wide range of infant and toddler behaviors, including motor skills, perceptual and cognitive capacities, and early language.

Bayley and many others were interested in whether the infant measures could predict scores on later IQ tests. Bayley herself conducted one such longitudinal study with children who were first tested shortly after birth and then repeatedly tested throughout childhood, until age 18 (Bayley, 1949, 1969, 1993, 2005). She did not find significant correlations between any of her measures and later intelligence test scores, nor have later researchers (Bornstein, 1994a; Hack et al., 2005, Kopp & McCall, 1990). The latest, revised version of Bayley's test (2005) does contain some elements that are similar to more recent infant measures discussed below, and researchers are asking if there might be stronger links to later intelligence test scores (Luttikhuizen dos Santos et al., 2013).

In more recent years, new measures of infant cognition and perception have been devised that partially predict later intelligence test scores. Rather than looking at motor tasks, early language, and other sorts of measures used by the Bayley Scales, recent researchers have tried to assess an infant's ability to encode, remember, and respond to information at different levels of complexity. As described in Chapters 3, 4, and 5, habituation measures of infants provide a superb way to study these abilities. But in this context, researchers are not using habituation as a means of measuring aspects of infant perception and cognition in general, such as whether infants of a certain age can recognize faces or have certain expectations about objects. Instead, these studies are focused on individual differences among infants in their patterns of habituation. Thus, researchers assume that the more "intelligent" infants will habituate more quickly to stimuli; they will process the information more efficiently, such that it more rapidly becomes familiar and loses its appeal (see Figure 11.6).

Researchers have known for some time that children who have brain damage likely to cause mental retardation take longer to habituate (Bornstein, 1994b). Building on this finding, researchers have investigated whether variations in the habituation times of developmentally normal infants would predict later ranges in their intelligence

FIGURE 11.6 Habituation and intelligence. When an infant loses interest in a novel object, the speed at which she loses interest predicts intelligence test scores several years later.

scores. Surprisingly, several research groups have found such relationships in longitudinal studies (Bornstein et al., 2006; Colombo, 1993, 2004; Colombo et al., 2004; Fagan, 1990; McCall & Carriger, 1993; McCall & Mash, 1995; Rose & Feldman, 1995; Rose et al., 2009; Slater et al., 1989). In one line of work, children's habituation measures in infancy correlated significantly with their intelligence test scores at age 11 (Rose & Feldman, 1995; Rose et al., 1997, 2005, 2012). A related finding showed that children who were more inclined to explore and seek stimulation at age 3 scored significantly higher on intelligence tests at age 11 (Raine et al., 2002).

These studies reported correlations ranging between .35 and .50, which are statistically significant predictors, although the relationship is not especially strong. In statistical terms, a correlation of .50 between infant habituation measures and IQ scores at age 11 means that the correlation with infant measures accounts for only about 25 percent of the variation in childhood IQ scores. This leaves 75 percent of the variation to be explained by other factors.

Correlations as high as .50 are certainly interesting and provocative. They suggest that some key parts of intelligence may be present in young infants. Nonetheless, it would be a serious mistake to conclude from these correlations that habituation rates in infancy predetermine later intelligence test scores or that intelligence is largely unchangeable over the course of development. In addition, while there are differences in intelligence scores between ethnic, racial, and socioeconomic groups of older children and adults (as discussed shortly), no such differences are found in any of the infant measures (Fagan, 2011). This suggests that those group differences must arise from factors other than those that are present in infants. Interestingly, stronger correlations with later test scores appear around the age when children typically enter formal schooling, at about 5 to 6 years of age. At this point, intelligence test scores do begin to predict later scores—not perfectly, but increasingly well as the child matures, rising from a correlation of about .85 (between 5- and 6-year-olds' scores and 18-year-olds' scores) to .95 (between 11- and 12-year-olds' scores and 18-year-olds' scores) (Neisser et al., 1996). Nonetheless, because habituation measures partially predict future intelligence test scores, this argues that important aspects of intelligence may have a genetic component.

Q: What sorts of measures of preverbal infants can partially predict scores on traditional intelligence tests years later?

The Heritability of Intelligence

Long before Alfred Binet began designing the first IQ tests, people believed that differences in intelligence were largely the result of innate differences in intellectual powers, even if they had no idea how those innate differences were physically realized in the body. More recently, those inborn differences have been attributed to genes. There are many strands of support for the claim that genes are one source of the differences in intelligence. But it is critical to remember that environmental factors are also at work, including a variety of prenatal and postnatal biological influences. Genes that influence intelligence do not determine a specific level of ability; instead, they can be thought of as specifying a range of skill levels that vary as a function of the environment. As an analogy, consider that a child of short parents might grow to heights ranging from very short to average height, depending on his diet, exercise, and other factors, whereas a child of tall parents might have a height ranging from average height to very tall, depending on the same set of environmental influences.

As described in Chapter 2, behavior geneticists talk of the *heritability* of a trait as a way of describing the extent to which, within a particular population, the variations in that trait are due to genetic differences rather than environmental ones. The more the variations in a particular trait among a group of people can be accounted for by differences in their genes, the closer that trait's heritability approaches 1 for that population in that environment. On the other hand, the more the trait's variations within the group are due to environmental variations, the closer its heritability approaches 0. Height, for example, has a high heritability of roughly .80 in most populations and environments, while hair length has a heritability close to 0. Thus, individual variations in height tend to be closely linked to genetic variation, whereas differences in hair length (excluding cases of baldness) are almost completely linked to variations in the environment. The same sort of analysis can be applied to psychological traits such as intelligence, shyness, or even knowledge of a particular city. Shyness turns out to have a relatively high heritability, while individual variations in familiarity with a particular city would be almost completely determined by experience.

Heritability is a measure of a population, not of an individual. It intrinsically depends on how a trait varies across members of a group. For that reason, it makes no sense to say that 80 percent of an individual's height is caused by his genes, even though height might have a heritability of .80 in the population from which the individual is drawn. In addition, the heritability of a trait for a particular population can vary over time. As we will see shortly, the same group of people can have a different heritability value for intelligence when they are children than when they are adults. To see how this can happen, suppose we wish to measure the heritability of allergy to bee stings. Initially, the measured heritability is low, since people usually do not react strongly to the first sting. Over time, however, as people experience more stings, those who are likely to have allergies will show stronger and stronger responses, such that the heritability in adults might be quite high. Similarly, the heritability of acne or ulcers might vary considerably with age. In the same way, a population's heritability value for intelligence can change over time, depending in part on the effects of environment and experience.

Heritability also varies depending on the diversity of environments in which the population of interest is studied. If all the members of a population grow up in a very similar environment, such as an isolated village in which everyone lives in much the same way, the heritability of a given trait might be quite high. But if this trait is then studied in a population that experiences a huge range of environments, like the residents of a large city, who range from the homeless to the very wealthy, the same trait's heritability may be very small for this population. The environment that the villagers experience does not vary enough to cause many differences among them, but the range of environmental variations in a large city would likely influence the expression of many physical and psychological traits. Heritabilities also vary across population groups. Thus, the heritability of a trait might be lower among a group that has intermarried for many generations than it would be among residents of a highly diverse university.

For all of these reasons, finding a very high heritability value for a trait does not provide evidence that the trait depends on a particular gene. A high heritability simply means that in a given population and environment, some pattern of genetic variation, quite possibly involving many genes and their interactions, accounts for most of the variation in how a trait is expressed.

Q: What does heritability measure?

There are many ways of assessing heritability, and they all attempt to explore differences in the relative contributions of genes and environments to trait variations within a specific population. With intelligence, the strongest demonstrations have involved studies of monozygotic (MZ) twins, who as you will remember have genes that are identical, and dyzygotic (DZ), or fraternal, twins, who share roughly half their genes, just like any pair of siblings (see Chapter 2). Using complex analyses, researchers can compare the intelligence test scores of large groups of MZ twins with those of large groups of DZ twins (of the same sex) and use the differences to calculate heritability scores. These analyses can be influenced by many factors. Researchers, for example, have studied special groups of MZ twins reared apart (who share their genes but grew up in different environments) and compared them with groups of unrelated children who were adopted and raised in the same family (who share their home environment but not their genes) to maximally contrast environmental and genetic influences (Plomin et al., 1997, 2001; van Soelen et al., 2011).

Of course, all such studies have to be carefully scrutinized for possible methodological problems. MZ twins in the same families are often treated more similarly than DZ twins, and MZ twins reared apart are often not kept perfectly apart, or they are reared by closely related relatives in similar economic circumstances (Kamin, 1974). Nonetheless, across large numbers of these sorts of studies—and accounting for their methodological issues—consistent heritability estimates for intelligence have emerged (see Figure 11.7). For normal

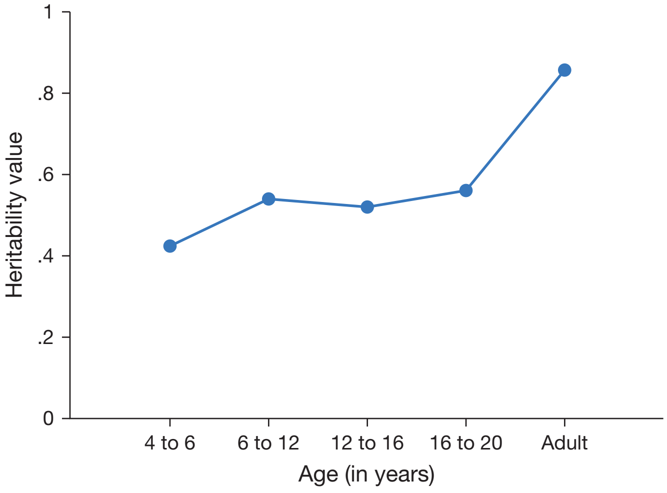


FIGURE 11.7 How the heritability of intelligence increases with age. Across several studies, there is a consistent pattern in which the heritability of intelligence rises from roughly .45 in childhood to roughly .75 in late adolescence. Adapted from Bouchard & McGue (2003).

Western children raised in a normal range of environments, the heritability of intelligence averages around .45 and rises to about .75 by late adolescence (Bouchard & McGue, 2003; Deary et al., 2006; Neisser et al., 1996; Plomin et al., 2001; van Soelen et al., 2011). As noted earlier, other groups and environments might well show different heritability values for intelligence.

It may seem odd that groups of adolescents and adults show higher heritability values than children, since it would seem that the longer a person is in an environment, the more environmental effects could cause individual differences, reducing the heritability of intelligence. In fact, the opposite seems to occur: heritabilities for intelligence are almost always considerably higher in older populations than in younger ones. One possible explanation for this pattern is that as people age, they are increasingly able to seek out the environments that best mesh with their own inherited mental characteristics. In many societies, children are treated much more similarly by educational systems than adults are in the careers they choose. Thus, by seeking out certain environments to which they are well suited, perhaps adults can express their genetic traits more fully. It may also be that some later-developing aspects of intelligence, such as executive functioning, have stronger heritabilities that do not appear until the cognitive trait is more fully expressed (Deary et al., 2010; Miyake & Friedman, 2012; van Soelen et al., 2011).

Q: How can a trait have a high heritability and yet not be strongly linked to a single gene?

The study of genes and intelligence is likely to take on new dimensions in the coming years. For example, many researchers have examined the tissue volumes in different brain areas and the extent to which volume differences within a population are attributable to genetic variation. Studies using MRI analyses of the brains of monozygotic twins have found high heritabilities for the volume of some regions in the frontal lobes and in the hippocampus, suggesting links to executive functioning and memory skills. In some areas of the frontal lobes, heritabilities higher than .90 have been reported (Peper et al., 2007; Toga & Thompson, 2005; see Figure 11.8). Other, more posterior regions tend to show lower but still significant heritabilities (Deary et al., 2010). Brain volume has been correlated with intelligence test scores (Brans et al., 2010; Hulshoff Pol et al., 2006; Peper et al., 2007; Taki et al., 2012; Toga & Thompson, 2005), although the correlations are sufficiently low (for example, .3 to .4) as to allow for major influences of other factors besides brain volume on intelligence test scores.

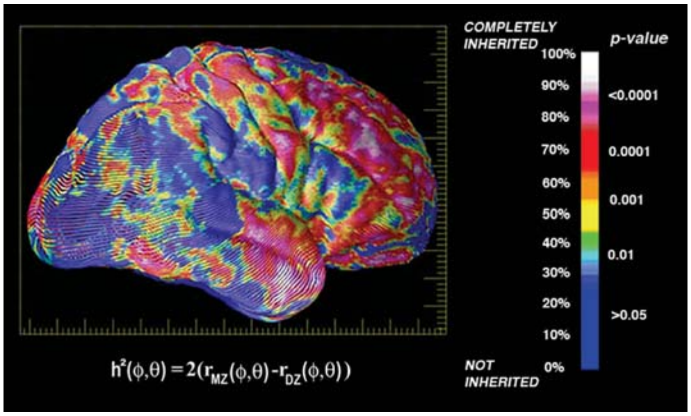

FIGURE 11.8 Heritability of brain volumes. Studies of monozygotic and dizygotic twins have shown substantial differences in heritability of brain volumes. Areas in the frontal lobe (the right-hand region in the view shown here of the right hemisphere) show especially high heritabilities, sometimes higher than .90. Differences in brain volumes have in turn been linked to differences in intelligence test scores, although the relationship is not particularly strong. From Toga & Thompson (2005).

Even when particular brain regions show high heritability values for tissue volume, environmental factors may also play a substantial role. Suppose, for example, that having larger frontal lobe regions makes complex choice tasks somewhat easier and that, consequently, people with larger frontal lobe volumes gravitate to those tasks more than others would. Choosing to engage in those tasks more often could then provide experiences that foster further brain growth, making the tasks even easier. In this way, a modest early advantage could become larger. Evidence for this kind of developmental pattern comes from studies showing that experience in some kinds of focused tasks, including motor tasks, musical practice, or spatial navigation, can cause brain regions that support the task to increase in volume. The effects can be quite closely linked to experience. For example, taxi drivers have larger hippocampal volumes (which are associated with spatial cognition) than do bus drivers in the same city, presumably because the bus drivers always take the same route. Moreover, the longer the taxi driver has been working, the larger the hippocampal volume (Maguire et al., 2006). These sorts of studies clearly illustrate that experience and some brain regions can interact in ways that would influence heritability (and alter the size of those brain regions).

Notwithstanding the complexity of studying the genetic bases of intelligence, much of this research points to a simple conclusion. Genes contribute to intelligence as they do to many other traits. Genes do not, however, account for anywhere near the full range of variation in intelligence. Even within the same family, there can be large variations in intelligence. Across families, the differences are much larger. Yet, common family environments and common social experiences make a huge contribution to intelligence. Because of the complex interactions between genes and environments, there is no easy way to state which influence usually dominates. Thus, no one can state that intelligence, at least as measured by intelligence tests, is either strictly inherited or solely a product of experience.

Despite substantial heritabilities of intelligence (most often linked to *g* as opposed to cognitive subcomponents), it has not been possible to link intelligence strongly with variation in any particular gene (Deary et al., 2009, 2010; Johnson et al., 2011).

In the first years of the twenty-first century, it was thought that one outcome of the Human Genome Project would be the linking of variations in single genes to major components of intelligence. But the actual genetic influence seems to work through a complex interaction of many genes and their interplay with environmental factors over extended developmental periods. Such a finding is not that unusual and extends far beyond behavioral traits. For example, height has a very high heritability, usually above .80 (Visscher et al., 2008), but no single gene has been found to be strongly associated with variations in height (Johnson et al., 2011; Visscher, 2012).

Interestingly, height also has higher heritabilities with increasing age, which may be a general characteristic of traits that result from complex interactions of many genes over time (Johnson et al., 2011). It now seems clear that there is no "intelligence gene" or even a few genes strongly linked to intelligence, even though genetic variation strongly contributes to variations in intelligence. As with height and many other human traits, new models are still needed to provide detailed mechanisms for how large sets of genes and environments might interact to produce traits.

Group Differences and Intelligence Tests

No area of psychological research is more controversial than group differences in intelligence test scores. In the discussion that follows, it is critical to remember the difference between these scores and real mental abilities. You only need to imagine taking an intelligence test on little sleep, with the flu, or in a state of high anxiety to know that IQ tests do not always reflect a person's full intellectual capacities. With respect to group differences, it is equally easy to imagine how a group that is, on average, more apprehensive about tests may tend to do worse than a group that tends to be more relaxed. Similarly, people who live in a noisy neighborhood or who get inadequate nutrition might well be more fatigued than other test-takers.

Substantial group differences in intelligence test scores have been reproduced hundreds of times in very large samples of subjects. The main groups compared in these studies have been males and females and various ethnic groups—usually African Americans, Asian Americans, Hispanic Americans, and European Americans. Of course, many ethnic groups outside America have been studied as well, but intelligence testing has certainly been most pervasive in North America, which has provided the largest data sets for study. We will begin by examining sex differences in test scores.

Sex Differences

Between men and women, overall IQ scores are equal, a fact that is difficult to interpret, since the tests have been standardized to achieve this result. The tests' creators assumed that men and women should have the same overall level of intelligence, so even though men and women score differently on specific subtests, the subtest scores are weighted in a way that yields equivalent scores overall between the two groups (Neisser et al., 1996). Still, it is useful to consider the differences between the sexes in certain components of intelligence tests.

Spatial skills are one component of intelligence tests in which males and females show different patterns of performance (see Figure 11.9). Males tend to have higher scores on spatial tasks, especially those that involve performing mental operations on visual/spatial images in memory. Such tasks include mental rotation (imagining how various three-dimensional figures would look in another orientation), finding an embedded figure in a large display, and generating and maintaining an image in memory (Voyer et al., 1995). At the same time, females fare better than males on some tasks with spatial components, including remembering the locations of objects (Lawton, 2010; Lejbak et al., 2009; McBurney et al., 1997). In other tasks involving working memory for spatial information, females have also performed better than males. Some researchers have suggested that the differences may involve anatomical variations between the sexes in parts of the prefrontal cortex and the hippocampus (Colom et al., 2013; Duff & Hampson, 2001; Ecuyer-Dab & Robert, 2007). Males tend to perform at higher levels on many mathematics-related tasks. Some have argued that sex differences in visual/spatial skills might

A B

FIGURE 11.9 Sex differences in spatial skills. Although **(A)** males may show higher mean levels of performance on spatial tasks, such as mental rotations and maze learning, **(B)** females may show higher mean levels of performance on tasks involving memory of locations of objects, such as remembering where certain toys can be found.

be at the root of this mathematics disparity, since men are more likely to use visual/spatial strategies on complex math tasks (Halpern & LaMay, 2000).

In other memory tasks, women tend to show consistent advantages, outperforming men at recalling lists of words, numbers, and faces, among many other items. Women also tend to do better on language-based tasks, whether they involve fluency, spelling, or reading comprehension (Halpern, 2004). In addition, girls tend to start speaking earlier than boys and have larger vocabularies at comparable ages (Halpern & LaMay, 2000).

There is tremendous interest in trying to link brain differences to cognitive differences between the sexes (Hampson & Moffet, 2004). A number of biological differences between male and female brains have been documented, many of which appear in infancy and persist throughout the lifespan (Hines, 2011). They include a higher rate of blood flow saturated with oxygen in females (Gur & Gur, 1990), overall larger brains in males, different ratios of white and gray brain matter, larger orbitofrontal regions relative to other brain regions in females (Gur et al., 2002), and differences in the thickness of the cerebral cortex in specific regions (Sowell et al., 2007).

It is difficult to decipher the connection between these sex-related differences in brain anatomy and differences in brain function (Cosgrove et al., 2007; Halpern et al., 2007; Lawton, 2010). More certain, however, is the existence of cognitive sex differences in their own right, several of which have been reliably demonstrated across cultures. One broad, well-supported difference lies in the distribution of test scores between the sexes. There tend to be more males at the extremes of performance, both at the highest and the lowest levels (Halpern et al., 2007; Johnson et al., 2008; Strand et al., 2006).

The emergence of some cognitive differences between the sexes early in life has led several researchers to think that these differences are partially influenced by hormones (Bull et al., 2010; Levine et al., 1999). At the same time, the social influences on sex differences in intelligence should not be underestimated (Hines, 2010a, 2011; Spelke, 2005). Parents interact with girls and boys quite differently, and parents, peers, and the surrounding culture generally provide girls and boys with very different environments. Starting when their children are very young, parents tend to offer them different kinds of toys depending on their sex (see Figure 11.10). If a boy is more frequently offered a truck and a girl a doll, these choices create different kinds of play experiences. Parents also tend to approve of different kinds of play activities for boys and girls, encouraging boys to engage in sports and girls to engage in more social activities that might develop verbal skills (Leaper & Friedman, 2006). Of course, parents and cultures can vary considerably in the extent to which they treat boys and girls differently, a topic explored in more depth in Chapters 13, 14, and 15, but there are clearly many social and cultural influences that could contribute to sex differences in cognition (Lawton, 2010).

In sum, sex differences on the various components of intelligence tests are attributable to a wide range of causes (Halpern et al., 2007; Lawton, 2010). Biological factors may play a role, but given the potential for abuse based on such alleged differences, it is critical to remain skeptical and carefully consider socialization explanations as well. That is, even if some biological sex differences can be clearly linked to cognitive differences, this tells us little about the effects of different learning experiences. Even if girls devote less of a particular brain region than boys to, say, visual/spatial tasks, they may simply use other regions to support the same level of visual/spatial skills as boys, given comparable encouragement and instruction. We simply know far too little about brain structure and function to make any stronger inferences.

Finally, it is important to remember that the research shows sex differences between population averages, not between individuals. The range of variation in cognitive skills among women or among men is far larger than the

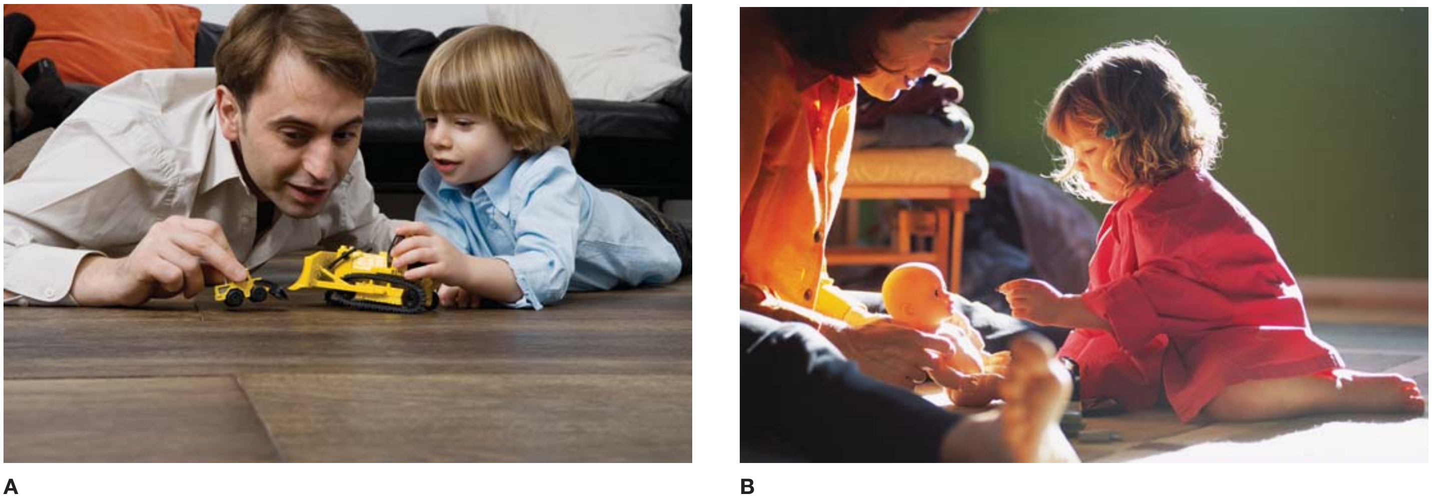

FIGURE 11.10 Sex differences in experiences with specific kinds of toys. Sex differences in cognitive abilities in different domains may occur because parents provide children of one sex with much more experience with a certain kind of toy. **(A)** Here we see a father and son playing with toy construction equipment, and **(B)** a mother and daughter playing with a doll.

differences between men and women. Therefore, it is not possible to make any statements about any individual's cognitive skills based on his or her sex.

Ethnic and "Racial" Differences

The bases of sex differences in intelligence subtest scores are controversial, but this controversy pales next to the heated debate over ethnic differences in test scores. Nevertheless, some facts are clear. There are large differences in average IQ scores across ethnic groups: as much as 15 points between some samples of European Americans and African Americans, where European Americans may have a mean centering around 100 and African Americans may have a mean centering around 85. Despite above-average academic performance, Asian Americans have only slightly higher intelligence test scores than European Americans, a finding that runs contrary to some stereotypes. Finally, Hispanic Americans perform roughly in between the European-American and African-American levels.

It is critical to use the term *ethnic group* and not *race* for groups such as European Americans, African Americans, and Asian Americans. The reason is simple: the entire notion of racial groups is biologically suspect (Hirschfeld, 1996). For example, in many analyses, African-American groups have been shown to be made up of heterogeneous peoples with much larger genetic differences among them than there are between them and European Americans (Cavalli-Sforza et al., 1994; Olson, 2001). Despite common beliefs and prejudices, ethnic groups rarely map in a straightforward way onto biological groups of humans. At the same time, as we learn more about the human genome, it becomes clear that some alleles that are more common in certain groups are related to a greater susceptibility to certain diseases and different responses to specific treatments (Bamshad, 2005; Bamshad at al., 2007; Helgadottir et al., 2006; Mountain & Risch, 2004; Rotman, 2003).

Explaining Group Differences

What do group differences in test scores mean? Some people simply deny the results, arguing that they are fabrications of racist testers and researchers. This criticism seems problematic, since researchers from all political persuasions and backgrounds tend to find similar results with the same tests. Nonetheless, it is still possible that implicit racial attitudes are influencing test construction and design. More detailed criticisms focus on how well intelligence tests really measure what we think of as intelligence and whether they provide equally accurate measurements for different groups. The issues are complex, and much more extensive treatments can be found elsewhere (Ceci, 1990; Fish, 2002; Gould, 1981; Hunt & Carlson, 2007; Nisbett, 1998, 2005; Nisbett et al., 2012; Rushton & Jensen, 2005; Sternberg, 1994). In the main, there are four types of explanations for the significance of group differences in IQ scores: irrelevance, biological differences, socioeconomic factors, and sociocultural stereotypes.

Are Group Differences Irrelevant? One frequent argument is that IQ tests are largely irrelevant and that the group differences they uncover are not meaningful for any other kind of setting. For example, perhaps members of economically disadvantaged groups are less familiar with the content of some test items that have little or no relationship to any other tasks or settings. If this were the only reason for group differences, then IQ tests would not be useful predictors of how members of disadvantaged groups would perform in other contexts, such as the classroom.

More specifically, if African Americans tended to achieve academically at a much higher level than their IQ scores predicted, then the IQ tests would be *predictively biased* against African Americans. For example, perhaps an African-American student with an IQ score of 100 performed in school at the level of a European American student with a score of 120. Although some people believe that such a bias exists, it does not—at least not in typical North American school settings. African-American children with IQ scores of 100 do about the same in school as European-American children with IQ scores of 100 (Reynolds & Brown, 1984). For an individual who grows up in a highly disadvantaged environment and suffers from discrimination, a score of 100 might be a much more impressive achievement than it would be for an individual who comes from a privileged upbringing. Nonetheless, that person's academic achievement might also be heavily negatively influenced by his disadvantaged background.

Genetic Factors For many years, some researchers have argued that intelligence is largely an inherited trait. Based on that claim, they then argue that differences in IQ scores among ethnic groups are also caused by genetic differences. In fact, the two arguments are not connected, and the tendency to link them is a widespread and dangerous fallacy (Gould, 1981).

To understand why they are not linked, consider again the example of height. The heritability of height may be high, say .80, such that height differences in a population are mostly accounted for by genetic variations. Thus, within a group of North American children, differences in height might be highly predictable from their patterns of genetic variation. But now consider a second population of children from a famine-ravaged region of Somalia. In that group of children, height could also have a heritability of .80, with genetic variations again strongly predicting height differences. But when you compare the two populations, you find that the malnourished children are 3 inches shorter, on average, than the North American children at three different ages. Despite the similarly high heritability of height in both groups, there is no reason whatsoever to attribute the 3-inch difference in average heights to genetic factors. This fallacy would become especially obvious if food became plentiful in that region of Somalia and subsequent generations showed no significant height difference with North American children.

Many of the same issues apply when people try to use general heritability estimates for intelligence to explain group differences in IQ scores. Even if intelligence had a heritability of .90 and one ethnic group reliably scored 15 points lower than another, it does not mean that the group difference in scores has any basis in genetics. High heritabilities alone cannot explain differences between populations.

When more objective studies have examined whether there is a genetic basis for group differences in IQ, no reliable group differences have been attributed to genes. Perhaps the most dramatic evidence comes from studies that have investigated whether the degree of African ancestry among Americans correlates with their intelligence test scores. Through analyses of blood chemistries, it is possible to determine the extent to which people share common ancestors. Studies that examine the degree of African ancestry through blood analysis find no relation between degree of African ancestry and IQ scores (Scarr et al., 1977). As noted earlier, the entire notion of African ancestry is problematic as a category, given that the genetic diversity within Africans as a group is larger than that between those with African ancestry and other groups, such as Europeans (see Figure 11.11).

It seems that the "social" category of being an African American is a far stronger predictor of test scores and academic performance than any biological category. In short, there is no reliable evidence that genetic differences between ethnic or racial groups account for any group differences in intelligence test scores. For that reason, it makes sense to assume that some aspect of sociocultural factors is responsible for the differences.

Socioeconomic Factors Among the sociocultural factors that could be responsible for ethnic differences, one class of explanation has focused on socioeconomic influences. Indeed, between ethnic groups in America, differences in IQ scores are dwarfed by differences in income levels, quality of employment, and quality of life. Could those large disparities in economic resources and opportunities affect intelligence test scores? They are certainly likely to be factors, but such simple economic effects seem implausible as the entire explanation, since the ethnic differences still exist even when individuals are matched for economic levels. Moreover, some researchers argue that it is unlikely that the side effects of poor economic conditions, such as malnutrition and poor health care, inevitably cause large drops in IQ scores, given humans' striking resilience in times of severe malnutrition (Lumey et al., 1993; Stein et al., 1975). Nonetheless, members of impoverished groups are more likely to be trapped in inferior schools with vastly fewer resources, and as we will see later in the chapter, schooling can powerfully influence intelligence. But the persistence of ethnic differences in IQ scores, even when in matched economic situations, suggests that differences in school quality cannot be solely responsible for differences in scores between ethnic groups.

FIGURE 11.11 Genetic diversity. People of African descent show greater genetic diversity among themselves than between themselves and other groups, such as Europeans. These differences raise doubts about claims of intrinsic abilities of people from different "racial groups."

Sociocultural Stereotypes The most plausible explanations for ethnic group differences in IQ scores seem to involve people's views of their roles relative to the dominant culture in which they live. The anthropologist John Ogbu has offered a cross-cultural explanation emphasizing the ways that minority groups differ, not just from the majority group but also from each other. His theory describes three distinct types of minority groups that tend to show sharply different outcomes in both intelligence testing and school achievement (Ogbu, 1978; Ogbu & Stern, 2001). One type of minority group chooses, on its own initiative and without economic or social penalties, to be distinct from the majority culture. American examples would include various religious groups, like the Amish, or those who live in communes. The second type of minority group seeks out new opportunities through migration, despite temporarily being at an economic disadvantage in the new culture. Such groups of immigrants tend to see themselves as better off for having decided to leave their home culture and join a new one, in a subordinate status, with the goal of working their way up to affluence.

Finally, there are minority groups whose members are put in a subordinate, disadvantaged class without any choice, usually from birth. They often have the feeling of being trapped in that class. Ogbu argues that such groups include African Americans, lower caste members in India, the Maori of New Zealand, and any other groups with a similar sense of being forced against their will into a lower category. He contends that members of this third kind of minority group have little confidence that their academic efforts will be appropriately rewarded, and they may come to regard school as a futile waste of time. Perhaps the most revealing aspect of Ogbu's analysis is that when precisely the same racial group that constitutes this kind of trapped minority in one culture constitutes a more advantaged minority in another culture, the minority members' academic performance rises as well.

Social psychologists Claude Steele and Joel Aronson have made a related argument concerning how some groups are influenced by their beliefs about society's view of their intellectual capacities. Steele and Aronson refer to the phenomenon of **stereotype threat**, in which the very fear of confirming a negative stereotype leads to reduced performance on a task or test. They argue that African Americans face powerful stereotypes about their not doing as well on intellectual tasks. These stereotypes are not only entrenched in the dominant European-American culture but well known to African Americans as well.

In one series of studies, Steele and Aronson (1995) varied the extent to which African-American students saw a challenging verbal test as truly indicative of intellectual ability and then compared their performance with that of European-American students with matching SAT scores. Thus, some students were told that the test was a very reliable measure of intellectual skills, whereas others were informed that it was simply a difficult verbal puzzle. Steele and Aronson predicted that this manipulation would cause the first group of subjects to fear that their performance might confirm a negative stereotype about African Americans' intellectual abilities and that this stereotype threat could damage their performance. In fact, they found that African-American students performed worse than European-American students only in the condition that imposed the stereotype threat. The manipulation had no influence on European-American students, since it did not impose a threat (Steele & Aronson, 1995). This pattern of results has been repeatedly found in hundreds of studies of both ethnic and gender-related stereotypes (Appel & Kronberger, 2012).

This finding is an intriguing twist on the idea of sociocultural influences on disadvantaged groups, and its implications extend across a wide range of intellectual tasks. Steele argues that the most potent influence on how members of those groups perform on intellectual tasks is how they perceive their culturally and socially expected role in that task (Steele, 1997). Moreover, it is possible, and even relatively simple, to reduce stereotype threat and improve standardized test performance in threatened minorities. This can be done by indicating before the test that intellectual ability is malleable and not an intrinsic property of an ethnic group (Good et al., 2003; Inzlicht & Good, 2006). Stereotype threat can also be reduced by focusing on those aspects of cognitive performance that are most affected. For example, math problems can impose high loads on working memory, which is easily impaired by stereotype threat. But by practicing math techniques so that they become stored in long-term memory (rather than routines to be computed in working memory), students become less susceptible to stereotype threat (Beilock et al., 2007).

Other studies have shown that reframing a task can greatly reduce stereotype threat. For example, in one study, researchers produced large stereotype threat effects in African-American children taking a mathematics test by having the children report their race just before taking the test. The researchers required the children in the control group to report their race after taking the test. Yet, when the same test was described as a challenge, the stereotype threat effect disappeared, and the children in the experimental group did as well as those in the control group (Alter et al., 2010). The challenge framing was created by simply having the experimenter describe the test as a useful learning experience as opposed to a true measure of their ability.

Stereotype threats can be countered in more informal ways as well, such as in attitudes conveyed by parents. In one study, researchers asked mothers of young elementary school girls their opinions about claims that girls had less ability in math. When mothers strongly rejected stereotypes of girls doing poorly in math, their daughters showed no effects of stereotype threat on math task performance. But when the mothers did not reject the stereotypes, standard stereotype threat effects occurred (Tomasetto et al., 2011; see Figure 11.12). Of course, without random assignment of girls to conditions where mothers make such statements and where they do not, we cannot be sure if this correlation reflects maternal behavior directly countering stereotype threats. There may be other independent factors—for example, especially high math ability in those girls—that both counter the threats and increase the mothers' anti-stereotype statements.

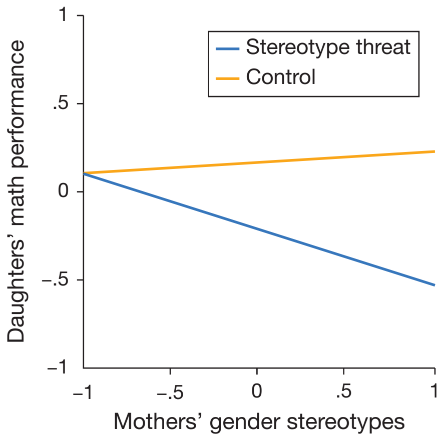

FIGURE 11.12 Stereotype threat and attitudes of mothers toward the stereotype. When mothers express strong disagreement with the stereotype of girls being bad at math (−1 score), their daughters do not show the effects of stereotype threat. When mothers agree with the stereotype (+1 score), however, their daughters do show an effect of the stereotype threat. In the stereotype threat condition, gender was made salient. In the control condition, it was not. Adapted from Tomasetto et al. (2011).

It appears that stereotype threat can affect children quite early in development. In one study, Asian-American girls in elementary and middle school engaged in one of two different types of tasks before doing several math tasks. One task was designed to make the girls think about their gender: coloring a drawing of a girl playing with dolls. The other task, coloring a picture of two Asian children eating with chopsticks, was intended to make their ethnic background salient (Ambady et al., 2001). When their gender was made salient, the elementary school girls did much worse on math-related tasks than control children who colored a landscape. When their ethnic background was made salient, their scores were markedly higher than the scores of the control children. Thus, by early in elementary school, children can pick up on the stereotypes associated with various cognitive tasks. Moreover, thinking about those stereotypes can influence their test performance in different directions.

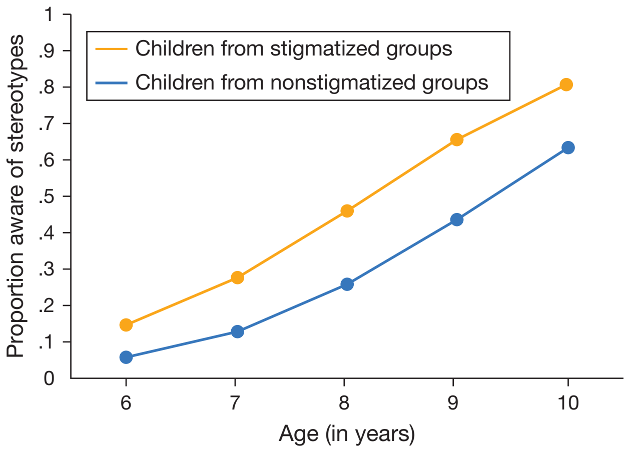

FIGURE 11.13 Stereotype awareness. From at least 6 years of age, children in stigmatized groups are more likely to be aware of stereotypes relevant to themselves. This awareness aggravates the influence of stereotype threat. Adapted from McKown & Weinstein (2003).

For stereotype threats to have an influence, children need to be aware of the stereotypes held by the dominant culture, and the extent of their awareness should also be related to the strength of the effect. Such a relationship has been found in a study that looked at approximately 200 children between the ages of 6 and 10 who came from African-American, Latin-American, European-American, and Asian-American backgrounds. In the first of two tasks, the children were asked about various ethnic stereotypes for real-world groups and for imaginary groups who interacted in ways that involved prejudice. The children saw African Americans and Latin Americans as stigmatized with respect to intellectual abilities, and the children's sensitivity to stereotypes increased markedly as they grew older (McKown & Weinstein, 2003).

In these studies, children from stigmatized groups were much more likely to be aware of stereotypes than were children from nonstigmatized groups (McKown, 2004; McKown & Weinstein, 2003; see Figure 11.13). For example, African-American and Latin-American 7-year-olds were twice as likely as their European-American or Asian-American age-mates to be aware of the stereotypes. In contrast, the children showed no differences on tasks involving the fictional groups' stereotypes, leading the researchers to conclude that their awareness was related to experiencing real-world stereotypes and not to some more general stereotype sensitivity. The most striking finding, however, concerned the effect of stereotype awareness on cognitive task performance, when the relevant stereotype threats were either made salient (for example, "These problems tell us how good you really are at this") or downplayed (for example, "These problems will help us understand how children learn different kinds of things"). When the threat was made salient, the stereotype's negative effects were closely linked to the extent that children were aware of them, with children from stigmatized groups being more severely influenced (McKown & Strambler, 2009). On average, the children moved from virtually no awareness of stereotypes at age 6 to a strong awareness of stereotypes at age 10. Notably, this awareness emerged earlier and strengthened continuously in children who belong to stigmatized groups.

Group Differences over Time

Any analysis of IQ scores and group differences must also take into account the surprising finding that IQ scores have not remained constant over the past few decades (Neisser, 1998). Because test designers often revise the tests so that the mean scores for a population stay at 100, it might seem that average IQ has always been around 100. But when we statistically correct for the adjustments to maintain a mean score of 100, it turns out that there have been dramatic IQ gains over time in country after country throughout the world (Flynn, 1984, 1987, 1999, 2007). Thus, scores have crept up over time, but this rise was masked by regular downward adjustments of the entire score distribution so that the average would remain at 100. This rise in scores, known as the **Flynn effect** after its discoverer, James Flynn, amounts to roughly a 15-point increase in IQ over the last 60 years or so in many different ethnic groups and cultures (see Figure 11.14). Thus, the average IQ test score of African Americans in the 1990s was the same as that of European Americans in the 1940s. Intelligence test scores throughout the world have shifted up almost a full standard deviation in one generation.

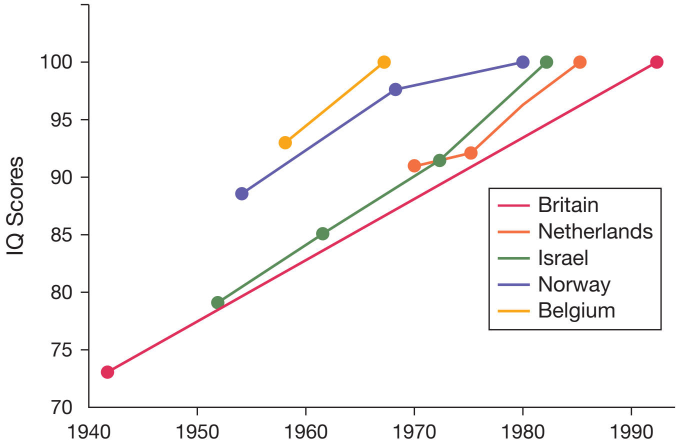

FIGURE 11.14 The Flynn effect. The Flynn effect across several different countries. Intelligence test scores rose dramatically from the 1940s onward. Adapted from Flynn (1998).

A gain of almost 3 IQ points per decade constitutes a massive shift, and no one yet knows why it has occurred. Note that genetic explanations of these differences are out of the question. No one seriously thinks that the genetic makeup of Americans has changed so substantially in several decades that it could account for a 15-point increase in IQ scores. Thus, the Flynn effect highlights the substantial influence that little-understood environmental factors can have on intelligence test scores (Neisser, 1998). A better understanding of the Flynn effect will surely also provide insights into other group differences.

The Flynn effect has been attributed to many possible causes, ranging from better nutrition throughout the world to the increasingly advanced technological skills that the modern world requires (Neisser, 1998). We know that the effect is strongest for those aspects of intelligence that are supposed to be the most independent of culture—skills like spatial ability and analogical reasoning, rather than vocabulary or literacy-based skills. These differences in the magnitude of the Flynn effect illustrate the challenge researchers face in explaining the potential environmental effects on IQ scores.

At present, the Flynn effect shows that environmental effects can be huge and can occur in ways that defy our first intuitions. One proposal argues that increasingly complex cultures make ever-larger demands on the kinds of analytical skills that are important for IQ tests, giving people more practice using those skills. An especially provocative view argues that television has become more cognitively complex in recent years, containing far more characters and interweaving story lines and thereby creating a form of cognitive enrichment (Johnson, 2005). Moreover, if decision makers in business and education are drawn from the ranks of high scorers on analytical intelligence tests, they might naturally make the environments they manage even more intensely geared toward fostering this kind of intelligence (Dickens & Flynn, 2001). This explanation, however, must also address the finding that the Flynn effect also occurs in rural societies with relatively little influence from industrialized cultures. As shown in Table 11.3, rural Kenyan children with an average age of 7 show a dramatic Flynn effect (Daley et al., 2003). In that study, parents' literacy, family structure, and children's nutrition and health seemed to be the strongest explanations of the effect. The size of the effect is comparable to that found in Europe and North America.

There is some evidence that the Flynn effect may be reaching a plateau in Western technological societies. Perhaps this indicates that the influences of modern technological culture on intelligence test scores have reached their limit (Sundet et al., 2004; Teasdale & Owen, 2005). Some researchers argue that this plateau may also help explain an apparent narrowing of the gap between European-American and African-American test scores in recent years (Dickens & Flynn, 2006; Fryer & Levitt, 2004; Nisbett, 2011). In such accounts, the Flynn effect may still be improving scores for some disadvantaged groups while having reached its limit for groups that have long had more advantages. Researchers on intelligence, however, do not all agree with this view. Some think it is possible that IQ scores could still rise 3 points a decade for all groups and that both the plateau and the narrowing of the gap may not be a consistent finding (Weiss, 2010).

Environmental Influences on Intelligence Test Scores

The environment exerts both biological and social influences on IQ scores. There are a host of biological factors that can lower intelligence test scores, ranging from general malnutrition to specific vitamin deficiencies, lead poisoning, or a mother's excessive alcohol consumption during pregnancy. Some of these factors were discussed more broadly in Chapter 2. It suffices to say that these biological effects are real, although they are often smaller than we might assume. Hence, malnutrition has to be at a very substantial level to have marked effects on intellectual functioning (Pollitt et al., 1993). The question of whether a highly enriched nutritional environment confers a biological advantage is much more difficult to answer. Part of the problem lies in determining precisely what is meant by a highly enriched nutritional environment.

In the social realm, deprived environments involving abuse or isolation clearly can lower intelligence test scores

Test	1984 study (*n* = 118)	1998 study (*n* = 537)
Raven's Progressive Matrices	12.82	17.31
Verbal meaning	24.47	27.04
Digit span	4.64	5.03

TABLE 11.3 The Flynn effect in rural Kenya. In a study with 7-year-old Kenyan children, a large increase in test scores was found between 1984 and 1998 in a rural agricultural population largely unaffected by the industrialization and technology of the developing world. All differences between the two time periods are statistically significant. Adapted from Daley et al. (2003).

FIGURE 11.15 Birth order and intelligence. In the population as a whole, birth order is correlated with intelligence test scores, with slight drops in scores for each later birth. The reasons for this association are not well understood.

and academic achievement (Curtiss, 1977). Conversely, particular social influences can have positive effects on IQ scores and school performance. In many cases, positive parenting styles (discussed further in Chapter 14) have many good outcomes, including positive impacts on intelligence test scores and school performance. These approaches to parenting involve practices such as listening carefully to children and responding in ways that are sensitive to their thoughts and feelings. Parents' education levels have an impact as well, and parents may boost their children's tests scores and school performance by role modeling academic goals and mentoring their children (Williams, 1998). Schooling, which has the most obvious and often the most dramatic effects on intelligence, is discussed in a separate section later in this chapter.

Many other factors can also influence intelligence, such as the child's home life and caregivers (see Chapter 14). Family size may have an impact, as smaller families can devote more resources to each child, providing more complex and engaging intellectual experiences. For related reasons, children's birth order also has an influence (see Figure 11.15). On average, IQ scores tend to drop a little for each successive child, perhaps because parents often have more time to devote to a first-born child and less to later-born children (Belmont & Marolla, 1973; Zajonc & Markus, 1975; Zajonc et al., 1979). Of course, like the other group differences, these birth order effects apply only at the population level, and many later-born children score higher than their older siblings. Considerable controversy remains about the true source of birth order effects (Armor, 2001; Rodgers, 2001; Wichman et al., 2006; Zajonc, 2001; Zajonc & Sulloway, 2007), but the correlations are substantial and need to be understood.

In all of these cases, it is critical to keep in mind the errors inherent in inferring causation from correlation. For example, we know that education levels of parents are highly correlated with their children's IQ scores. But is their educational level directly influencing their children's scores? Certainly, being more educated might lead parents to spend more time with their children on activities that develop skills used in intelligence tests. The correlation, however, may also arise from another factor, such as shared genotypes between parents and children. To the extent that IQ is heritable, and that IQ scores, in turn, predict level of education, we would expect highly educated adults to have children with higher IQ scores. Thus, a second factor (genetic relatedness) could be behind the correlation between parents' education level and children's test scores. Researchers who study these kinds of social influences have tried to show that these factors affect intelligence even when nonsocial influences, such as shared genotypes, are taken into account. This work is still under way, and the distinct paths of influence have not been fully disentangled (Davis-Kean, 2005; Kirkpatrick et al., 2009).

Enhancing Early Environmental Influences: Head Start Programs

One kind of influence deserves further discussion and is a natural lead-in to the topic of schooling. It concerns attempts to develop preschool programs that have a long-term positive impact on a child's performance years later, continuing into elementary school. Among these programs, the most widely known is Head Start (see Figure 11.16), initiated in the United States in 1965 as part of the

FIGURE 11.16 Head Start. Head Start programs, such as this one in New Mexico, were designed to provide early educational experiences that would counter the effects of disadvantaged environments on academic performance.

Johnson administration's War on Poverty. The idea behind Head Start and similar programs is that the right kind of early experiences can have a profoundly positive long-term impact on a child's intellectual functioning. The content of individual Head Start interventions varies, but they share the goal of helping children who are at risk for underperforming later in school. The programs usually include nutritional support, health care, and day care support, as well as exposure to certain academic topics and modes of interaction, including reading to the children, playing mentally challenging games with them, and exposing them to arithmetic concepts.

Because these programs are partially funded by the federal government, it is not surprising that their claims to benefit children should come under special scrutiny. Many critics have charged that despite the funding that Head Start programs receive, their students have shown no long-term academic improvements. In reality, their benefits are real, but not always obvious at first glance. It is true that after several years in elementary school, children who had been in Head Start programs did not have better grades or test scores than children from similar backgrounds who were not in the programs. Nonetheless, the programs had other long-term positive effects.

Head Start children were less likely to be held back or put into remedial programs, and they were more likely to finish high school (Anderson et al., 2003; Darlington, 1986; Darlington et al., 1980). It is interesting that IQ scores were not different, given these other differences. But the lack of IQ differences should not mask the clear positive outcomes that, in many people's eyes, more than justify these programs. It is important to note that participation in Head Start (as well as in an earlier version called "Early Head Start") is associated with greater school readiness both in academic terms (math and reading readiness) and in social-emotional skills when children enter kindergarten (Lee et al., 2013). The disappearance of those advantages 3 years later may reflect the challenges that some schools face in building on the early gains provided by those programs and not the inadequacies of the programs themselves.

Head Start remains a fascinating laboratory in which to investigate how planned interventions might facilitate children's intellectual development (Zigler, 2003; Zigler & Muenchow, 1992; Zigler & Styfco, 2004). Although long-lasting direct gains on such measures as analytical intelligence may be difficult to document, they are not the only measures of interest. Measures that are more embedded in the social context in which the child develops, such as rates of children being held back or being put in remedial programs, suggest important, lasting effects of the Head Start program. Further discussion of possible environmental factors that can influence intelligence is perhaps best treated as a topic of its own by looking more closely at the most obvious environmental influence: schooling.

Schooling

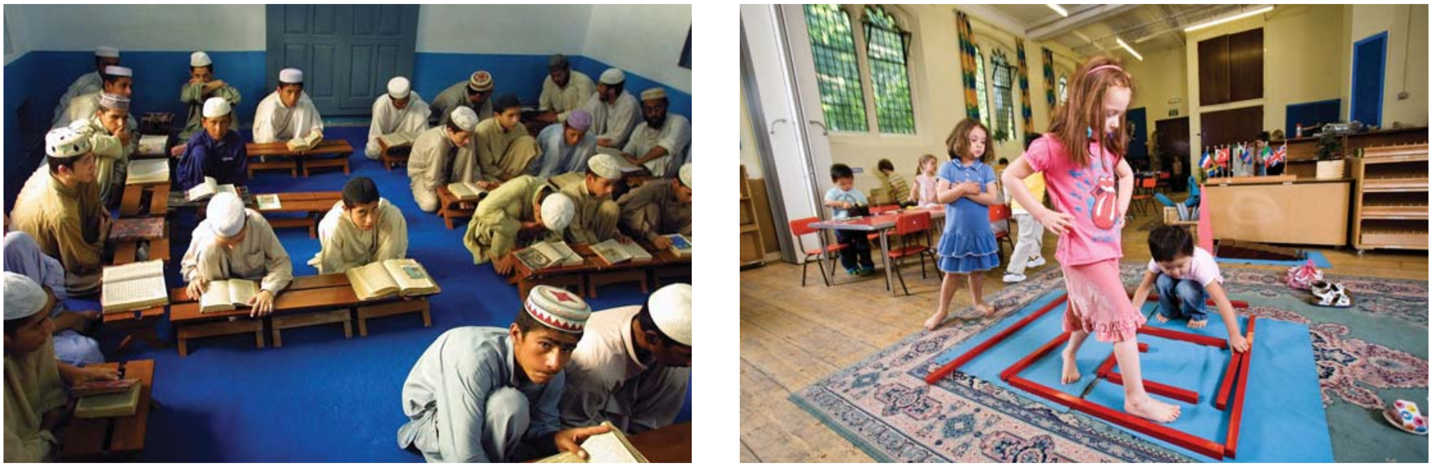
The many kinds of schools in the United States represent only a small fraction of the different schools throughout the world. Moreover, all kinds of schools have a wide variety of effects on their students. Some effects, such as teaching children how to read and write and do arithmetic, are explicitly mentioned in the curriculum, but other equally important influences are implicit in the local school culture. In this section, we will focus on the different ways that schools affect children's thinking and intelligence. We will first consider the range of school types and then examine schools' multiple roles, including serving as socializing agents, cultural institutions, and conveyers of values. Finally, we will explore how schools influence cognitive development, including intelligence.

Characterizing Schools

From age 5 until at least age 16, children in most countries are in school 6 hours a day, 5 days a week, for almost 40 weeks a year. In the United States, most children stay in school until at least age 18. Thus, in many cultures, children spend more than 16,000 hours in schools before finishing their education. What is happening to them during all this time in school?

The answers are complex, and they depend on the nature of the myriad classroom experiences. A classroom environment varies dramatically as a result of local culture, economic resources, and time of the year. Even within the same country, the variations across classrooms of children of the same age are enormous. One classroom may have 16 children quietly and attentively hanging on a much-loved teacher's every word. In another classroom in the same school, the children may be anxious about interacting with a stern, punitive, and widely feared teacher. In a different setting, often one of poverty, the classroom may have more than 30 children exuberantly interacting while a frustrated teacher tries to get their attention. In some of those classes, the teacher is passionately committed to trying to make a difference, while in others the teacher watches the clock, hoping for the day to end, just as many of the students do.

Across cultures the differences can be even more dramatic. Consider the Haqqania madrassa, a Pakistani school of 28,000 students who range in ages from 9 to 30 (see Figure 11.17A). The school is open only to boys and men.



A

B

FIGURE 11.17 Differences among schools. Schools throughout the world, such as **(A)** this madrassa in Pakistan and **(B)** this Montessori school in London, can vary radically in their structure, curriculum, class size, and many other factors.

The younger boys' instruction largely consists of hearing passages of the Koran read in Arabic, even though the boys do not understand Arabic. Instead, they speak Pashto, a local language in Pakistan. The curriculum is meant to be absorbed without question by those who learn it (Goldberg, 2000). After several years, many of the students can recall and recite long passages of the Koran perfectly.

By contrast, consider private Western schools such as the Montessori school shown here (see Figure 11.17B). In such a school, teachers help children explore in more individualistic ways. Children are encouraged to question everything, and they feel free to challenge every statement. They are, in many ways, in charge of their own learning, with teachers serving as guides and facilitators of the students' curiosity.

Finally, consider a school in one of the wealthiest suburbs of New York City. Even though it is an elementary school, the school and the children's parents are already thinking about which colleges will admit these students. The teachers test the children frequently with standardized tests to make sure the children are comfortable with that format. Extensive homework is assigned that is geared toward improving performance on those tests. So that students will stay ahead of statewide norms, the school helps arrange for tutors to meet with their students outside the classroom. By the second grade, students are already intensely competitive and see every activity as a way to succeed and surpass others—or to fail and fall behind.

As these examples show, the nature of classroom experiences varies widely. Some of these variations correlate highly with the affluence of the neighborhoods in which the schools are located. On average, schools in impoverished areas are much less effective learning environments than schools in affluent suburbs. It is therefore not surprising that many U.S. civil rights activists in the 1960s worked to implement forced busing, which allowed underprivileged children access to schools in affluent communities.

Two Prominent Models of Education In the United States, two dramatically different models of education emerged early in the twentieth century (Scribner, 1988). The first came from the American philosopher, psychologist, and educator John Dewey. Expanding on a tradition eloquently described by the French philosopher Jean-Jacques Rousseau (Dewey, 1902/1991), Dewey's approach to education was designed around the child's natural mental abilities and interests and focused on material relevant to the child's daily activities. Building on this "natural" foundation, teachers could introduce the basic concepts of mathematics, literacy, geography, and science. Dewey's emphasis was on the student's mind, not on the subjects to be taught, and he favored projects that require integrating many kinds of knowledge. The Dewey model led to a child-centered form of instruction, one that viewed the child as a spontaneous, active individual who brings many abilities and interests to the learning situation. These abilities and interests would then serve as raw materials and points of departure for further education.

The second approach to schooling began with an Indiana school superintendent, William Wirt, who in 1910 developed the idea of a **platoon school**. This was a school in which every room was used to maximum efficiency, and children moved from classroom to classroom to pick up different intellectual skills, such as reading or mathematics (Scribner, 1988). Similarities between Wirt's approach and the assembly-line model of industrial manufacturing are difficult to ignore. As the psychologist and education researcher Sylvia Scribner put it:

> The educational program did not grow from the children, however, as Dewey's program did. Knowledge was attached to children, somewhat as the parts of an automobile—bumper, headlights, and so on—are attached to basic frames. The same efficiency concepts that led to the development of the assembly line, in fact, were at the heart of the platoon school movement. (Scribner, 1988, p. 23)

The platoon school movement was linked to the rise of behaviorism in America, with its focus on behavioral inputs and outputs rather than on the mind (Scribner, 1988). In platoon schools, behaviorist concepts such as reinforcement and repetition were used as guiding principles in the classroom. Teachers largely relied on external rewards and punishments to encourage maximally effective learning. The platoon school approach came to heavily dominate American education, and similar forms of education have become common throughout much of the developed world.

Q: How does the platoon school approach to education contrast with Dewey's approach?

What Schools Do

Beyond the wide range of school types, there are some common effects produced by most schools, especially in countries such as the United States, where one kind of schooling dominates. Our main focus in this section is on the effect of schools on children's thought. But to understand these effects, it is essential to briefly consider the broader influences that schools have as social and cultural institutions and conveyers of values.

FIGURE 11.18 Socialization in schools. In addition to the curriculum, schools are socializing agents that can teach children how to sit and listen quietly in groups for extended periods.

Schools as Socializing Agents Just as important as teaching knowledge and skills, schools teach students how to cope, and perhaps even to thrive, in a highly regimented setting, surrounded by peers, where competition increases each year. Both the active child and the bored child must learn to sit still and be quiet (see Figure 11.18). The impatient child must learn to wait for feedback on work or the answer to a question. All children must learn to work within a system of rewards and punishments designed to shape their behavior, whether these are grades, awards, or trips to the principal's office. Children must also learn to "read" teachers' intentions, to know what teachers really want, what materials they think are important to learn, and what behaviors they expect. Finally, children learn a great deal from interacting with their peers, often acquiring behaviors and beliefs from peers that were not intended by parents or teachers.

The nature of this socialization may also be changing. For example, in many school districts in the United States, recesses have been eliminated or cut back for budgetary or security reasons (Bornstein, 2011). This change in turn may require children to sit quietly and be physically inactive for much longer stretches of time. That requirement may present large challenges to some children.

Schools as Cultural Institutions Schools also transmit to children many aspects of the culture of the dominant groups that organize, fund, and manage the schools. For children growing up within these dominant groups, this process of enculturation, or cultural learning, may seem appropriate and helpful. For children from nondominant groups, however, the same enculturation may conflict with the values and priorities conveyed by their families and communities. Some cultures, for example, believe that men and women should have different social roles and start to teach those differences in the earliest stages of schooling. Boys and girls may receive different forms of instruction and be rewarded and punished in different ways. A child whose family embraces these major distinctions between gender roles would feel no conflict between the cultures of home and school. Indeed, the school may help advance that child's entrance into her parents' society. But for another child, whose family feels separate from the dominant culture, school can be an alienating experience.

It has been argued that some aspects of African-American culture are at odds with the implicit cultural teachings of most U.S. schools. The psychologist Wade Boykin (1994) and his colleagues argue that African-American culture tends to emphasize affect, communal action and interaction, movement, interpersonal harmony, and oral interaction. In contrast, the dominant U.S. culture, including the schools, tends to emphasize affect-free problem solving, individual effort, sitting still, competition, and written performance and literacy. Thus, a child from the dominant culture enters school with all the values from home dovetailing nicely with the school's structure, whereas some African-American children enter school at odds with much of the implicit structure (Boykin et al., 2005; Marryshow et al., 2005).

This kind of conflict between schooling patterns of the dominant culture and the values of local subcultures occurs elsewhere in the world as well. For example, consider the conflict between the Inuit community members of Baffin Island, Arctic Bay, and the "southern" school systems of Canada (Douglas, 1994; McGregor, 2010). In many Inuit communities, children are expected to help out during the day in such activities as taking care of younger children or helping to unload fish from a large catch. When a child helps out in this way, however, the "southern schools" mark down the child as "truant." This practice creates considerable tension for the children both with their families and their schools. In almost all such cases, children in the non-dominant group become alienated from the schools and do not perform as well. These effects are often related to schools that see the traditional culture as somehow deficient rather than merely different.

Schools as Vehicles of Values Finally, the idea that schools teach children certain cultural values or, conversely, erode those values has become increasingly prominent in the United States. In this view, schools are seen as helping to instill a moral sense or a moral compass. This can be seen in efforts to make children sensitive to the needs of others, to ethnic and group differences, and to certain ethics of work and self-discipline. Whether schools should play such a role is highly controversial, and many parents feel that in doing so, schools undermine the parents' own attempts to teach their children values.

In the United States, this conflict has repeatedly emerged in the controversy over whether prayer should be allowed in the public schools. The U.S. Constitution, which requires separation of religion and state, has been interpreted as disallowing any religious practices in schools that are supported by public funds. But many religious parents feel that depriving children of exposure to prayer at school compromises a parent's ability to instill important religious values. Thus, they see schools as central to instilling values in their children. We will consider in much greater detail the question of moral values and their emergence in children in Chapter 12.

All three types of influences—socialization, enculturation, and the instillation of moral values—overlap and work together; they are not easy to keep separate. Nonetheless, it is useful to see them as three different, interrelated sources of schools' influence on children. All three types of influences are discussed more broadly, in contexts other than schools, in the next few chapters.

Q: What are some ways in which schools influence children besides educating them in the curriculum?

Schools and Thought

When we look to the more explicit influences that schools have on thought and intelligence, there is little doubt that schooling increases intelligence in all the ways it is normally assessed. A variety of studies have shown that the number of years of schooling children receive seems to directly influence their performance on intelligence tests (Ceci, 1991, 1999; Falch & Sandgren Massih, 2011; Teasdale & Owen, 2000; Winship & Korenman, 1997). Furthermore, between June and September, intelligence test results tend to drop for children who are on summer vacation. Just 2½ months out of school seems to be enough to cause a decline in performance equivalent to roughly a month of progress (Cooper et al., 1996). One remarkable demonstration of these effects occurred when schools in parts of Virginia were closed in the 1960s to avoid racial integration. Some children were deprived of school for a year or more. Compared with children whose schooling was not interrupted, those unable to attend lost roughly 6 points on intelligence test scores for each year of school they missed (Green et al., 1964; Neisser et al., 1996).

Besides imparting information, schools teach analytical skills, test-taking skills, and certain ways of thinking. In this respect, the effects of schooling on intelligence test scores resemble the effects of practice and training on athletic skills. Although people's athletic abilities differ, everyone can benefit from good coaching, training, and practice. If you haven't done the right exercises to develop your muscles, your performance will suffer, and appearing "coordinated" in more complex motor tasks is as much a product of practice as it is of native abilities. Practice and training appear to be at least as important for intelligence as they are for motor skills.

Q: In what ways do schools have an influence on intelligence test scores?

In addition to improving intelligence test performance, schooling has broad effects on thought that differ from the effects of simply growing older. In one study of the ways schooling and age each affect mathematics and numerical reasoning, researchers compared performance within three groups of kindergarten and first grade students. In the first group, students differed in age, but they had all experienced the same amount of schooling. In the second group, students were all the same age, but some had been in school for longer than others. The students in the third group differed in both their age and their amount of schooling.

The comparisons revealed that children improve at conservation of number (see Chapter 9) as they got older, regardless of how long they are in school. For mental arithmetic, on the other hand, schooling (and not age) correlates with the most improvement (Bisanz et al., 1995). Other kinds of cognitive skills show similar contrasts. For instance, schooling seems to improve children's memory for stories by teaching them about narrative forms and styles (such as how to introduce a story), which helps them to encode and retrieve narratives efficiently. By contrast, age seems more important than schooling for improving children's general memory capacity, independent of the use of story formats (Varnhagen et al., 1994). Schooling seems to contribute more than age does to the development of transitive reasoning skills (as in the reasoning task about sticks' relative lengths, discussed in Chapter 9; Artman & Cahan, 1993), and it improves performance on common tests of executive functioning (McCrea et al., 1999). The type of schooling seems to matter as well. Children in more academic tracks of large school systems show larger intelligence test gains from schooling than children in vocational tracks (Gustafsson, 2001).

The pattern that emerges is that the effects of schooling predominate for cognitive skills used more in the classroom than in the child's daily life outside school. In contrast, simply growing older provides more opportunities to develop the skills commonly used in everyday life, so age effects predominate over schooling effects in these cases. Because IQ tests tend to tap both sorts of cognitive skills, we would expect different effects of schooling on IQ subscores, which is the result normally found. Thus, math problems and reading skill are closely related to school experience, but some spatial tasks are less closely related. Overall, however, there is at least some degree of influence on most subscores.

In addition to teaching specific cognitive skills, schooling also accustoms students to focusing on tasks taken out of their real-life contexts, which may also improve aspects of intelligence test performance. In short, schools do enhance intelligence. It is true that children who are more intelligent for other reasons often stay in school longer and thereby reap larger benefits. But even when others determine the length of time children spend in school, the intelligence-enhancing effect remains (Ceci, 1999). Of course, not all schools are equally effective, and many researchers are exploring why some schools work so much better than others.

Cognitive Science and Teaching As we have seen in several chapters, children have a rich, complex array of intuitive beliefs about the world that they have gradually built and consolidated over several years. It seems obvious that instruction will be most effective when teachers understand these intuitive beliefs and can take each child's knowledge into account to optimize instruction for that child (Keil, 2011). Currently, most schools do not emphasize what each child brings to the classroom, nor do they encourage much individual exploration or interactive dialogues (National Research Council, 2007). To a certain extent, these shortcomings are inevitable, given that many major discoveries about cognitive development have been made relatively recently (National Research Council, 2007). It takes time for this research to be incorporated into teaching methods. Thus, despite the evidence that children's reasoning is not constrained by Piaget's global stages of cognitive development (see Chapter 9), many elementary school teachers still cite these stages as a reliable way of determining what a child can and cannot be taught at a given age.

Three Cognitive Science Themes for Education Some of the most promising studies linking cognitive science research to educational practice arise from careful task-based analyses of precisely what is involved in learning specific cognitive skills and how that process relates to other aspects of cognitive functioning. The Community of Learners program, developed by psychologists Ann Brown and Joseph Campione, provides a prime example of how cognitive science can be used in education and illustrates a few of the factors that can make some schools more effective than others.

Brown and Campione (1994) developed the Community of Learners program because they believed that three major findings from cognitive science research should change the nature of educational practice. The first of these findings is that learners actively build their own knowledge and understanding, rather than passively receiving information from others. The second is that metacognitive awareness, or an understanding of our own cognitive states (see Chapters 9 and 10), is extremely important to the learning process. The third finding is that people are not simple, all-purpose learners, but organisms with propensities to learn some kinds of knowledge more easily than others. As we have seen, these propensities arise both from our human biological preparedness for some forms of knowledge and, at an individual level, from building expertise in specific domains. In the classroom, Brown and Campione used these three findings as the basis for many specific innovations, a few of which are illustrated here.

The first key idea that Brown and Campione emphasized, *active learning*, leads to teaching techniques such as "guided discovery," in which children are urged to discover new ideas and relations through active, often hands-on exploration. The researchers found, however, that an insightful teacher must guide the discovery process, or else

SCIENTIFIC METHOD: Direct versus Inquiry-Based Methods of Instruction

Hypothesis:

Although inquiry is thought to capture naturalistic ways of learning that lead to deeper conceptual insights, in many situations direct instruction may be more effective.

Method:

1. A total of 57 children (mean age 9 years) participated.
2. Children were randomly assigned to one of four groups: (a) high guidance followed by high guidance (High + High), (b) high guidance followed by low guidance (High + Low), (c) low guidance followed by high guidance (Low + High), and (d) low guidance followed by low guidance (Low + Low).
3. All children were pretested on their ability to design a simple physics experiment.
4. Experimenters taught children with direct instruction and/or unguided discovery in one of the four combinations.
5. Transfer of ability to design good experiments was measured.

Results:

High + High and High + Low guidance conditions were far more effective than the other two conditions in instilling a deep conceptual insight into how to design unconfounded experiments by using control of variables strategies (CVS).

Conclusion:

In at least some learning tasks, leaving children more on their own to discover the best ways to design experiments is less effective than providing more direct instruction, even if the direct instruction involves only half as many manipulations of physical systems. Direct instruction plus discovery was almost as effective.

students will likely "discover" many falsehoods, especially in science education (Klahr & Nigam, 2004; Klahr, 2013; Matlen & Klahr, 2013). For example, in guided discovery activities about evolution, children often "discover" the misconception that organisms evolve in their own lifetimes, unless they are guided toward understanding how natural selection happens over successive generations. In learning how to design the best ways to understand simple physical mechanical systems, more explicit guidance not only provides better learning with fewer trials, but also promotes deeper conceptual understanding (Matlen & Klahr, 2013; see Scientific Method box).

Teaching methods that foster active learning are also linked to Vygotsky's notion of the zone of proximal development (Vygotsky, 1978), described in Chapter 9. The zone of proximal development represents the next level of ability or understanding that a child can learn with appropriate, supportive teaching. Brown and Campione stressed that each child always has zones of proximal development in many different areas of learning. Good teachers try to make as many of them available as possible so the child can actively choose her own route to knowledge.

Active learning and zones of proximal development can also influence children's relationships with peers who are somewhat more competent. In many cases, student collaborations can provide opportunities for active learning, since they give students with different strengths the chance to teach one another (Tudge, 1992). More broadly, Vygotsky saw these educational interactions with both adults and peers as part of the process of internalizing the knowledge and practices of the students' own culture. Schools play an important part in this process, both in terms of the skills and information they teach and in terms of the cultural values and norms they convey in less explicit ways (Davydov & Kerr, 1995).

Brown and Campione's second theme, fostering *metacognitive awareness*, translates into classroom practice by using methods that encourage students to pay attention to their own cognitive states. The method of "reciprocal teaching" can foster this kind of awareness, as each member of a group of roughly six children and a teacher takes turns leading the discussion. By requiring each student to present ideas, explain them, and answer questions about them, this method encourages children's awareness of the nature of their own knowledge. When children can develop their own areas of expertise, they can act as resources to the whole community of learners. In some cases, students who have trouble learning certain computational or reasoning skills when they are taken out of context can excel at learning to apply these same skills within a particular domain or context. Each child can take pride in his own area of expertise, and as the children learn to rely on each other, this distribution of knowledge fosters interactive learning and interdependence.

Clearly, these techniques for improving metacognitive awareness are closely tied to Brown and Campione's third theme, the importance of *domain-specific learning*. In addition to its metacognitive benefits, allowing students to develop some individualized areas of expertise also allows teachers to observe how each child acquires knowledge in different domains at different rates. These insights can help teachers carefully diagnose each student's proficiency in order to determine a zone of proximal development for each child in a particular domain. Such domain-specific assessments allow teachers to see, for example, that a child has not yet mastered the concept of the number line. In that case, he should not yet be taught mathematics that relies on that concept (Bruer, 1997). Domain-specific assessments of preparedness are crucial here, since a child who is cognitively well prepared for learning may still need more help understanding specific concepts within a particular domain.

Q: How is the zone of proximal development concept useful to education?

Implementing Cognitive Science Ideas in the Classroom Cognitive science is offering many new approaches for teaching (Bruer, 1993a; Duit & Treagust, 2003; Klahr & Li, 2005; Klahr et al., 2011; Metcalfe & Kornell, 2007; Richland et al., 2005; Wieman, 2010), some of which are now making their way into the classroom. To see how their results measure up, consider Figure 11.19, which compares test performance among three groups of students: those taught with the Community of Learners program methods for a full year, those exposed to these methods for half a year and normal instruction for the other half, and those taught all year in a regular classroom. The Community of Learners methods had dramatic impacts on the amount of knowledge that students acquired and retained. As the second-semester graphs show, the program's impact increased over the months, such that children immersed in it for a full year learned much more than children who learned the same material in a more traditional format.

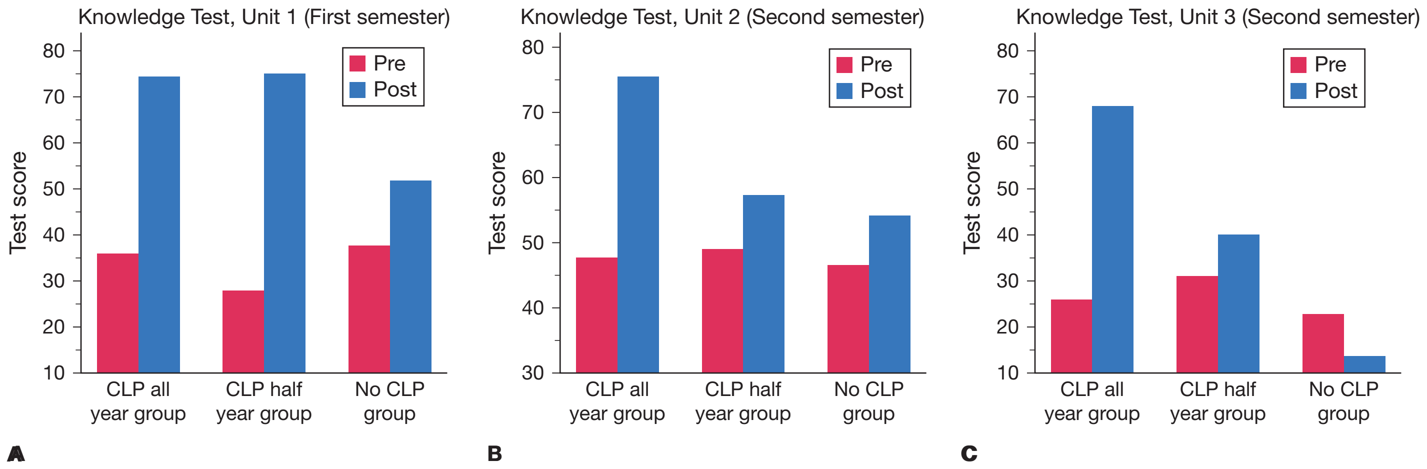

FIGURE 11.19 Effects of the Community of Learners program of instruction. The first group (CLP all year) was exposed to the Community of Learners program methods for a full year. The second group (CLP half year) was taught with these methods during the first semester, then switched to regular instruction for the second semester. The third group (no CLP) had regular classroom experience all year. The Community of Learners program clearly enhanced student test performance. **(A)** Unit 1 test results during the first semester when both the CLP all year group and the CLP half year group did research, but the no CLP group did not do research. **(B)** Unit 2 test results during the second semester when only the CLP all year group did research. **(C)** Unit 3 test results during the second semester when again only the CLP all year group did research. Adapted from Brown (1992).

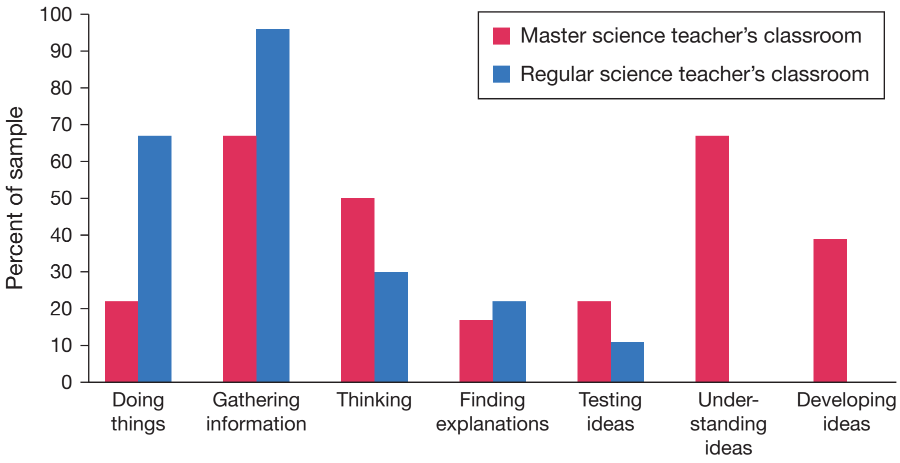

FIGURE 11.20 Teaching children how to think about science. When sixth grade students taught by a master science teacher were compared with students taught by a regular science teacher, there were striking differences in the sorts of questions the students asked in discussions about science. For example, among the master teacher's students, metacognitive questions—that is, questions about the thought processes involved in doing science—were seven times more common than they were among the regular science teacher's students (the comparison classroom). By contrast, more descriptive questions were three times more common in the comparison classroom. Adapted from Smith et al. (2000).

Q: How has cognitive science started to influence educational practice?

It is especially encouraging that teachers do not need to be immersed in the latest cognitive science research to implement many of its messages in the classroom. Master teachers often use these principles on a daily basis. In a small parochial school in Wisconsin, a teacher known as Sister Mary Gertrude Hennessey taught science to the same group of children for most of their elementary and middle school years (Smith et al., 2000). She used many of the principles that Brown and Campione advocate, and her students' progress was remarkable (see Figure 11.20). Like many master teachers, Sister Gertrude also deeply understood her discipline. Moreover, she also had earned a doctorate in philosophy, which she felt greatly enhanced her teaching of science. Her great success demonstrates that after several years in an extraordinary teacher's classroom, ordinary middle school students can show patterns of scientific reasoning and conceptual understanding that typically do not emerge until late in high school or in college (Smith et al., 2000). Stories of such exceptional teachers provide more than encouragement; they also serve as critical cases for careful research. If master teachers can support such high levels of achievement, it is important to help more instructors to incorporate their methods.

Aptitude-Treatment Interactions Not all students approach learning in the same way. Even when children have very similar levels of intelligence and background knowledge, their most effective ways of learning will vary. Therefore, the methods that a teacher uses to help one child blossom may not work well for another child. Looking at this relationship in the inverse: a learner's specific strengths (her aptitudes) and weaknesses impact the effectiveness of a particular teaching method (the treatment) (Cronbach, 1975; Cronbach & Snow, 1977). This reciprocal relationship is known as **aptitude-treatment interactions**. Aptitude-treatment interactions provide an educational example of the idea of "goodness of fit" that we encountered in Chapter 7. There we considered how an infant's temperament fits with that of his caregiver, affecting their interactions and thereby helping to shape development. Here the idea of "fit" is narrower, focused on the interaction between a student and a particular manner of instruction.

Many studies have documented aptitude-treatment interactions involving a broad range of cognitive factors, often called "learner characteristics." Some people learn better when they adopt *holistic strategies*, considering many aspects of a problem at once. Others may do better by using *local strategies*, breaking down the problem into small, distinct components. Some people learn more effectively from visual imagery, while others may do better with verbal approaches (Riding & Cheema, 1991). Still other studies show that some students benefit more from didactic forms of instruction (similar to lectures), while others learn better from more interactive kinds of instruction (Snow, 1989, 1992). More broadly, teaching situations that are highly structured—in which teachers provide a great deal of control over student activities and give clear, direct instructions—work best with students of low ability, high anxiety, and/or poor organizational skills. But this approach can actually hinder highly capable students, who often do much better in less structured environments that emphasize student exploration (Snow, 1989, 1992). Optimal student-teacher interactions clearly depend not only on social and motivational factors, but also on both people's cognitive aptitudes and how they relate.

Aptitude-treatment interactions illustrate the importance of recognizing that children are individuals with different cognitive strengths, since what works well for one child might be a disaster for another (Pakarinen et al., 2011). The challenge, of course, is to develop more sensitive ways of assessing and understanding these differences and adjusting instruction to take them into account. The concept of aptitude-treatment interactions may be particularly useful when devising instructional programs for children who have special needs or who are especially gifted. As children depart from cognitive norms, it becomes more likely that their ideal learning environment will differ from that of most children. For example, when developmentally delayed children experience different educational settings, the most delayed children tend to benefit more from highly directive instruction, whereas somewhat less delayed children benefit more from instruction that involves more interaction (Dale et al., 2005).

Q: Provide a specific example of how two groups of children might thrive optimally in quite different educational settings.

Creativity

Aptitude-treatment interactions demonstrate that people vary cognitively in far more ways than IQ subscores can measure (Riding & Cheema, 1991; Sternberg & Zhang, 2005). One widely described pattern of variation that is distinct from intelligence is **creativity**, the ability to come up with novel insights and new ways of solving problems. We all know of people with impressive analytical abilities and extensive practical knowledge, but who never seem able to escape conventional ways of thinking. We also know of people who seem less analytical and informed, but who frequently devise powerful new ideas and solutions. Such creativity is valuable and can lead to great advances in such fields as industry, medicine, and teaching. For these reasons, most researchers believe that creativity varies independently from intelligence—that is, the two measures are only weakly correlated or not correlated at all (Furnham & Nederstrom, 2010; Kaufman, 2009; Runco, 2007). But creativity is extremely difficult to measure. When you ask people to define creativity in testable ways, they express a wealth of opinions about the ability's core nature. Does it primarily depend on the ability to draw new analogies, to defy conventions, to think "laterally" instead of "vertically," or to break old patterns of thought and to be open to new ones? Such questions have generated a great deal of research; several thousand studies of creativity have been published in the last 10 years alone. We will highlight several themes that have emerged from this work and consider a couple of common ways of assessing creativity.

One controversy about creative ability concerns whether people are creative largely because of their intrinsic qualities or whether there are certain kinds of situations that make virtually anyone highly creative (Kasof, 1999). Both kinds of influences on creativity are relevant, but here we will focus more on the internal, or dispositional, influences. In Chapter 13, we will see how socialization affects creativity.

Measures of Creativity

One classic approach to defining and measuring creativity is based on the idea of achieving a novel perspective on a problem. People can often become trapped in a particular perspective on a problem. Creative people seem more able to break that focus on the conventional way of looking at a task to adopt a novel perspective (Eysenck, 1994). A variety of methods have been used to measure this aspect of creativity:

- *Nonverbal tests*—for example, drawing lines to elaborate on a simple shape (Torrance, 1974).
- *Category generation*—for example, listing as many things as possible that have gears or listing things that get smaller over time (Wallach & Kogan, 1965).
- *Generating consequences*—for example, imagining what would happen if all laws were abolished (Guilford, 1954).
- *Alternative meanings test*—for example, writing as many meanings as possible for ambiguous words such as *cut* or *duck* (Getzels & Jackson, 1962).
- *Alternative uses*—for example, generating as many alternative uses as possible for familiar objects such as bricks or paper clips (Getzels & Jackson, 1962; Guilford, 1962).

Alternative uses have been studied extensively in overcoming **functional fixedness**—that is, the bias to use an object or tool in a conventional rather than a novel way to solve a problem. Creative people are not as likely to stay "fixated" on an object's standard function. For example, in a classic study by Karl Duncker (1945), participants were asked to attach a candle to a wall and were given a box of matches, a box full of tacks, and a candle. The solution (see Figure 11.22) required a novel way of using the tacks and the melted wax from the candle. It was thought that only creative people could break out of the familiar uses of each component and come up with the solution.

All these ways of measuring creativity have allowed researchers to investigate two closely related developmental questions: Can creativity be taught? And do people's levels of creativity remain stable as they age (for example, are kindergartners who are considered creative more likely to also be viewed as creative in adulthood)? These two questions are linked because, to the extent that creativity can be taught (and thereby increase over time), it is likely to be less stable over the lifespan.

DEVELOPMENT AND SOCIAL POLICY

Computers and e-Learning in the Schools

Computers have had a dramatic impact on many cultures. Many children in industrialized countries spend more time looking at computers or cell phone screens than they do watching television (Taylor & Keeter, 2010). Using the Internet to search for information, play online games, or interact on social networks has become a commonplace event. But before these uses became commonplace, children were using computers in schools. Today, the vast majority of schools in developed countries make Internet-linked computers available to their students (see Figure 11.21).

The use of computers in the schools on such a large scale since the 1980s raises questions about how they affect education. Do they support more efficient learning? Are they more helpful in some academic disciplines than in others? Does access to the wealth of information on the Internet contribute to children's conceptual growth, or does it overwhelm them with too much information, much of it dubious? Computer use in the schools varies so widely that there are no easy answers to these questions, and so controversy remains regarding their academic value (Cuban, 2001; Hew & Brush, 2011; Joshi et al., 2010; Sandholtz & Reilly, 2004; Tamim et al., 2011). Nonetheless, some general messages are emerging about the most effective ways of using computers to enhance learning.

The cognitive science approach to educational practice has helped promote the use of computers to further educational goals (Roschelle et al., 2000). Rather than simply providing positive and negative reinforcements in automated drills, computers can be used to improve students' access to information, to further communication, and to provide some domain-specific assessments of the child. Computers can be most effective in the classroom when teachers have clear, specific goals for incorporating them into lessons and evidence that these goals are feasible. Too often, school districts buy a large number of computers, set them up in the classrooms, and then are dismayed to find that they have little impact on learning. But when computers have been used in the context of cognitive theories of learning, there have been some striking successes (Sandholtz & Reilly, 2004; Tamim et al., 2011). Brown and Campione's Community of Learners program used computers to help teachers hone in on students' zones of proximal development (see Chapter 9). Software designed for classroom use can help teachers get more precise moment-to-moment snapshots of a child's progress on an academic task. This can help teachers determine which new topics would be challenging but still within the student's capability.

Computers and other modes of Internet access can also enhance education by supporting collaborative learning. With computer networks, students can collaborate over long distances and large time frames by posting their work in a com-

FIGURE 11.21 Computers in the schools. Although computers are now used in virtually all schools in developed countries, controversy remains concerning their usefulness as supplements to more traditional forms of education.

In fact, an individual's performance on common creativity tests remains fairly stable over time, but there is less consistency on creativity tests than on intelligence tests (Simonton, 2000). To the extent that creativity test performance is less stable than intelligence test performance, it supports the view that anyone can become at least somewhat more creative by learning and practicing specific ways of thinking (Murdock, 2003; Sternberg et al., 2004). These techniques include using mental images to explore new possibilities (Smith et al., 1995), exploiting the power of analogies (Holyoak & Thagard, 1995), and radically reframing problems (Polanyi, 1966). In addition, simply focusing on developing task-relevant cognimunal space on a server or on a social networking site. Cognitive science researchers have shown considerable interest in trying to understand the special nature of learning and thinking in groups where intellectual resources are shared (Hutchins, 1996). Internet access allows children in one classroom to develop collaborative working groups that span several continents. Web 2.0 software and supporting hardware enable children to create content and evaluate content created by others (Kitsantas & Dabbagh, 2010). Children may not always use social networking sites, wikis, and other Web 2.0 technologies in productive ways (Carr, 2010), but the potential for increased information access and evaluation is there. At the same time, there may be some unintended cognitive effects of having information easily accessible through search engines. Thus, when individuals bookmark search results, they are much more likely to forget those results than when they do not click on a bookmark (Sparrow et al., 2011). Thus, while search engines can greatly increase access to knowledge, they may also sometimes result in individuals' knowing less on their own.

As computers become more powerful, flexible, and easier to use, they have the potential to become collaborative partners in the learning process and not just passive tools (Linn & Hsi, 2000). Advances in artificial intelligence already allow computers to interact in increasingly conversation-like ways with students and to be sensitive to students' cognitive and emotional states (Graesser et al., 2007; Song et al., 2004). We do not understand how this kind of "collaboration" will enhance learning or which sorts of students are most likely to benefit, but many education researchers are exploring the benefits of these forms of learning (Bransford et al., 1999). An important component of the success of computer-supported collaborative learning seems to be the awareness of the knowledge and areas of expertise of other group members and the presence of software tools to help optimize that awareness (Janssen & Bodemer, 2013).

One recurring problem is that computers are often in special resource rooms and only used sporadically by students, sometimes as little as 1 hour a week (Cattagni & Ferris, 2001). That sort of limited access may largely thwart the most effective ways in which computers can be used. Those limitations, however, are rapidly changing. Many schoolchildren can now access the Web anywhere with their smartphones, and some school districts are providing all the students in a classroom with tablet computers. These devices enable children to have continuous portable access to the Internet and to simple computer programs (Hu, 2011). These changes may facilitate collaboration, information access and transmission, and more rapid feedback. Before school districts rush to invest in such new technologies, however, they must take care not to repeat the mistakes of prior failed computer implementations. Large-scale pilot studies should be run to ascertain the potential benefits and efficacy of smartphones and tablets, thereby avoiding any unnecessary expense for information technology in the classroom (Hu, 2011). In making the decision as to whether to commit limited resources to purchasing tablets and other devices, school districts, especially poorer ones, will need to know how this new generation of computers affects educational experiences. They will also need to ask hard questions about cognitive tradeoffs of Internet access. Some critics suggest that continuous Internet access can reduce attention span under the guise of "multitasking" and create what some call an "Internet-induced ADD" (Carr, 2010). Texting, Web surfing, and interacting with peers in an unsupervised manner on social networking sites are not always positive educational experiences. Throughout the world, the issue for schools will soon not be whether children have personal computers in the form of smartphones (they almost all will, even in the least developed countries); it will be when it is educationally effective for them to use those devices in the classroom.

E-learning in all of its forms is becoming a central part of the modern classroom. If designed efficiently, e-learning can save money rather than increase expenses because it allows children to practice certain kinds of problems, such as math exercises or vocabulary drills, with less direct teacher involvement. Indeed, some charter schools have relied heavily on blending traditional teaching with e-learning to meet their budgets (Abramson, 2011).

As computers get better at tracking each child's individual strengths and weaknesses, there is the potential for tailored instruction that may not always be possible in a traditional classroom. Computers and their software programs are increasingly being designed as "pedagogical agents," helping children to build on their skills in an optimal fashion (Graesser & McNamara, 2010; Graesser et al., 2012).

tive skills and heuristics can lead to more creative thought (Hennessey & Amabile, 2010).

These kinds of training do seem to improve certain aspects of creative thinking, but it is not clear whether similar experience-dependent effects account for most people's creativity. Certainly, many people like to think that there is an intrinsic component as well. Some researchers suggest that because creativity appears to run in families, there may even be a substantial genetic contribution (Eysenck, 1995). It is difficult, however, to disentangle genetic effects from those that might occur from growing up in an environment fostered by highly creative parents.

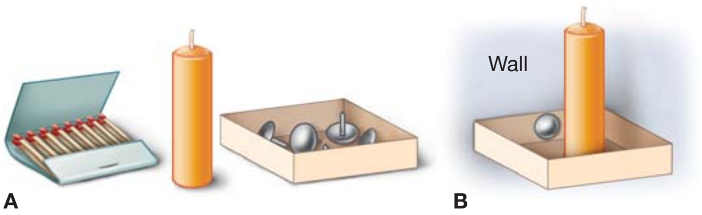

FIGURE 11.22 Functional fixedness. In this classic problem studied by Karl Duncker in 1945, creativity was measured by the extent to which participants could avoid being fixated on **(A)** the standard functions of matches, candles, and thumbtacks and **(B)** come up with novel and creative uses. Adapted from Duncker (1945).

The Development of Extraordinary Creativity

Howard Gardner (1994, 1997), whose theory of multiple intelligences was discussed earlier in the chapter, has advocated a different approach to studying creativity. Gardner argues that the common psychometric approaches to defining and measuring creativity have yielded several important insights, but they largely fail to truly identify the people who are most creative in everyday life. Instead, Gardner advocates studying extraordinarily creative people as a way to uncover creativity's critical components.

Two approaches best capture Gardner's proposals for how to study creativity. The first of these, the **idiographic approach**, involves studying case histories of highly creative individuals to see whether they seem to cluster into different types. The second method, known as the **nomothetic approach**, involves comparing the lives of especially creative individuals to look for common patterns or principles (Simonton, 2000). Thus, we might ask if extraordinary creativity typically emerges late in life, or we might ask whether more highly creative people tend to live during times of dramatic cultural change.

Gardner has often taken the idiographic approach, studying in detail the lives of creative geniuses. He used several criteria to choose these individuals. First, he sought out people who exemplified creativity in seven of the eight multiple intelligences he had defined in his earlier research: linguistic, logical/math, musical, spatial, bodily/kinesthetic, interpersonal, and intrapersonal intelligence. As Table 11.4 shows, each kind of intelligence lends itself to particular professions, and Gardner studied creative geniuses in each one.

Gardner emphasized that most outstanding people spent many thousands of hours of practice or sustained effort in their chosen domain. Thus, creativity rarely just appeared without a passion to invest time and effort in a domain (Ericsson, 1996). In each area, Gardner chose people who had continually excelled in their domain by solving problems, fashioning products, or raising issues. Moreover, their contributions had to be recognized as new and different and yet be broadly accepted in a way that had dramatic influence on the culture at large. Thus, the recognition of extraordinary creativity must always be seen as a social judgment relevant to a particular cultural group. People are not creative in isolation, but only in terms of how their accomplishments relate to the society in which they live (Csikszentmihalyi, 1997; Harrington, 1990). This observation also resonates with Vygotsky's ideas about how children come to internalize the sociocultural context in which they grow up. Similarly, creativity emerges as an individual becomes embedded within a set of cultural and social structures.

Although Gardner's sample of seven people is too small to form strong conclusions about how creativity develops, he was nevertheless struck by the many ways in which these people's life experiences differed from what we might expect from a random sample of the population. Taking a nomothetic approach, Gardner looked for similarities between their lives and began to uncover some common principles. The following patterns hold true for most, if not all, of the seven geniuses:

1. Most were born near great cultural centers or cities.
2. Most came from middle-class backgrounds, rather than from the intellectual elite, wealthy families, or poor families.

TABLE 11.4 Creativity in different domains. Gardner originally suggested that there are seven separate intelligences and that each one can result in its own form of creative genius. (Naturalistic intelligence was later added as an eighth kind of intelligence. Charles Darwin would be a creative genius in naturalistic intelligence.)

Kind of intelligence	Profession	Creative geniuses
Linguistic	Poet, writer	T. S. Eliot
Logical/mathematical	Scientist, mathematician	Albert Einstein
Musical	Composer, musician	Igor Stravinsky
Spatial	Sculptor, painter, sailor	Pablo Picasso
Bodily/kinesthetic	Dancer, athlete, choreographer	Martha Graham
Interpersonal	Teacher, salesperson, leader	Mahatma Gandhi
Intrapersonal	Counselor, psychologist	Sigmund Freud

3. Their families were usually intact and had strong work ethics.
4. Most experienced no pressure to achieve in a particular profession, just to work hard at whatever was chosen.
5. Most had strong emotional ties to nonfamily members, such as caregivers and early mentors.
6. Most did not choose which profession to pursue until around the age of 20. Few were child prodigies.
7. At around age 20, most moved to major centers of culture.
8. Most sought out like-minded people and immersed themselves in groups of literary companions, artists, scientists, and so on.
9. The older they got, the more their work became an all-consuming part of their lives.
10. Most had an unusual combination of intellectual talents, not just the one in their domain of endeavor.

These common patterns are fascinating, but they do not neatly coalesce into a sensible account of what makes a person creative. Gardner also uncovered other factors in these people that seem to more directly relate to the manifestation of great creativity. For example, most of them went to greater-than-average lengths to promote themselves and to advance their own reputations. Even the most modest, Einstein, was careful to make sure that others were aware of his work and that it was presented in the right way. They also tended to have difficult relationships with those close to them, ranging from Einstein's near total disregard for others to Picasso's sadistic behavior. Gardner felt that to some extent, all of these people sacrificed their relationships in service of their work.

Q: Describe two different approaches to the study of creativity and the merits and problems of each.

Bringing similar approaches to bear on the developmental factors associated with creative genius, researchers have repeatedly found that highly creative adults often have adverse childhoods. It appears that, in many cases, a difficult childhood that runs against the normal social grain, as well as a childhood experience persevering in the face of adversity, may be important (Simonton, 1994, 2000). But remember that these early experiences themselves do not necessarily enhance creativity (or do so alone). Even if these experiences are formative, the real cause may be genetic. That is, parents of creative children may also be somewhat rebellious individualists, likely to create nonstandard environments for their children that pose unique challenges.

These parallels among the lives of some of the best-known creative minds in recent history suggest many hypotheses about what creativity is and how it develops. We know that creativity is expressed in diverse domains, from the symbolic worlds of literature, art, and mathematics to the world of human understanding. Some masters, like Mozart, exhaust an existing art form, making way for new ones to emerge. Others, like Beethoven, invent a new style or come up with other novel creations. But we are still left with the mystery of why one person becomes so much more creative than another.

One possibility is that these extraordinary people are the way they are not from an excess of creativity but from other aspects of their character and experience. These other aspects may have helped them project their creativity far more than other, equally creative people. Thus, being a strong self-promoter, being able to tolerate catastrophic interpersonal relations with intimates, and being able to neglect all else in their lives except their creative pursuits may have set these people apart from countless others with as much creative spark.

Conclusions

One key theme of this chapter is that intelligence is tightly intertwined with social and cultural contexts. Intelligence tests assess a particular kind of cultural adaptation, and test performance is often closely linked to a person's social class or status in a society. Moreover, intelligence tests seem to assess only a small subset of the cognitive abilities that allow some people to thrive in school or at work. Social intelligence, creativity, and certain kinds of cognitive flexibility seem to be of equal importance. Even more broadly, we once again see how cognitive abilities are intertwined with social domains and how factors such as social attributions, motivation, and other emotions can interact with cognitive abilities. Because we do not yet have well-developed measures for these other sorts of cognitive abilities, intelligence tests remain the best tool for predicting academic and workplace success. But this may change as new assessment tools become more refined and standardized.

The social aspects of intelligence are especially apparent when we consider large group differences that have not been well accounted for by other kinds of explanations, such as genetic explanations. In addition, birth order effects, in which IQ scores gradually drop for each later-born child, are likely to have social explanations. Similarly, the Flynn effect, the gradual rise of IQ in many populations worldwide, is likely to be almost fully explained by social and cultural effects. In the chapters that follow, we will examine some of these social influences on the mind and behavior in much greater depth.

Schooling provides the most vivid example of how social and environmental factors can influence intelligence. Not only do children with high IQ scores tend to stay in school for more years, but the longer children of various IQ levels stay in school, the more their intelligence rises on a wide variety of fronts, ranging from transitive reasoning to storytelling and comprehension skills. As schools bring children within the framework of the dominant culture, the effects on patterns of thought and cognitive performance can be profound.

Schools need to be sensitive to the individual child and the ways in which a child's particular aptitude interacts with instructional techniques. Consideration of such "learner characteristics" also reinforces the view of development as an active exploratory process and not simply one of the child acting as a passive recipient of experiences. More broadly, as the rate of technological change accelerates, schools must confront the problem of teaching only a fixed set of skills. Rather, students must hone the ability to acquire new sets of skills as the world around them changes. If the curriculum becomes focused on training students for high-stakes standardized tests, teachers may not have the chance to prepare students to be adaptive, flexible learners. The problem is not with the tests themselves, but with designing tests that go beyond simply assessing factual knowledge and that do not cause high levels of test anxiety.

Clearly, the research on the development of intelligence draws together several familiar developmental themes. With respect to the nativist/empiricist debate, the links are more remote than they first appear. The classical nativists and empiricists debated about human nature and how people acquire knowledge. They rarely, if ever, were concerned with the kinds of individual differences that are a major focus of intelligence testing. (Unfortunately, the term *nativist* has sometimes been used to describe those who believe that differences in intelligence have a strong genetic basis. This sense of the word, which focuses on how people differ from each other, is completely separate from the meaning we have been using in this book, which is instead concerned with what is common to all humans in comparison with other species. The two meanings should not be confused.) More commonly, controversies about how differences in intelligence develop are referred to as the nature/nurture debate, where differences among people are seen as largely a consequence of their intrinsic natures or of how they are nurtured. By contrast, both sides of the nativist/empiricist debate have classically focused on how to characterize patterns of development that are common to all people.

In several places in this chapter, we have discussed the advantages of viewing developmental psychology as the study of emerging competencies and abilities rather than the gradual disappearance of cognitive deficits that plague the younger child. Likewise, this perspective has been valuable in thinking about intelligence in relation to models of education. It is far less helpful to ask what younger children are "missing" with respect to intelligence and creativity than to explore the nature of the earliest roots of cognitive abilities—roots that can stretch back to infancy. We have seen that schooling is more effective when it focuses on abilities that children bring to the classroom and works on developing those abilities further while linking them to other skills in an integrated fashion. Fortunately, this kind of focus on early competencies is what the best teachers do naturally.

STUDY AND REVIEW

SUMMARY

What Is Intelligence?

- Despite frequent, widespread references to intelligence, there is relatively little consensus on what it really means to be intelligent. Traditionally, researchers have focused on a psychometric approach, using tests that attempt to quantify intelligence in terms of analytical intelligence, the ability to engage in computations and abstract comparisons.
- Psychometric tests of intelligence reliably show a positive correlation among their subtests, including those for language, mathematical, and visual/spatial abilities. Some researchers have argued that these correlations indicate that there is a single underlying factor, a general intelligence, or *g*, which affects performance on all intellectual tasks.
- Other explanations for the positive correlations among components of intelligence tests either do not require a *g* factor or see it as only a part of overall intelligence. Carroll's hier-

archical three-stratum theory of intelligence is an influential approach that describes how different cognitive abilities might be distinct components of intelligence occurring at three levels: narrow abilities, broad abilities, and a part that corresponds to *g*. However, through computer modeling, it is possible to show enough simulated intersections of cognitive abilities over time that a "virtual" *g* materializes in a cognitive system where no real *g* component was originally present. Developmental cognitive neuroscience may help ascertain the degree of utility of *g* as it pertains to intelligence.

- Alternative approaches to intelligence consider how and why people excel at a wider range of contexts and situations. These theories have been used to measure forms of intelligence quite different from those measured by IQ tests. Gardner's theory of multiple intelligences and Sternberg's theory of successful intelligence are two examples that do not map neatly onto traditional notions of intelligence. Researchers are also exploring broader notions, such as social and emotional intelligence.
- IQ tests tend to predict school performance and even job performance better than most other available measures, but by no means with great accuracy. As new ways of assessing intelligence become more widespread, they may be better predictors than traditional IQ tests in many settings.

Origins of Intelligence

- All forms of intelligence undergo dramatic changes during childhood and adolescence. The speed at which infants habituate to novel displays partially predicts analytical intelligence many years later, a finding that poses new challenges for accounts of how intelligence develops.
- Intelligence test scores show a substantial heritability, meaning that in most populations, a substantial proportion of the individual differences in intelligence is due to genetic differences. At the same time, there is still a significant amount of variance that is due to environmental factors. Furthermore, no matter how large the heritability is, it does not mean that any differences *between groups* are due to genetic factors. This is an important misconception that has led to much confusion in the popular understanding of intelligence research. The search for a gene or small number of genes that might represent the essence of intelligence has been fruitless. It is now clear that despite a high heritability, genetic causal pathways are likely to involve large numbers of genes in complicated nets of interactions with other genes and the environment. In addition, any model of the genetic influences must explain why heritability increases quite dramatically with age from young childhood well into adolescence.

Group Differences and Intelligence Tests

- On average, overall intelligence test scores are equal between men and women, partially because the tests' components are weighted to equalize the overall scores across genders. Nonetheless, there are reliable sex differences on sections of most intelligence tests. The sexes also differ in their distributions of scores. There are more men than women among the extremely high scorers and the extremely low scorers.
- There are large group differences in overall intelligence test scores between ethnic groups, but no compelling evidence has emerged showing that those differences arise from biological factors, as opposed to social and cultural ones.
- Stereotype threats are a powerful sociocultural influence that affects some groups more than others. People do less well on tasks when they fear that their poor performance will confirm negative stereotypes about them. A strong awareness of stereotypes develops during the elementary school years. Among children who perceive stereotypes about intellectual ability as relevant to themselves, this awareness is linked to declining performance.

Environmental Influences on Intelligence Test Scores

- A wide variety of environmental influences, ranging from malnutrition to parental involvement and birth order, can influence intelligence test scores. One of the most important influences is schooling, where time in school is clearly related to performance on intelligence tests.
- Preschool programs, especially Head Start, can have long-term positive effects on a child's intelligence and prospects in life.

Schooling

- Schools provide far more than the education that fosters analytical intelligence. As socializing agents, schools teach children how to behave in large, controlled settings. As cultural institutions, they expose children to the dominant culture. As vehicles of values, schools often aim to instill self-discipline and encourage students to be sensitive to others' needs. Whether and how schools should explicitly teach particular values has been a topic of controversy.
- Cognitive science has made major advances in understanding what kinds of educational practices help children learn. Studies have shown that focusing on students' metacognitive awareness and using Vygotsky's theory of the zone of proximal development to guide students' progress can enhance their learning. But educators should be aware of aptitude-treatment interactions, the finding that different sorts of learners thrive in different sorts of teaching environments.

Creativity

- Creativity, the ability to devise novel insights and solutions, is one of the most valued human traits and one that can vary greatly among people with similar levels of analytical and practical intelligence. Although there is only a weak consensus on how best to measure creativity, most creativity tests attempt to measure the ability to take novel points of view or come up with novel solutions to familiar situations or problems.

- Researchers using the idiographic approach to studying creativity have examined the lives of creative geniuses and tried to understand what made them different. This approach suggests that creativity may flower in different ways that correspond to different kinds of intelligences. The nomothetic approach has explored broader principles concerning when and how creativity is likely to emerge in development. These different approaches suggest some commonalities among highly creative people; perhaps the most surprising is that they seem unusually likely to have experienced significant adversities in childhood.

THOUGHT QUESTIONS

1. Some scholars have argued that the trend of rising intelligence test scores, or the Flynn effect, is starting to level off, while others think that it is still rising and will continue to rise for several decades to come. Which view do you favor? Support your view by examining possible mechanisms underlying the Flynn effect.
2. An early Head Start program in a small town proposes to have all pediatricians conduct a standardized habituation test of all infants in the town at age 10 months so as to identify those infants who might be most at risk for having lower intelligence test scores later on. The goal is to then to be able to intervene more effectively to help those infants early on. Do you consider this proposal to be a good idea?
3. In an attempt to improve the quality of education in a school district, the school board is evaluating two proposals: to lengthen the school year by 3 weeks or to lengthen the school day by 2 hours. It can only afford to implement one of these two options. Which do you think would be more educationally effective? Do you think the best option might vary as a function of the age of the child?
4. To address budget cutbacks, an elementary school principal proposes doing away with recesses, which require additional supervisory staff and playground maintenance. A parent objects that this change will discriminate against boys and will cause an increase in ADHD diagnoses in boys in that school because some boys will simply not be able to sit still in a classroom for an entire school day. State your reasons for agreeing or disagreeing with the parent.

Conclusions

Summary

On April 11, 2013, Emil Kapaun was posthumously awarded the U.S. military's highest honor, the Medal of Honor, even though he never fired a shot or engaged in any form of aggression toward others. Indeed, he showed kindness and compassion to his enemies. During the Korean War, Kapaun served as a chaplain in the army. When his battalion was encircled by the Chinese army in a battle in North Korea, he dodged heavy enemy fire to drag many wounded and dying soldiers to safety. Although he could have retreated with the army when combat conditions worsened, he chose to stay behind and care for the wounded soldiers. Kapaun and others were captured and forcibly marched 87 miles to a brutal prison camp under extremely harsh conditions. On the march and in the camp, many men died of starvation, extreme cold, lack of medical attention to their wounds, and from disease. Throughout his incarceration, Kapaun engaged in repeated heroic acts of sacrifice for his fellow prisoners. He gave them his own clothes for warmth, he stole food from the guards to give to those who were starving, and he shared his own pitiful food rations with the other prisoners, even as he himself was wasting away. He scavenged for rags to use as bandages to prevent infection from wounds and thereby saved many soldiers from death. He stood between a captor and a wounded fellow soldier who was about to be shot, saving the soldier's life by carrying him away. Kapaun died of pneumonia while he was still incarcerated, even as his last known acts were attempts to help his fellow prisoners. In an interview in April 2013, one of his fellow prisoners who survived said: "People had lost a great deal of their civility. . . . We were stacking the bodies outside where they were frozen like cordwood and here is this one man—in all of this chaos—who has kept his principles." (Robert Wood, quoted in the *Washington Post*, April 11, 2013).

Kapaun grew up in modest conditions on a farm in rural Kansas and had an unremarkable childhood. He was known to be a good student and a polite but somewhat shy child, but there are no records that indicate that he showed the kind of extraordinary moral behavior that would come to distinguish his later life. It is not known how a seemingly ordinary farm boy grew up to adhere to the highest moral principles while under conditions of extreme duress, nor is it known how those principles emerged in the course of his development.

Kapaun's life illustrates the complexity of moral thought and behavior. We may all have strong intuitions about the morality of actions, yet we vary greatly in how those intuitions become organized into larger systems of beliefs that motivate us toward action. Where do those intuitions come from? On what basis do we make our judgments of morality? How does the ability to make those judgments emerge in childhood? How does it lead to actions? How can a boy who grows up having an apparently normal childhood become such a remarkable moral individual while other boys growing up in highly similar environments and families end up with very different moral convictions and behaviors? How can a group of individuals all believe they are acting correctly and morally but nonetheless do very different things in the same situations?

In this chapter, we will examine the origins of moral thought, theories about moral development and moral reasoning, and the imperfect link between moral thought and moral action. With respect to moral thought, we will explore whether young children have qualitatively different ways of thinking about what is right and wrong, and we will once again discuss Piaget as well as another classic scholar in the field, Lawrence Kohlberg. We will then turn to more recent views of moral judgment and ask about the extent to which moral judgments should be thought of like the rest of analytical cognition or whether they require more intrinsic roles for emotion.

After examining moral judgment and reasoning, we will discuss moral actions, asking about the ways in which moral thoughts might be related to tendencies to actually act in good and bad ways. We will see that the links between thought and action are far more complex than they might appear to be at first. We will then consider actions more directly in their own right. We will ask whether there are biological bases for individual differences in morality and will also discuss social and cultural influences on moral behavior. In addition, we will look at different kinds of punishment and modeling and will ask how they can affect moral behavior. Finally, we will consider the development of conscience and its possible relations to parent-child interactions.

The Development of Moral Thought

Examining the development of moral thought raises questions about its origins, its evolutionary and psychological bases, and its degree of domain specificity. Do children across the world develop some common moral principles, or are cross-cultural differences so broad that there are no moral universals? What kinds of psychological processes contribute to moral thought, and how do these processes change with age? And is moral reasoning truly a separate realm of thought with its own special characteristics and developmental patterns? We will consider all of these questions in this section, but first we need to take note of how moral thought relates to moral actions.

Having beliefs about what is right and wrong is quite different from behaving well or badly. We all assume that moral thoughts are related to moral behavior, but as we will see, the relations are intricate and often difficult to predict. It is common to say that people often act against their better judgment, which implies that a person can have a clear intuition about how he should behave but not be able to do so because of other impulses. This lack of a clear link between moral thoughts and actions raises interesting developmental questions. Is the link even more tenuous in younger children because they have even less ability to formulate clear moral judgments and then stick to them? In addition, are even the most analytical moral judgments ever really free of the influences of emotional impulses, and are such influences stronger in younger children?

Debating the Origins of Moral Thought

For hundreds of years, philosophers and other scholars have debated about the moral characteristics of young children and how morality develops. Two broad views have characterized much of that debate: (1) the idea that young children have some kind of inherent moral nature, and (2) the contrasting notion that they have no inherent moral characteristics and must learn about morality from their social and cultural experiences. Within these views there can also be strong variations.

Consider the view that the young child comes into the world with certain moral propensities. The eighteenth-century French philosopher Jean-Jacques Rousseau, for example, proposed that young children are intrinsically good. He believed that infants and young children are pure in heart and mind and would always behave in morally appropriate ways if not for the corrupting influences of society. In this view, a primary goal of child rearing should be to shield children from society's corrupting influences so that their intrinsic moral sense has time to mature and become less vulnerable to such influences. The French physician Jean Marc Gaspard Itard undertook a dramatic and disturbing "test" of this premise by administering random beatings to Victor, the "wild child" discussed in Chapter 8. Itard wanted to see whether Victor would show outrage at the abuse, even though he had spent much of his childhood alone and isolated from social rules and norms. When Victor did show outrage, Itard reasoned that this response revealed the boy's deep-seated, unlearned sense of justice.

Others who believed in an inherent moral nature took a darker perspective. They saw children as selfish creatures who need to be civilized by society. The same negative view persists today in more subtle forms. For example, William Golding's classic novel *Lord of the Flies* describes how a group of children stuck on a deserted island become unmoored from society's social and moral constraints and descend into antisocial and even violent actions (see Figure 12.1). This account suggests that children are filled with base impulses that need to be controlled and suppressed by civilization.

FIGURE 12.1 **Are children inherently antisocial?** In his novel *Lord of the Flies*, William Golding suggested a view of morality in which children, once removed from the constraints of society, develop into cruel antisocial beings. Shown here is a film still from the 1963 film based on the book.

The other view of moral development sees no moral capacity and no inclination toward either good or bad in infants and young children. Many who hold this view argue that very young children are no more moral than animals because they lack the cognitive capability to have a moral sense. They hypothesize that young children are initially amoral and that they learn morality as a consequence of development. In general, proponents of this view believe that infants and young children are not cognitively and emotionally capable of moral thought, so they are not fit to be judged as either good or bad. In this view, it makes no more sense to think of a young child as good or bad than it does to judge a tiger's morality in its behavior toward prey.

In short, there is a long history of thinking about children's moral development as if they were primarily bad or good from the start, or as if they only gradually acquired moral capabilities after being exposed to the values of their society. The views favoring an inherent moral nature did not ignore society's effects; they just saw them as interacting with preexisting moral natures. The views that saw children as amoral held that society's effects are largely responsible for children's morality, much like the empiricists' view of the child as a blank slate.

More recently, these two types of views have been complemented by perspectives arising from evolutionary and cultural psychology. Although these modern perspectives acknowledge many kinds of influences on the development of moral thought, they often disagree about which influences are most powerful, leading them to focus on different kinds of research questions.

Evolutionary and Cultural Psychology and Morality

In recent years, morality and its development have been major areas of study in both evolutionary psychology and cultural psychology. These two approaches share the assumption that children are not intrinsically good or bad. But they differ in the extent to which they see biological constraints as shaping the nature of moral thought.

Evolutionary psychology considers morality from the standpoint of how certain moral behaviors and patterns of thought might have been selected in the course of evolution. This perspective is committed to the idea that humans have a certain moral sense because it has had adaptive value in the emergence of the human species (Cosmides & Tooby, 2013; Levy, 2004; Pinker, 2002; Singer, 2005; Wright, 1994, 2010).

Many evolutionary psychologists argue that emotional empathy and the tendency to consider fairness and sharing conferred a selective advantage among our species' ancestors, as in cases where primates engage in mutual grooming (see Figure 12.2). Individuals with these traits may have had fewer enemies, more success finding mates, or a better ability to work together in social groups (Haidt, 2007, 2008; Hauser, 2006). As a result, they had more offspring—and more chances to pass on their genes. Similarly, a tendency to ramp up aggressive or self-protective behavior in threatening situations could also convey a selective advantage. Such behaviors, which may be related to moral behaviors labeled as hurtful or selfish, could also promote an individual's survival and the ability to pass on his genes. According to this account, some aspects of morality are universal because all humans share the biologically based core morals that have been selected over many generations.

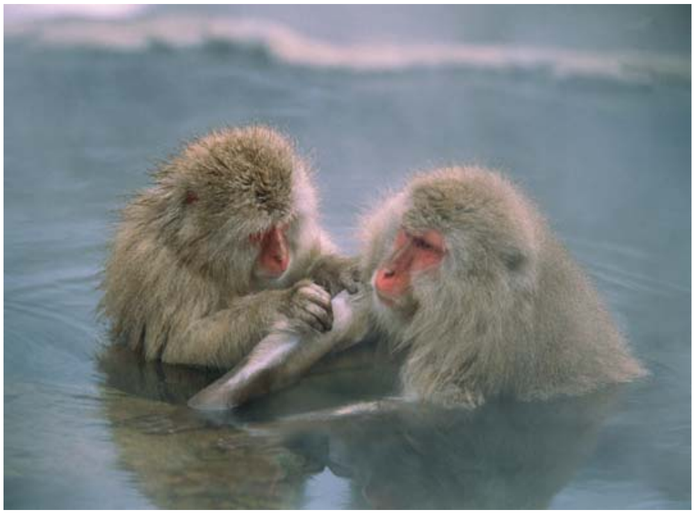

FIGURE 12.2 Reciprocal altruism. Many primates, such as these Japanese macaques, engage in mutual grooming even when they are not related. Evolutionary psychologists suggest that these kinds of cooperative behaviors may be related to prosocial behaviors in humans.

Even though views based on evolutionary psychology clearly favor inherent biological constraints on moral behavior, these views do not conclude that young children have inherent moral natures. These views see evolved constraints on moral thought as the basis for a survival function and not as the basis for judging an agent as bad or good. Thus, views from evolutionary psychology allow for mixtures of all sorts of basic moral components, including sharing, hoarding, deception, aggression, intimidation, and compassion. In addition to the idea that there must be a core morality that all people share, evolutionary psychologists also acknowledge that learning and culture significantly influence these universal aspects of morality.

By contrast, the field of **cultural psychology** approaches the study of moral thought and behavior by focusing on how cultures instill ways of thinking and fostering certain behaviors. This approach recognizes that there may be some basic universal moral concerns, but it argues for more powerful influences of culture on various aspects of morality. Richard Shweder, for example, shows that different cultural groups have dramatically different patterns of moral reasoning, ruling out a single dominant moral belief system. He does, however, recognize three clusters of basic moral values related to justice, community, and spirituality within which specific moral rules in each culture fall (Shweder, 1982; Shweder et al., 1987, 1997; Shweder & Haidt, 1993). Shweder offers examples of moral judgments and behaviors in some Eastern societies that, on the surface at least, seem almost incomprehensible to Westerners (see Figure 12.3). In U.S. history, the explorers Lewis and Clark reported a comparable bewilderment when they encountered Native Americans who held very different views than their own about the nature of possessions and whether people were entitled to take something that someone else was using (Ambrose, 1996).

The evolutionary and cultural perspectives on moral development offer distinctive emphases and interpretations, illustrating just how different the current psychological views of morality can be, even when all sides have access to the same data. Together these perspectives help to frame a wide range of accounts of moral development (Turiel, 1998) that seek to account for the influences of culture and of universal, biological constraints (Miller, 2006). Indeed, more recent accounts blend these two perspectives by arguing that evolution provided a basic set of intuitive moral "building blocks" that then got combined in different ways by cultural influences (Haidt, 2013; Haidt & Kesebir, 2010).

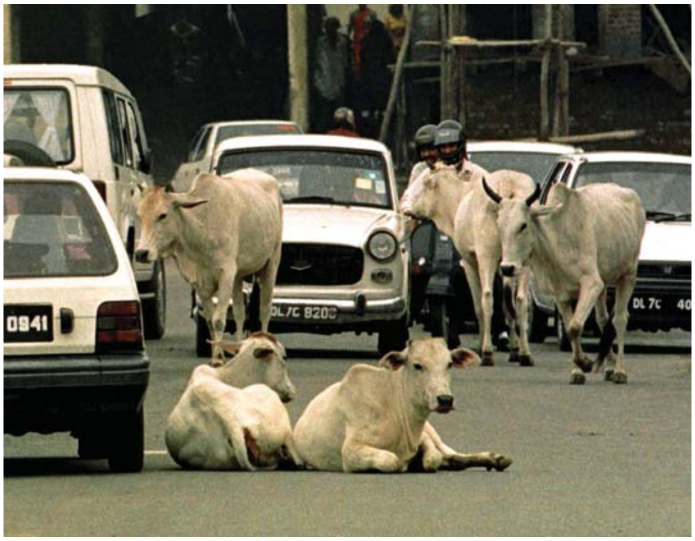

FIGURE 12.3 Moral beliefs across cultures. In many areas of India, cows are revered and granted nearly unlimited rights to go where they wish and when they wish, as in this street scene. Many Westerners, who do not understand the moral and religious beliefs leading to such practices, can have great difficulty understanding them.

Q: How do evolutionary and cultural views of morality differ in regard to the young child?

Characterizing the Basis of Moral Thought

To reach a better understanding of how the development of moral thought might fit with both evolutionary psychology and cultural psychology, it is useful to consider different ways of characterizing the psychological basis of moral thought. What sorts of psychological processes and structures seem to lead to judgments of right and wrong?

One view argues that there is really no reason to consider moral thought and that moral thoughts are largely window dressings that come to bear long after we commit to an action, perhaps as a way of justifying or rationalizing the action. According to this view, moral thought is a nonessential side effect rather than an important part of understanding moral behavior. This view asserts that other forces, such as positive and negative reinforcements, give rise to and control our actions, based on the tradeoffs between benefits and detriments (Skinner, 1971). Reinforcement-based views, which are part of the classical learning tradition, have largely disappeared in recent years as researchers have uncovered highly systematic and richly structured sets of moral intuitions, often about novel scenarios for which we could never have experienced reinforcements.
